The balance of how energy acquisition and expenditure is achieved differs for individual species and environments. For some species, sea otters (*Enhydra lutris*), sea lions, and fur seals, (Otariidae), very high rates of energy expenditure are met by high rates of energy acquisition. These animals may preferentially live in nearshore environments or upwelling regions where food is abundant. Sirenians represent the opposite extreme. These sluggish marine mammals exhibit comparatively low existence costs and are able to survive on a low-quality diet. They have adapted to a diet of grasses that are in high abundance but are of low quality, energetically. They are able to do this because they live in the climatically benign tropics where maintenance costs may be kept to a minimum.

The seasonal migrations of large cetaceans demonstrate this interrelationship among energetic demand, energy availability, and local productivity. Although maintenance costs may be elevated in the polar regions, the ability to take advantage of the seasonally high productivity associated with the sea ice during the polar summer appears to more than compensate. When confronted with the high energetic costs of reproduction and of winter conditions, the mysticete whales opt for the more benign tropics. Further, their large body size makes the cost of migration extremely low. Prey availability may be low, but so too are the existence costs, especially for a large animal that is able to utilize energy reserves stored in the blubber.

The distribution of energy into the various physiological processes is outlined in Fig. 1. Ingested energy is the total energy consumed by the animal. Metabolic energy (ME) is energy available for maintenance, growth, or reproduction. Energy expended for maintenance includes key processes such as basal metabolism, digestion (heat increment of feeding), thermoregulation, and activity (locomotion, grooming, feeding, etc.).

I. Energy Acquisition

Not all of the ingested material consumed is digestible. Food energy remaining after digestion and elimination of fecal energy is known as apparently digested energy. The apparent digestibility for a DIET of fish ranges from 88 to 97.9%, whereas

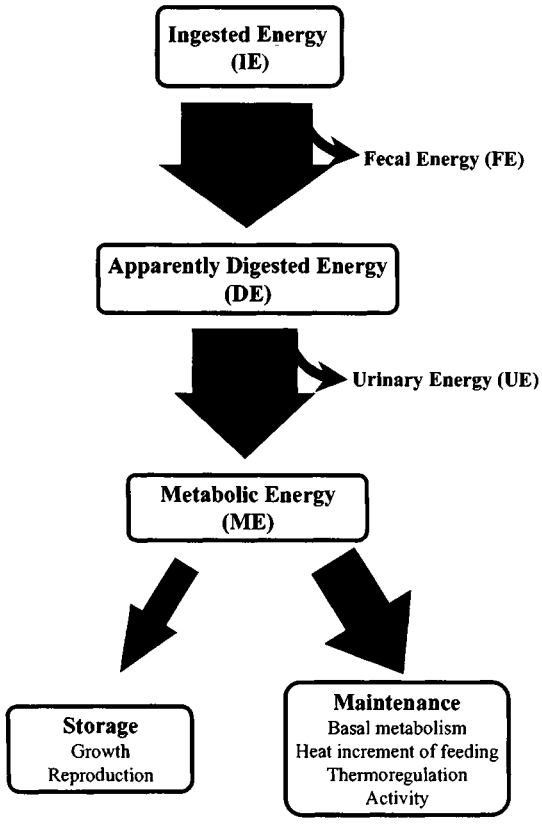

Figure 1 *Pattern of energy flow through a typical mammal.*

invertebrate prey with a high chitin content, such as shrimp, are lower at 72.2%. Plant material is less digestible because it contains cellulose, which is difficult to digest. Although sirenians extract less energy from their food than other marine mammals (84.6%), they are more efficient than other hindgut fermenters, such as horses (45–59%).

Chemical energy is also lost in the urine as urea and other metabolic end products and is defined as urinary energy. Metabolizable energy is the net energy remaining after fecal and urinary energy loss and represents the energy available for growth or reproduction and for supporting metabolic processes such as work (locomotion) and respiration (thermoregulation, maintenance metabolism, heat increment of feeding). The ME for pinnipeds varies from 78.3% for a squid diet to 91.6% for an anchovy diet.

II. Energy Expenditure

A. Cost of Maintenance Functions

Maintenance costs are those associated with homeostasis and include basal metabolism, the heat increment of feeding, thermoregulation, and activity.

1. Basal Metabolism It has generally been assumed that the basal metabolic rates (BMRs) of aquatic mammals are elevated when compared to terrestrial mammals of similar size. The current view of basal metabolic rates of marine mammals is more complex. Many previous studies did not conform to standardized criteria for measurements of basal metabolism. These criteria require that the subjects be adults, resting, thermoneutral, nonreproductive, and postabsorptive. This has been further confused by the expectation that all marine mammals should employ the same metabolic response. Specialization for marine living has occurred independently in three mammalian orders: sirenians, cetaceans, and carnivores. Further, within the carnivores there are three separate transitions to a marine existence: pinnipeds, sea otters, and polar bears, *Ursus maritimus*. Based on this diversity, we might expect different metabolic adaptations among the groups (Fig. 2). Manatees, *Trichechus manatus*, have BMRs lower than values predicted, whereas phocid seals have BMRs equivalent to those of similar-sized terrestrial mammals. Conversely, sea otters, otariids, and odontocetes appear to have BMRs greater than predicted.

The tremendous variation in body composition of marine mammals introduces another complicating factor when attempting to compare basal metabolic rates. Some species such as sirenians and walrus, *Odobenus rosmarus*, have dense bone, whereas seals may be composed of as much as 50% fat. When metabolic rates are expressed relative to body mass, a disproportionate amount of fat or particularly dense bone will lower the apparent metabolic rate. This is due to the low metabolic rates of bone and adipose tissue in comparison to lean tissue. Metabolic rate comparisons are further complicated by the wide variation in individual body composition. Many marine mammals undergo prolonged fasts that are accompanied by profound changes in body composition. Most of the mass change during fasting is due to loss of adipose tissue with a comparatively smaller change in lean tissue. For example, northern elephant seal females, *Mirounga angustirostris*, lose 42% of their initial mass, but of this only 14.9% comes from lean tissue with 57.9% coming from adipose tissue. This results in the overall change in body composition of 39% fat at parturition to 24% fat at weaning. Because lean mass is the primary contributor to whole animal metabolism, the whole body metabolism of the animal is likely to change little even though there has been a major change in its body mass. Such wide variations in body composition within and between marine mammals make comparison of metabolic rates problematic, especially relative to terrestrial animals that typically do not undergo such tremendous variations in body composition.

2. Fur vs Blubber It is important to consider the potential differences in the energy budgets of animals that use fur or blubber for insulation. Nonetheless, the overall time–energy budget of an animal that uses fur (fur seal or sea otter) is fundamentally different from an animal that uses blubber (sea lion, seal, or dolphin). Although fur is not a living tissue, it requires that an air layer be maintained, which is done by frequent grooming. Sea otters spend up to 16% of their day grooming. While sea lions, seals, and dolphins spend no time grooming, they must take in sufficient food to lay down a thick blubber layer, which is a living tissue and must be supplied with blood. Furthermore, blubber serves dual roles as an insulator and as an energy store. During fasting or periods of low

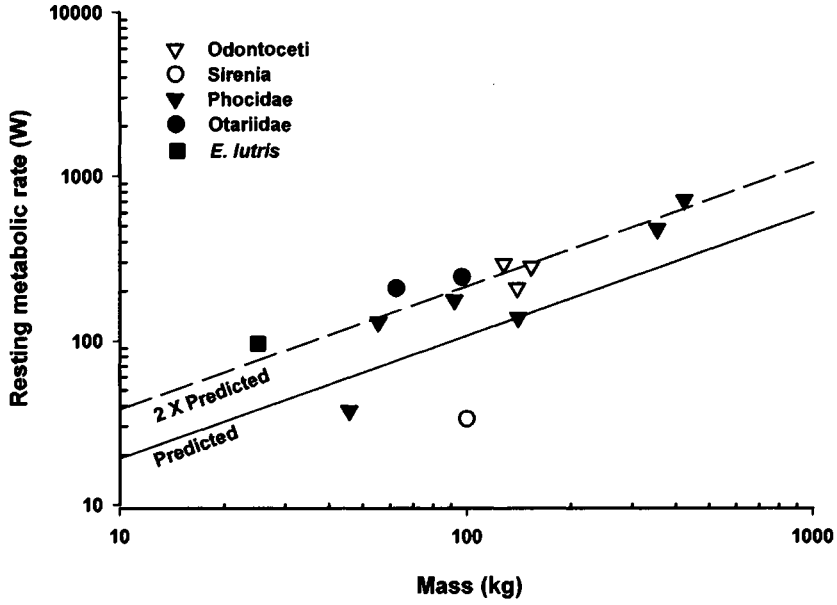

Figure 2 *Resting metabolic rate of marine mammals in relation to body mass. Measurements were made for the animals resting in water. The solid line denotes the predicted metabolic rate for equal-sized terrestrial animals; the dashed line represents two times the predicted levels. Species included are Odontoceti,* Stenella attenuata *and* Tursiops truncatus; *Phocidae,* Phoca vitulina, Pusa hispida, Leptonychotes weddellii, Pagophilus groenlandicus, *and* Haliochoerus grypus; *Otariidae,* Zalophus californianus; *and Sirenia,* Trichechus manatus.

food availability, a marine mammal must balance its utilization of blubber for energy needs with the potential loss of the blubber layer as an insulator.

3. *Heat Increment of Feeding* When food is consumed, the animal's metabolic rate increases over fasting levels. The heat increment of feeding (HIF), also known as the specific dynamic action (SDA), may be considered the "tax" that is required to process food energy for conversion to metabolizable energy. The magnitude of energy allocated to HIF varies between 5 and 17% of the ME. In addition, the duration of HIF following a meal will depend on the amount of food consumed and its composition. In many mammals, the HIF is considered excess or waste heat. However, sea otters incorporate the additional heat increment of feeding to reduce their already high thermoregulatory costs. Sea otters are the smallest marine mammal and therefore have a very high rate of heat loss. In order to reduce their already high maintenance costs, sea otters use the heat liberated from activity and HIF to augment their thermoregulatory requirements. While grooming, feeding, and swimming, sea otters use the heat produced from these activities to supplement their thermoregulatory needs. Sea otters typically rest or sleep after feeding and use the HIF to compensate for the decreased heat production from activity. In sea otters, the HIF results in a 54% increase in metabolism that returns to basal levels within 4–5 hr. Sea otters incorporate the heat produced from HIF to augment their thermoregulatory needs while resting (Fig. 3).

B. Cost of Growth and Reproduction

For growth and reproduction to occur, an animal must acquire energy and nutrients in excess of that required for supporting maintenance functions. These additional energetic costs vary with the species of marine mammal, the sex, and reproductive pattern. In pinnipeds, polar bears, and sea otters (and

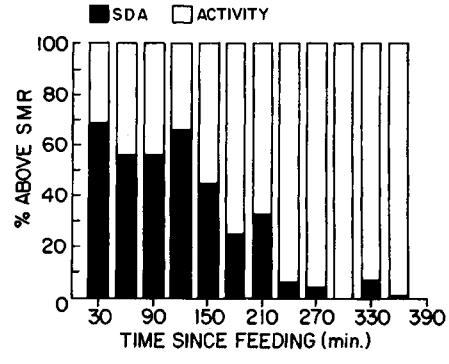

Figure 3 *The thermal budget of sea otters relies on heat production above standard metabolic rate (SMR, equivalent to BMR). The contribution of SDA (or HIF) to the overall metabolism is highest immediately after feeding and reaches zero within 390 min after feeding. As SDA decreases, the animal becomes more active and thus compensates for the decrease in heat production from SDA. From Costa and Kooyman (1984), by permission of University of Chicago Press.*

probably mysticetes and sirenians), the cost of the reproduction in males is limited to the cost of finding and maintaining access to estrous females. Evolution favors a pattern of energy expenditure that maximizes reproductive success in males. Costs associated with reproduction in aquatic and terrestrially breeding males are quite similar when normalized for differences in body mass. A larger body size is preferred in terrestrially breeding male pinnipeds because it confers both an advantage in fighting and allows the male to maintain terrestrial territories longer. In addition, larger animals can fast longer because they have a lower mass-specific metabolic rate than smaller animals. In species that compete for females in the water, we find that the males are comparatively smaller than the species that breed on land. For aquatic breeders, underwater agility is more important than large size when competing for mates. Nevertheless, even in aquatic breeders, large males have an advantage over small males because they do not need to make as many foraging trips and thus have more time to compete for females.

The cost of reproduction for females can be broken down into the energetic requirements of gestation and lactation. The cost of gestation is small relative to the cost of lactation. Even given the considerable variation of maternal investment in marine mammals, there is little variation in fetal mass at birth. Marine mammals also appear to invest more energy into gestation than terrestrial mammals (Fig. 4). However, as a group, marine mammals exhibit considerable variation in both the duration and the intensity of overall maternal investment (Fig. 5). Phocid seals and mysticete whales have extremely short lactation durations, which are compensated for by a higher rate of energy investment that enables the young to grow rapidly (Fig. 6).

Although phocid pups are weaned early, they still rely on maternally derived energy, stored as blubber, for weeks or months after weaning. The disadvantage of this rapid growth is that most of the mass and energy are stored as fat with proportionately little protein. The advantage of longer lactation is that young get more protein and other nutrients, allowing greater growth of lean tissue. However, longer lactation is energetically more expensive.

1. Variation in Milk Composition The rapid growth of marine mammal young is made possible by the ingestion of extremely lipid-rich milk. With a few exceptions, most terrestrial animals produce milk that is low in fat; cows and humans produce milk that contains 3.7 and 3.8% milk fat, respectively. Lipid-rich milk allows the mother to transfer high levels of energy in a very short period. Hooded seals, (*Cystophora cristata*), are most impressive, with a 4-day lactation interval and a milk

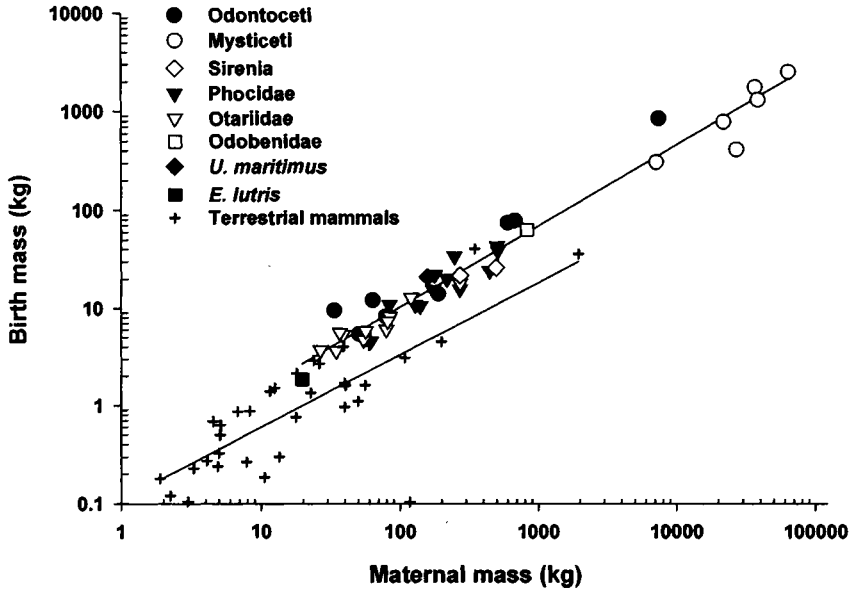

Figure 4 *Birth mass plotted in relation to maternal mass for marine and terrestrial mammals. Figure 5 *Time to weaning plotted as a function of maternal mass for marine mammals. Lactation durations of phocid seals and mysticete whales are shorter than all other marine mammals. Species are the same as in Fig. 3.*

fat of 65% lipid. In view of this, it is not surprising that marine mammals with the highest growth rates produce milk with the highest lipid content.

Lactation also enables mothers to optimize the delivery of energy to their young. The energy content of the milk is independent of the type or quality of prey consumed or the distance or time taken to obtain it. Although milk is ultimately derived from the prey consumed, a mother can process, concentrate, or utilize stored reserves to produce milk. For example, some species feed on fish, whereas others feed on fish or squid. However, all of these species provision their offspring with milk of significantly greater energy density than the prey consumed.

2. Body Size and Maternal Resources: The Role of Maternal Overhead Fasting during lactation is a unique component of the life history pattern of many marine mammals. With the

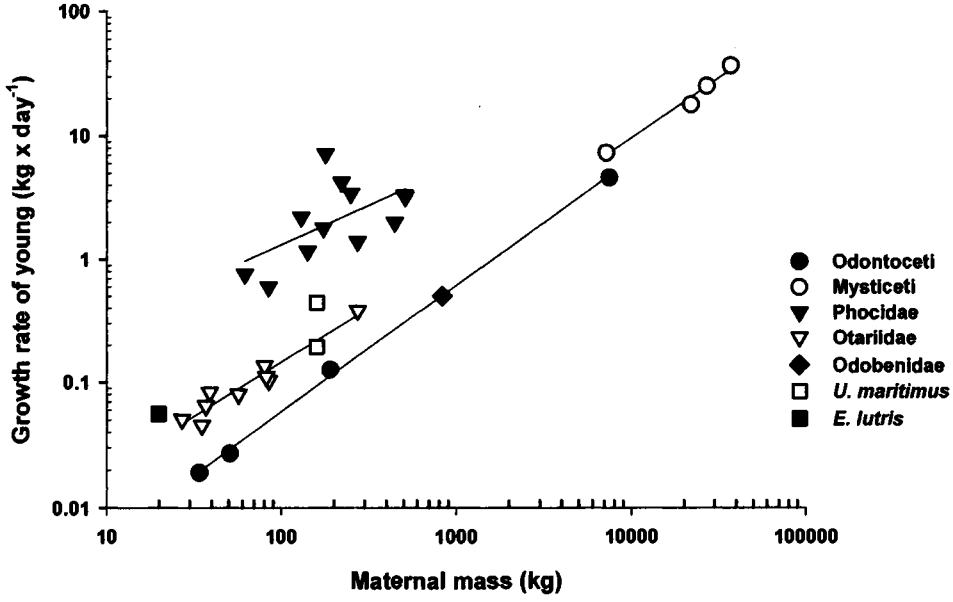

Figure 6 *Growth rate of suckling marine mammals as a function of maternal mass. Lines represent least-square regressions for each taxonomic group. Species are the same as in Fig. 3.*

exception of bears, no other mammal is capable of producing milk without feeding. By undertaking this energetic challenge, mysticetes and pinnipeds are able to separate where and when they feed from where and when they breed. In mysticete whales, this allows them to feed in the highly productive polar regions of the world's oceans but retain the thermal advantage of breeding in the calm sub-tropical regions. Migrating to warmer waters for parturition reduces the thermal demands on the newborn calf and additional thermal savings for the mother.

Among pinnipeds, the separation of feeding from lactation is necessary to allow for terrestrial parturition. Most phocids store sufficient energy reserves for the entire lactation period, whereas all otariids must feed during lactation. Phocid mothers typically remain on or near the rookery continuously from the birth of their pup until it is weaned; milk is produced from body reserves stored prior to parturition. Although some phocids feed during lactation, most of the maternal investment is derived from body stores. Their reproductive pattern is less constrained by the time it takes to travel and exploit distant prey, which may allow utilization of a more dispersed or patchy food resource. By spreading out the acquisition of prey energy required for lactation over many months at sea, northern elephant seal females only need to increase their daily food intake by 12% to cover the entire cost of lactation.

The ability of a marine mammal female to fast while providing milk to her offspring is related to the size of her energy and nutrient reserves and the rate at which she utilizes them. When food resources are far from the breeding grounds, as may occur for some phocids and large mysticete whales, the optimal solution is to maximize the amount of energy and nutrients provided to the young and to minimize the amount of energy expended on the mother. The term "metabolic overhead" refers to the amount of energy a female expends on herself while onshore (seals) or while in the calving grounds (whales). Larger females have a lower metabolic overhead than smaller females. This is because maintenance metabolism scales as $\text{mass}^{0.75}$ and fat stores scale as $\text{mass}^{1.0}$. As body size increases, energy reserves increase proportionately faster than maintenance metabolism.

3. Energy Investment and Trip Duration Many phocids fast throughout the lactation interval, whereas otariid females feed intermittently between suckling bouts onshore. Otariid mothers modify the timing and patterning of energy and nutrient investment to optimize energy delivery to their young. Otariid mothers making short feeding trips that provide their pups with less milk energy than mothers that make long trips. In comparison to otariids, phocids may have a reproductive pattern that is better suited for dealing with dispersed or unpredictable prey or prey that is located at great distances from the rookery. However, fasting during lactation places a limit on the duration of investment, which limits the total amount of energy that a phocid mother can invest in her pup.

C. Field Metabolic Rates

A number of approaches have been used to study the metabolic rate of animals at sea. One approach, time budget analysis, sums the daily metabolic costs associated with various activities. Field observations of behavior are coupled with metabolic rate measurements made in captivity. Other methods rely on predictive relationships between physiological variables and metabolic rate. For example, metabolic costs can be assessed indirectly by measurements of changes in body mass and composition, variations in heart rate or ventilation rate, or dilution of isotopically labeled water.

Field metabolic rates (FMR) provide insight into the energetic strategies used by marine mammals. The best data exist for pinnipeds and the bottlenose dolphin, *Tursiops truncatus* (Fig. 7), and indicate that foraging otariids and bottlenose dolphins expend energy at 6 times the predicted basal metabolic level. In contrast, the metabolic rate of diving elephant seals and Weddell, *Leptonychotes weddellii*, seals are only 1.5 to 3 times the predicted basal rate. The lower diving metabolic rate of phocid seals contributes to their superb diving ability.

Field metabolic rates are quite variable both between and within species (Fig. 7). Such variation is thought to be associated with year-to-year changes in both the abundance and the availability of prey. For example, California sea lions, *Zalophus californianus*, significantly increased their foraging effort in response to reductions in prey availability during the 1983 El Niño event. Foraging effort will also vary with the type of prey consumed. Northern fur seals, *Callorhinus ursinus*, foraging on mature pollock during 1981 had lower metabolic rates than fur seals foraging predominately on juvenile pollock during 1982. Surprisingly, bottlenose dolphins, *Tursiops truncatus*, in Sarasota Bay had lower metabolic rates in the winter than in the summer. These dolphins either worked harder to lose heat in the summer or spent more time looking for prey. The importance of the thermal environment on field metabolic rate can also be seen in Galapagos fur seals, *Arctochepalus galapagoensis*, which due to the warm equatorial climate have a substantially reduced FMR compared to other otariids. The field metabolic rate integrates all of the costs incurred over the measurement interval and reflects differences in the foraging intensity as well as the thermal budget of the animal.

1. Energetics of Prey Choice The amount of work and therefore energy expenditure that an animal puts into locating prey vary as a function of the energy content, availability, and location of the prey. Both size and proximate composition (fat, carbohydrate, protein, and water content) affect the energy content of prey. Prey availability varies as a function of the absolute abundance of prey (amount of prey per unit of habitat) and its distribution in the environment. A predator is more efficient when foraging on prey that is clumped than on prey that is evenly dispersed. Marine mammals forage in areas where prey has been concentrated as a result of oceanographic processes such as eddies, fronts, and upwelling regions associated with bottom topography.

Sea otters provide an excellent example of the factors that determine the energetics of prey choice. In recently occupied areas, sea otters feed on preferred prey items such as clams, abalone, or sea urchins. In such environments they find large, energy-rich, abundant prey that is easy to handle, consume, and digest. In such situations, lower quality prey items (turban snails, sea stars, mussels, chitons) are generally not eaten. These items

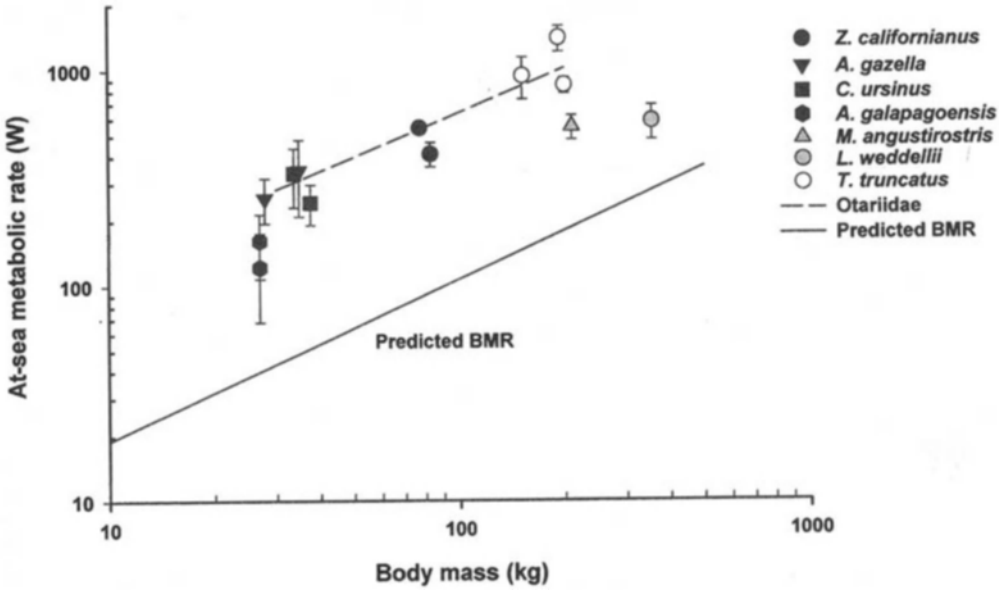

Figure 7 *At-sea metabolic rate measurements determined from the O-18 doubly labeled water method as a function of body mass. Data on* L. weddellii *were measured using open circuit respirometry on seals diving from an ice hole. The solid line represents the predicted basal metabolic rate for a terrestrial animal of equal size; the dashed line is the best-fit linear regression for the otariidae with the exception of data from* A. galapagoensis ($r^2 = 0.53$). *Error bars represent ± 1 SD. Multiple points for each species reflect measurements taken over different years and show the range of interannual variation within a species.*

may be abundant, but they are energy poor and difficult to eat and digest. As the ABUNDANCE and size of their preferred prey decline, sea otters switch to less preferred, but more accessible prey such as turban snails, kelp crabs, and, in some cases, chitons and sea stars. Some sea otters specialize on different types of prey and are more efficient predators than nonspecialists.

Polar bears represent another example of optimal prey choice and its relation to the prey energy quality. Feeding predominately on ring seals, *Pusa hispida*, polar bears eat the energy-rich blubber layer and leave behind the lean "core" of the carcass. Due to its high lipid content, the blubber has a per unit mass energy content almost 10 times greater than that of the lean tissue of the ring seal. Thus, polar bears consume the most energy-dense part of the ring seal and then move on to find another kill.

2. Variations in Foraging Energetics The relationship between prey availability and reproductive success has been examined for a wide variety of pinniped species. Otariids are more susceptible to variations in nearby food resources because their breeding pattern is linked to continuous prey availability directly offshore, whereas phocids are buffered against fluctuations in prey availability near the rookery because they accumulate the resources they need for lactation over the previous year. Successful reproduction by otariids requires that mothers use a foraging pattern that optimizes the amount of time spent feeding at sea with the amount of milk energy delivered to her pup waiting on the rookery. Studies of female otariids with dependent young show that as food resources decrease, mothers can either increase the time spent foraging at sea or the intensity of their foraging effort. However, simply increasing the time spent at sea increases the time between visits to the pup. Consequently, a greater proportion of the ingested milk energy is spent on pup maintenance rather than directed to pup growth. Increases in trip duration associated with declining prey resources result in slower pup growth because less milk is delivered over the same time interval.

Phocids are buffered from short-term fluctuations in prey availability due to their unique reproductive pattern. In phocids, reproductive performance (maternal investment) during a given season reflects prey availability over the preceding year and represents the mother's foraging activities over a much larger spatial and temporal scale than the foraging activities of otariids. It follows that the weaning mass of a phocid pup is an indicator of its mothers' foraging success over the previous year, whereas the subsequent postweaning survival of the pup is related to both its weaning mass (energy reserves provided by the mother) and the resources available to the pup after weaning.

Entrapment and Entanglement

JON LIEN
Memorial University, St. John's, Newfoundland, Canada

Fishermen use a variety of techniques to capture fish. A common method is the use of nets that hang passively, like curtains, in the water and ensnare fish that blunder into them, or make barriers that direct the fish into traps that hold them until they are removed.

Because fishing nets are an unusual barrier, cryptic and hard to detect, they also on occasion catch marine mammals. When nontarget species are accidentally caught in nets they are termed bycatch. Bycatches of some species of marine mammals, such as harbor porpoises (*Phocoena phocoena*), are common in several areas. Because of the strength of modern materials now used in constructing nets, even larger species of cetaceans are sometimes captured incidentally in fishing gear. Such entrapments seriously threaten the North Atlantic right whale (*Eubalaena glacialis*) population. Any species can be captured in nets; however, humpback whales (*Megaptera novaeangliae*), perhaps because of their abundance in coastal water where nets are commonly used or because of the many BARNACLES they carry, seem extremely vulnerable to entanglement in fishing gear.

In the late 1970s, humpback whales were seen in greater numbers in inshore waters of Newfoundland and Labrador as the bait fish capelin, which is their major prey, was seriously depleted offshore on the Grand Banks. The humpbacks moved inshore to feed on spawning capelin, which occur in the same areas where fishermen place their nets. Inevitably this meant trouble. Fishermen began to report whale collisions, which left nets badly damaged. On occasion, whales would actually be caught and held in the nets. About 50% of the animals that were caught died. Because this was a new source of mortality in this recovering humpback population, it was a serious conservation concern.

A program was established by the Whale Research Group of Memorial University of Newfoundland to aid both the whales and the fishermen when incidental captures occurred. If fishermen anywhere along Newfoundland's 17,000 km of coastline accidentally caught a whale they could call the Entrapment Assistance Program by a toll-free phone number. A trained team would be dispatched to release the whale alive and to save as much of the fishing gear as possible. Because there were real benefits for fishermen in minimizing gear losses and lost fishing time, they cooperated very well with the program and whales benefited as well. Humpback mortality as a result of entrapment was reduced to about 10% of the animals that were captured. These deaths occurred before help could reach the animal.

This did not solve the problem. During the 1980s, groundfish populations were being seriously depleting by fishing. To make a living, fishermen responded by adding more nets. Inshore effort by fishing nets increased dramatically. With more barriers, the frequency of collisions by whales, and entrapments, increased. In one fishing season the Entrapment Assistance Program received over 150 reports of entrapped humpback whales. In addition, other species, such as common minke whales (*Balaenoptera acutorostrata*) were also being caught. The program to release whales was extremely busy and effective. However, it was apparent that something was required to prevent collisions.

It was not practical to expect fishermen to stop fishing or to substantially modify where or how they fished. Instead, because cetaceans are acoustic specialists, scientists experimented with electronic devices that could be placed on nets. The hypothesis was that noisier nets would better alert the whales to their presence so they could avoid them. The alarms emitted higher frequency sounds that cetaceans could hear but were not detected by groundfish. Thus fish catches would not be similarly reduced. Such devices were used successfully in areas where the likelihood of collisions was high. Acoustic alarms reduced collisions by about 80%. This was good news for both whales and fishermen.

Other news was not good for fishermen, however. By 1992, groundfish populations were so seriously depleted by fishing that a moratorium on fishing was established. All nets were removed from the water. Collisions and entrapments of whales were reduced to near zero. The moratorium on groundfish fishing continued until 1998 when small quotas were once again established.

The quotas that were established were very small compared to historical levels, so far fewer nets were used. The reduction

in the number of nets kept accidents with humpbacks low. However, in addition, quotas were allocated in shares to individual fishermen. Thus, each fisherman did not have to fish competitively but was assured of a fair portion of fish that they could catch when they wanted, usually when they could realize the best prices for fish. In Newfoundland, best prices occur in the fall and most fishing occurred then, a period when whale abundance inshore is relatively low. This combination of lower total fishing effort and a shift in fishing effort to a different season had kept collisions and entrapments to a very low level.

The Entrapment Assistance Program continues to be available to release whales carefully and to aid fisherman in retrieving fishing gear. In areas where whale abundance is high, fishermen continue to place acoustic alarms on nets. However, at present, the incidental capture of humpback whales in nets off Newfoundland and Labrador is a minor problem for both whales and fishermen. Because fisheries are highly dynamic and changing activities that can importantly effect the environment, they must be monitored continuously to ensure the protection of cetacean habitat.

Estrus and Estrous Behavior

DARYL J. BONESS
National Zoological Park, Smithsonian Institution, Washington, DC

Estrus is a state of sexual receptivity during which the female will accept the male and is capable of conceiving. This behavioral state is under hormonal regulation involving the ovary and pituitary gland and precedes or coincides with ovulation, i.e., production of an egg. The existing anatomical and physiological evidence suggests that the physiological process underlying estrus in marine mammals is comparable to that in other mammals.

Our knowledge about estrus and estrous behavior in marine mammals is highly variable. Among cetaceans, most of it is derived from studies of the ovaries of animals killed during whaling or collected from beached and stranded specimens. The little behavioral information that is available comes mostly from studies of captive animals and a few observations of free-ranging animals. Among pinnipeds, we know far more from behavioral observations, but this is concentrated on those species that mate on land. There is almost a complete void of information on aquatically mating species, which comprise about half the pinnipeds and the majority of the phocids or true seals. Estrous cycles in marine mammals are relatively long compared to terrestrial mammals, usually a year or more, and are seasonal and synchronous within a species or population.

I. Hormones and Anatomy of Estrus

As noted earlier, the hormonal cycle associated with estrus and reproduction in marine mammals appears to be similar to what happens in other mammals. High plasma concentrations of estrogens at the time of parturition decline rapidly and then begin a sharp rise again (Fig. 1). This estrogen rise, along with a decline in progesterone, which inhibits follicle growth, is likely responsible for rapid follicular growth in the ovary and the onset of estrous behavior.

All marine mammals have a reproductive tract that has two uterine horns (bicornuate) terminating at the ovaries. In pinnipeds, the ovary and horn involved in reproduction alternates between successive reproductive periods. This is not the case in cetaceans, however. Among baleen whales, both ovaries are equally functioning, whereas in many odontocetes one ovary appears to function early in life and the other later in life.

II. Timing of Estrus

In pinnipeds, most of our knowledge about the timing of estrus comes from behavioral observations of mounting and mating behavior. Most species are monestrous, with the exception being the walrus (*Odobenus rosmarus*), which has two estrous periods within a year. The double estrus in walruses is undoubtedly linked to the 15-month gestation. With this long gestation, parturition occurs when there are few reproductively active males available, yet there is a postpartum estrus. The second estrus occurs 9–10 months after birth, during the peak of male sexual activity. Otariid seals show relatively little variation in the timing of estrus, with it occurring early in lactation during what has been called the perinatal period and within 4–14 days following parturition for most species. In a few species (California sea lions, *Zalophus californianus;* Steller sea lions, *Eumetopias jubatus;* and Galapagos fur seals, *Arctocephalus galapagoensis*), estrus occurs after maternal foraging trips begin, which may be as much as a month after parturition. Although a postpartum estrus may be an ancestral condition, the nearly yearlong lactation in otariids, along with the dispersal of males away from BREEDING SITES after mating, would have selected for estrus to be early in lactation and shortly after parturition. Linked to this ecological pattern of spatial separation between breeding on land and feeding at sea is the existence of delayed implantation in seals, which tends to synchronize parturition, and thus estrus. The benefit to otariid females being receptive shortly after parturition would then be having access to the most competitive and highest quality males because they are present on land.

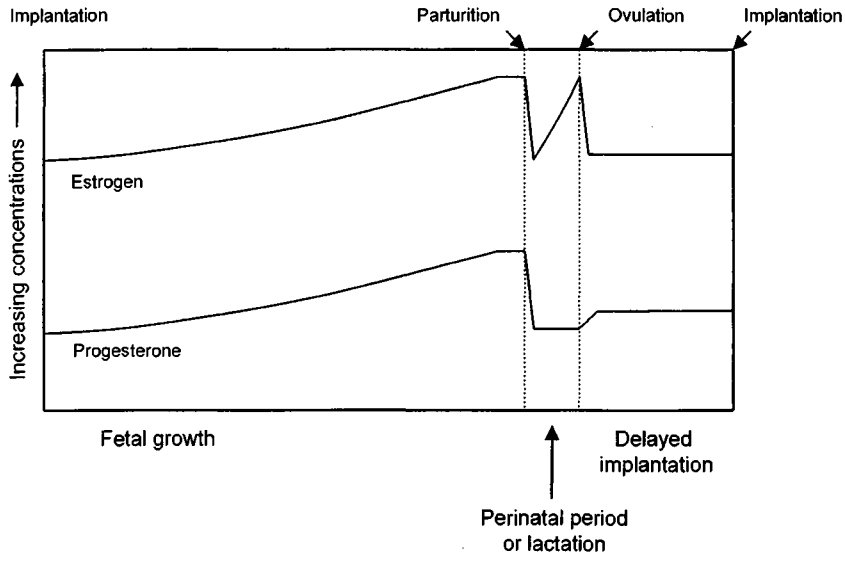

Figure 1 *A schematic of estrogen and progesterone levels in the circulatory system of female seals in relation to the timing of various reproductive events. Modified from Boyd* et al. *(1999).*

In phocid seals the timing of estrus is more variable with respect to parturition, ranging from about 5 days to between 1 and 2 months after parturition. In fact, estrus tends to occur in late lactation or after pups have been weaned in phocids. This accompanies a very different lactation pattern from that of otariids. All phocids have a short lactation ranging from 4 to 60 days. Although those phocids that have extremely short lactation periods will come into estrus within 2 weeks of parturition like most otariids, those species that lactate for a month or more have shifted estrus away from being juxtaposed to parturition if this was the ancestral pattern. Reasons for this difference between otariids and phocids are unclear. It may relate to phocid females being in estrus for longer periods of time, providing for greater opportunities to mate with multiple males and thereby increasing the quality of males fertilizing their offspring through sperm competition.

The duration of estrus in otariids appears to be very short based on observed copulatory behavior. In most species, females are observed mating once, although about 30% of females in some species are seen mating twice (see later for a possible explanation). These multiple matings still appear to occur within a 2-day period. We know nothing about the duration of estrus in the aquatically mating phocids, but for all three of the species that mate on land estrus lasts for several days. At the maximum, it may last up to 13 days in the northern elephant seal (*Mirounga angustirostris*) and 5–7 days in the southern elephant (*M. leonina*) and gray seals (*Halichoerus grypus*). An estrous period several days long is common in the sea otter (*Enhydra lutris*) as well, a species in which females are known to mate with more than one male.

Sea otters have an annual cycle like most pinnipeds. Female sea otters typically become receptive within a few days of weaning their pup and receptivity lasts 3–4 days. It is possible that ovulation is induced by copulation in this species as other mustelids exhibit induced ovulation. There is evidence of polyestrus in females that are not impregnated successfully during an initial estrus.

The cycles of cetaceans are much more variable than the cycles of other marine mammals. Many of the mysticete whales have a 2-year cycle. For example, the fin whale (*Balaenoptera physalus*) becomes receptive in the winter in low-latitude, warm water, where mating occurs, and then migrates to cooler high latitudes where it feeds through the summer. In the fall it again migrates to low latitudes to give birth, and after a second migration to cooler water for feeding and lactation the female weans the calf and has a period of anestrus for 5–6 months before becoming receptive again, having made another migration to warm, low-latitude waters. The North Atlantic right whale (*Eubalaena glacialis*) may have an even longer interval of 3–4 years between estrous periods, whereas the minke whale (*Balaenoptera acutorostrata*) appears to have an annual cycle.

Odontocetes have an annual breeding season with most mating occurring over a diffuse 2- to 5-month peak for many species studied. However, the estrous cycles of individual animals are not likely to be annual because of multiyear lactation periods for many species, which may inhibit cycling. Lactation periods of 2–3 years are common among odontocetes. Unfortunately, more behavioral studies in which individual animals are followed are needed. However, even this has its drawbacks in that copulatory behavior in some dolphins may have a nonsexual social component that could make it difficult to obtain a clear understanding of the estrous cycle from behavior.

Captive studies have provided some useful insights into the estrous cycle of nonlactating odontocetes. For example, a 3-year study with two common dolphin (*Delphinus delphis*) females and with four bottlenose dolphin (*Tursiops truncatus*)

females found somewhat similar results with respect to periods of estrus and anestrus. The common dolphin females exhibit extended anestrus of 1–2 years but also cycled as many as seven times within a year. There was no seasonality to these cycles. The bottlenose dolphin females also had a yearlong anestrus followed by polyestrus, although the maximum number of cycles within a year was only three. Along with this reduced number of cycles compared to the common dolphin the cycles were seasonal, occurring only in April and May.

Sirenians (manatees, *Trichechus* spp.; and dugongs, *Dugong dugon*) and polar bears (*Ursus maritimus*) appear to follow a similar pattern as the cetaceans with a multiyear lactation that results in an estrous cycle of 2 or more years. Among sirenians, after weaning a calf, females may also undergo polyestrus before becoming impregnated. Breeding may not be continuous, as 33 and 56% of a sample of ovaries from manatees and dugongs, respectively, showed that females were neither pregnant nor lactating. Little is known about the length of estrus in sirenians. However, given that males and females are solitary and need to search out each other for reproduction, it is likely that estrus is relatively long and ovulation might be induced. Mating or estrus groups, consisting of one female and multiple males trying to mate with the female, in manatees and dugongs last for variable periods of time, from a few hours to several days. There is anecdotal evidence for polar bears, which also live separate solitary lives except during breeding, to suggest that estrus occurs over multiple days with "courtship behavior" that may be necessary to stimulate ovulation.

III. Estrous Behavior and Signals

Inexperienced observers of the behavior of the two elephant seal species and the gray seal might come to the conclusion that females do not come into estrus, except that they ultimately do mate before departing from the breeding colony. Females generally show no soliciting behavior and appear to protest mounting attempts by males right up to the time females leave. However, upon closer observation, subtle differences in female behavior may become apparent. For example, females may reduce the duration of their protests when they are in estrus, but they may do this selectively to "potentially high-quality" males. In southern elephant seals, males reportedly will move from female to female, placing their head across the female's back and waiting for her reaction before either moving on or subsequently attempting to try to mount her. In northern elephant seals near the end of lactation, a female will not respond vocally to the harem master when he places his foreflipper over her back and she may even show a lordosis response by spreading her flippers and raising her tail end.

Most likely there are cues that signal the sexual status of these phocid females. For example, in the gray seal, attempts by males to mount females are not indiscriminate. They begin about a week before females are first observed copulating and increase in frequency linearly during that period (Fig. 2). As male gray or elephant seal males do not sniff the head or tail end of females prior to attempting to mount them, the existence of olfactory signals seems unlikely, especially in view of

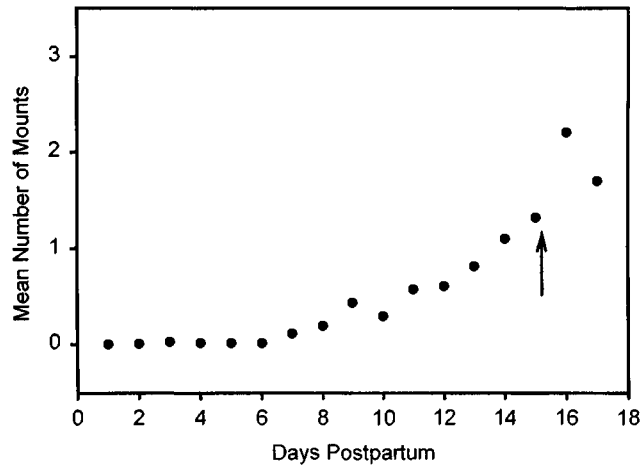

Figure 2 *Mean number of attempted copulations with females by gray seal males as a function of the number of days postpartum for the females. The arrow represents the average time of onset of estrus, defined by the first observed copulation. Modified from Boness and James (1979).*

such sniffing behavior preceding mounting in otariids (see later). One possible explanation for the discriminate mounting by gray seal males could be that they use either the body shape of females that are becoming depleted from fasting or the increased rotundness of their pups as they approach being weaned.

Another interesting example of behavior that likely indicates signaling (probably chemical) of estrus occurs in polar bears. As noted earlier, males and females are solitary and must find each other for reproduction. Males have been observed detecting the tracks of a female and following them up to 100 km to find the female. Manatee and dugong females may increase the range of their movements when they become estrous to increase the likelihood of encountering males.

Our best information about estrous behavior in pinnipeds comes from some elegant experimental work by Roger Gentry in his 19-year study of the northern fur seal (*Callorhinus ursinus*) in Alaska. These studies involved capturing groups of females, controlling their access to males, manipulating the size and age of males to which the females were given access, and using surrogates in place of males. Field observations found that prior to estrus, males engaged in sniffing the nose and mouth of females and that sniffing the tail region sometimes followed this. Investigation of the latter often led to a lordosis response. With this in mind, the studies were designed to determined the role of the male in triggering estrus, terminating it, determining the change in behavior of females, confirming the importance of olfactory cues, and understanding the mechanism of how estrus is terminated.

The following briefly summarizes the findings of Gentry's studies. Females prevented from copulating did not prolong estrus nor recycle, and receptivity lasted an average of 34 hr. A nonestrous female's behavior changed dramatically within as

short as a 5-min period, going from being aggressive to a male to emitting low-level estrous vocalization and showing lordosis. The change was reflexive in that either artificial means or a male elicited it. Copulation by a territorial male usually terminated estrous behavior within 15 min, whereas a juvenile or senescent male copulation did not terminate estrus quickly. All copulation led to fertilization, however. Males that actively suppressed the aggressive behavior of females appeared to enhance the speed with which females became receptive. Finally, there appears to be a "vaginal code" based on male size and thrusting pattern for the termination of estrus following copulation.

Very little can be said about the pre-estrous and estrous behavior of cetacean females. In one study of captive spinner dolphins (*Stenella longirostris*), an attempt was made to correlate behavioral and hormonal patterns, examining behaviors that could have a sexual function. The behaviors included genital-to-genital contact, beak-to-genital contact, other-to-genital contact, ventral presentation, chases, and nongenital contact. The only behavior that showed any relationship with hormonal states indicative of estrus was beak-to-genital contact. This involved females inserting her beak into the genital slit of the male, most often during the follicular phase of her estrous cycle.

Our best opportunity to better understand estrus and estrous behavior in cetaceans, sirenians, polar bears, and the aquatically mating pinnipeds will almost certainly come from further studies of captive animals because of our inability to observe individual animals for long periods of time in the wild. For odontocetes, there is the further complication of making inferences about receptivity from behavior alone because of the nonsexual use of sexual behavior in other social contexts.

Ethics and Marine Mammals

MARC BEKOFF
University of Colorado, Boulder

The whale in the sea, like the wolf on land, constituted not only a symbol of wildness but also a fulcrum for projecting attitudes of conquest and utilitarianism and, eventually, more contemporary perceptions of preservation and protection.
—Stephen R. Kellert, 1996

I. Humans and Other Animals: Multidimensional Encounters

Humans are a curious lot, and our intrusions, intentional and inadvertent, have significant impacts on other people, nonhuman animal beings ("animals"), plants, water, the atmosphere, and inanimate landscapes. Often our influence is subtle and long term. There are many important and difficult issues that demand serious consideration in discussions of the ethics of how human beings interact with animals. Their complexity is compounded because highly charged subjective opinions and passions run high. This article highlights just how complex and multidimensional these issues are. It is meant to be a starting point for a discussion of different perspectives; none is more important than others. What is important is that we all agree that ethics is an essential element in any discussion of human interactions with other animals.

This article concentrates on human–dolphin and human–whale encounters (e.g., hunting, keeping animals in captivity, swimming programs, using them for entertainment), for ethical questions that arise when considering these types of highly visible interactions can be used as illustrations for human encounters with other marine mammals, including the pinnipeds (seals, sea lions, and walruses), manatees (*Trichechus* spp.), and polar bears (*Ursus maritimus*). There is much public interest in these rendezvous.

Dolphins, whales, and other marine mammals have often been fabricated to be the animals we want them to be. Most descriptions of dolphins and other cetaceans picture them as highly intelligent and capable of experiencing pleasure and pain (sentient) animals with remarkable social and cognitive skills. Indeed, dolphins and other marine mammals seem to fulfill some criteria of "personhood" in that they are alive, aware of their surroundings, sentient, and may have a sense of self. Why, then, do some people feel comfortable intruding into their worlds if it will cause pain and suffering? Toni Frohoff (1998, p. 84) has poignantly noted: "Currently we are walking a fine line in our relationship with cetaceans. The same attraction that motivates us to protect them from harm is also what drives us to be close to them, to have them 'within reach.'" It is because dolphins and other marine mammals are thought to be attractive, harmless, endowed with mystical qualities, or to be of economic value as commodities for show or food that we

seek them out. However, we may bring much harm to them in our efforts to include them in our lives, even in ways that do not involve killing them.

Many issues that are pertinent when considering marine mammals are also raised when discussing other mammals such as terrestrial CARNIVORES. Wolves and whales have been among the most persecuted of animals during the last three centuries, wolves because they were feared predators and whales because of their economic value. The near EXTINCTION of both wolves and some whales was important in setting environmental policies. However, while many people swim and wade with dolphins, few if any truly dance or howl with wolves. Thus, the close contact that many humans have with some marine mammals leads to other questions that are unique to these encounters.

A. What Should We Do?

Human impacts on other animals, intentional and inadvertent, are universal. A major question in need of serious debate is should we ever interfere in other animals' lives—when might human interference be permissible? Thus, should we let other animals be and not intentionally interfere in their lives? Or, should we hunt them for food whenever we so wish? Should we hunt only when there are no alternative food sources? Should we interfere in other animals' lives when we have spoiled their habitats or when they are sick, provide food when there is not enough food to go around, provide care to young if a parent does not, stop aggressive encounters, stop predators in their tracks, or translocate individuals from one place to another, including zoos, wildlife and marine theme parks, and aquariums? Should human interests always trump those of other animals? If not, then when should the interests of other animals trump our own?

The question of when humans *should* intrude is a difficult one. However, just because we *can* do something does not mean that we *should* or *have* to do it. Furthermore, just because some intrusions may be *relatively* less malign than others, this line of reasoning places us on a very slippery slope and can, in the end, lead to narrow or selfish anthropocentric claims. Even in situations when humans have good intentions, those intentions are not always enough.

This article discusses some basic principles that underlie the use and exploitation of marine mammals, especially whales and dolphins, presents a few general questions, and discusses some representative examples. Definitive answers to these and other questions are quite elusive, but open discussion can provide guidelines for proactive decision-making. All too often we are left in the position of trying to rectify messy and difficult situations that we have created; proactivity needs to become the *modus operandi* for future actions. For many questions about how animals should be treated by humans there are no "right" or "wrong" answers. However, there are better and worse answers. Perhaps it will turn out that in some cases what we think is the "right" action is not when the big picture is carefully analyzed.

It is essential to remember that even if wild or captive marine mammals develop close social bonds with humans, these animals are socialized or habituated individuals, but they are not domesticated animals. Often people remark that individuals who interact closely with humans have become domesticated. However, domestication does not happen to an individual during his or her lifetime. Domestication is a long-term evolutionary process during which humans selectively breed animals for desirable traits. "Domesticated" and "socialized" or "habituated" are not synonyms.

B. Human Responsibilities

It generally is accepted that humans have unique responsibilities to other living organisms (and to inanimate environments). Our unique responsibilities stem from our (at least most of us) being moral agents who are responsible for our actions. It usually is assumed that neither animals nor young human infants and mentally impaired adults are moral agents. Rather, they are moral patients, not usually held responsible for their actions. They do not know "right" from "wrong" or "good" from "bad." Nature, too, cannot be good or bad, although the consequences of natural acts can be better (good) or worse (bad). Nature simply is. We do not have to apologize for nature's ways. Nor should her ways—her supposed cruelty and ruthlessness—be used as excuses for what we do to other animals (including humans).

It is important to stress that most, if not all, other animals depend on our goodwill and mercy. Individuals can choose to be intrusive, abusive, or compassionate. We do not have to do something because someone else wants us to it. We do not have to do something just because we can do it. Each of us is responsible for our choices.

II. Animal Rights and Animal Welfare: The Moral Status of Animals

In current discussions about the moral status of animals, there is an obvious "progressive" trend for greater protection for wild and captive animals. (This might be due in part to an increasing number of people moving from farms and rural areas to more urban environments.) This is clearly the case for marine mammals (Kellert, 1999). In a survey of American's perception of marine mammals, most respondents were opposed to commercial WHALING, often for ethical reasons. Concern was also expressed for the commercial exploitation of seals, sea otters, walruses, and polar bears. Most Americans also objected to commercial whaling by native peoples or the resumption of killing gray whales. A majority of Alaskans opposed oil and gas development if it injured or killed marine mammals. There also was an unsuccessful effort prior to the reauthorization of the Marine Mammal Protection Act in 1988 to prohibit any invasive research involving marine mammals unless that research would directly benefit the subject of the research.

In recent years, philosophers and scientists have devoted increasing attention to questions about the moral status of animals. Many people support a position called the *rights* view. To say that an animal has a right to have an interest protected means that the animal has a claim, or entitlement, to have that interest protected even if it would benefit us to do otherwise. Humans have an obligation to honor that claim for other animals (just as they do for humans who cannot protect their own interests). Thus, if a wild dolphin has a right to feed, then

humans have an obligation to allow her to do so and not do anything to interfere with her feeding activities. Likewise, if a dolphin has a right to life, she cannot be used in war games, warfare, or other activities in which death is possible.

Animal rights advocates stress that animals' lives are valuable in and of themselves (they have inherent value) and that their lives are not valuable because of what they can do for humans (their utility) or because they look or behave like us. Animals are not property or "things," but rather they are living organisms who are worthy of our compassion, respect, friendship, and support. Animals are not "lesser" or "not as valuable" as humans; they are not property that can be abused or dominated. Human benefits are irrelevant for determining how animals should be treated.

Many people believe that the rights view and the *animal welfare* view are identical. They are not. Animal welfarists focus on individuals' usefulness to humans. They practice *utilitarianism*, in which the general rule of thumb is that the right actions are those that maximize utility summed over all those who are affected by the actions. Often welfarists/utilitarians are called "wise users." They believe that while humans should not abuse or exploit animals, as long as we make the animals' lives comfortable, physically and psychologically, we are taking care of them and respecting their welfare. Welfarists are concerned with the quality of animals' lives. However, welfarists do not believe that animals' lives are valuable in and of themselves. Many conservation biologists and environmentalists are utilitarians who are willing to trade off individuals' lives for the perceived good of higher levels of organization such as populations, species, or ecosystems.

The welfarists' rule of thumb, and it is not a moral rule, is that it is permissible to use animals if the relationship between the costs to the animals and the benefits to the humans is such that the costs are less than the benefits. Welfarists believe that if animals experience comfort, appear happy, experience some of life's pleasures, and are free from prolonged or intense pain, fear, hunger, and other unpleasant states, then we are fulfilling our obligations to them. If individuals show normal growth and reproduction and are free from disease, injury, malnutrition, and other types of pain and suffering, they are doing well. Thus, welfarists argue that using animals in experiments, slaughtering them for human consumption, and using them for treating human disorders [e.g., dolphin-assisted therapy (DAT) programs] are permissible as long as these activities are conducted in a humane way. Welfarists do not want animals to suffer from any unnecessary pain, but they sometimes disagree among themselves about what pain is necessary and what humane care really is. Welfarists agree that the pain and death animals experience are sometimes justified because of the benefits that humans derive. The ends—human benefits—justify the means—the use of animals.

III. Hunting Whales

Whale HUNTING brings to light numerous issues that reflect utilitarian thinking. Whales are frequently viewed as commodities. Whether they are hunted centers on whether it is economical. Rarely are the costs to the individuals entered into the equation. In the past, many people thought that whales were an inexhaustible resource and historically there were few restrictions on killing them. When whale watching became popular, whales were more valuable alive than dead. They went from being a consumptive to a nonconsumptive resource.

Political and sociocultural motives also play a role in whale hunting. Various indigenous people (e.g., the Makah in Washington State) want to be able to hunt whales (in the Makah case, gray whales) because their ancestors did so, because it was part of their cultural heritage. They claim that the tradition of whale hunting defines "who they are."

The revival of aboriginal whaling is controversial in various parts of the world and involves species other than the gray whale. When the target species is on the brink of extinction, few argue that any type of whaling is permissible. Likewise, when killing whales is essential for food, few argue against the practice. However, when the whales are not endangered, people disagree about continuing to kill whales or reestablishing this practice. Some argue that whale hunting is permissible because it is part of the heritage of a given indigenous group (it is cultural revival), whereas others argue there are other cultural practices that are no longer followed and little effort to regain them. Why is whaling hunting so important if it is not essential for sustenance?

Methods of killing whales also are controversial. For example, the Makah used a rifle to kill a whale who had been wounded by a harpoon. A majority of Americans oppose the use of weaponry. Hunting whales produces much pain and suffering. Chasing and stalking individuals compromises their physical and psychological well-being and death usually is not instantaneous, frequently taking upward of 10 min. Furthermore, family groups are broken up. All in all, hunting whales and other animals, including such marine mammals as seals, raises numerous difficult ethical issues.

IV. Keeping Animals in Captivity

A. Swimming with Dolphins

"Swim with dolphin" and "petting pool" programs are very controversial. Such proffered reasons as "it's fun," "aren't the animals cute," or "it's a spiritual experience" are insufficient to justify these practices. Much attention has been given to the question of whether human encounters with dolphins may have negative effects on the dolphins. Human–dolphin interactions may be noisy and stressful. One study reported that captive dolphins showed enlarged adrenals, especially those individuals exposed to humans on numerous occasions. The long-term effects of swim programs on dolphin behavior and well-being still need to be studied systematically, but evidence shows that the stress associated with these programs may have long-term effects on the dolphins.

Swim programs are risky to humans. Dolphins are large and strong animals. While higher risks seem to be experienced more in noncontrolled swims, there are also serious risks in controlled swims that might be fatal. "Controlled" refers to situations when all interactions are directed by trainers, who give the dolphins commands at all times. "Noncontrolled" means interactions are allowed to occur spontaneously.

It is also important to know if DAT programs truly work. While some researchers claim that DAT is an effective therapeutic intervention for several disorders (e.g., depression, autism, cerebral palsy, mental retardation), others disagree. Criticisms center on the use of improper statistical methods and the lack of controlled studies. It often is very difficult to assess experimentally the positive effects of animals on people. In many programs, no other animals, including such domesticated species as dogs, were used as controls to see if they might be as or more effective than dolphins.

Another question that also is important to consider is whether programs that involve interactions with captive dolphins help educate people about these and perhaps other animals. More research is needed to determine if contacts with dolphins actually change people's attitudes about them. Intuitions are not enough. To date, there is no solid evidence that interactive captive programs with dolphins are more effective educationally than noninteractive programs. Indeed, some marine biologists fear that these programs may send the message that it is permissible to take animals from the wild and bring them into captivity and keep them in small tanks where they are bored, deprived, and needlessly die. There also are serious concerns about the fate of dolphins once they are too old or aggressive to partake in swim programs. Yet another concern centers on the possibility that these programs may teach people to expect the same kinds of interactions from free-ranging wild animals.

While there have been attempts to regulate swimming programs, little has actually been accomplished. In the United States, federal regulations controlling these programs, mandated in 1998 (after a delay of 4 years before finalizing them) by the U.S. Department of Agriculture's Animal and Plant Health Inspection Service (APHIS), were suspended in April 1999 soon after they were invoked because, according to their press release: "It has come to our attention that the language in the new regulations may be confusing to some. Therefore, we are suspending enforcement of the regulations in order to take a closer look at the language and make it more understandable." (http://www.aphis.usda.gov/lpa/press/1999/04/dolphin.txt) During this process, there are no regulations for these popular programs. Some people believe the federal regulations were suspended because of pressure from the lucrative industries that exploit dolphins.

B. Petting and Feeding Programs

Petting and feeding programs allow people to pet and feed captive dolphins. Many of these programs may not be adequately supervised or monitored. There are some major concerns with these programs, including that dolphins may be unable to avoid encounters with humans and may be highly stressed, the water in which dolphins and humans interact is often heavily chlorinated and may be unhealthy for dolphins (and humans), dolphins may be fed foreign objects that can harm them, and there seems to be little, if any, education value to these programs. There are few data that speak to these and other concerns and this information is needed to determine if petting and feeding programs can be properly regulated. One of the main questions is whether dolphins can be accessible to people in these programs and still be protected from harm.

While feeding and harassing wild dolphins is illegal in the United States, and there are severe penalties for engaging in these activities, this is not so for other countries. There are documented instances of wild dolphins being fed firecrackers, golf balls, plastic objects, balloons, and fish baits with hooks (so that hooked dolphins can be caught). Provisioning dolphins with fish has been associated with a change in the social behavior of free-ranging bottlenose dolphins (*Tursiops aduncus*) in Monkey Mia, Australia. Dolphins who have been fed also change their foraging behavior and frequent heavily trafficked harbors and marinas. Some get struck by boats. People have also been seriously injured trying to feed wild dolphins. The National Marine Fisheries Service and other organizations are mounting highly visible campaigns to stop the feeding and harassment of wild dolphins. It also has been noted that some problems associated with feeding terrestrial mammals (changes in foraging patterns and hunting skills) are relevant to concerns about the feeding of dolphins.

Clearly, much more information is needed concerning petting and feeding programs for captive and wild animals. Especially needed are data concerning the effects of these programs on dolphin mortality, health, and psychological and emotional well-being. It also is important to counter the possibility that feeding captive dolphins may send the message that it is permissible to feed wild individuals.

C. Zoos: Aquariums and Marine Theme Parks

The existence of zoos, including aquariums and marine theme parks, raises many important and difficult ethical questions. Certainly, numerous people are interested in exotic animals, including marine mammals. Kellert found that a majority of Americans objected to the captive display of marine mammals in zoos and aquariums if there were no demonstrated educational and scientific benefits. They were concerned with the care given to captive individuals. To date, no unequivocal data show that there are any significant educational and scientific benefits that help the animals, despite beliefs that such benefits accrue. An average zoo visitor spends only about 30 sec to 2 min at a typical exhibit and only reads some signs about the animals. A number of surveys have shown that visiting zoos to be entertained was the predominant reason people went to the zoo. In one study at the Edinburgh Zoo in Scotland, only 4% of zoo visitors went there to be educated, and no one specifically stated they went to support conservation. To date, very few empirical data support the notion that much educational information is learned *and* retained that helps the animals in the future. Indeed, some people worry that keeping animals in captivity for humans to view carries the message that it is alright to do so.

Many questions center on how individuals are captured, transported, and kept in various types of captive situations. Animals often are injured and otherwise stressed during capture and transport. Family groups may be broken up and the social structure of populations decimated. The effects of changing the social structure of wild populations are little known. Well-intentioned people often argue that the lives of captive animals are better, of higher quality, than those of wild relatives, but available data for marine mammals suggest that this claim is

not well supported. From an ethical perspective, one must consider whether this claim is even relevant, for keeping animals in captivity radically alters numerous behavior patterns that have evolved over millennia. Predation, starvation, and disease are part of what it is to be wild. Is a longer unnatural life in captivity better than a shorter natural life in the wild?

Breeding surplus animals for profit (e.g., polar bears who become the center of media parades and then are moved to other zoos when their resource value or utility is fully exploited) also demands serious discussion. Similarly, the trading, donating, or loaning of unwanted or surplus animals who cannot be released into the wild—treating them as property—also raises numerous ethical questions.

The benefits of keeping marine mammals in captivity, to the animals themselves, remain unknown. Because the social and physical environments of marine mammals are virtually impossible to replicate in captivity, ethical questions arise when these animals are maintained in unnatural environments. There can be little doubt that the quality of life is compromised. In captivity, evolved patterns of foraging, caregiving, and migrating are lost as are natural patterns of social organization (group size and composition). In captivity, for practical reasons, group sizes may be much smaller than those observed in wild relatives. Stereotyped behaviors often result from conditions of captivity, as do self-mutilation and unusually high levels of aggression. Furthermore, individuals often cannot escape from the glaring eye of the public and cannot choose when and where to rest.

There also seems to be higher mortality (spontaneous abortions, still-births) in captive versus wild individuals (especially killer whales, *Orcinus orca*). There also is higher mortality for adult killer whales in captivity. Limited data on annual survival rates suggest that there is high mortality during acclimation to captivity and differences in annual survival rates among different species and age classes within species.

There is little evidence that people leave zoos or aquariums with any long-lasting sentiments or knowledge that benefit either the animals they have seen or their wild relatives. Furthermore, few zoos are engaged in conservation efforts for marine mammals.

Many ethical concerns are also raised because first and foremost, zoos are businesses and their bottom line centers on money. It costs an enormous amount of money to bring marine mammals into captivity and to keep them there. It has been suggested that the money used to capture, transport, and keep animals in captivity would be better used to do research in the wild. Also, much money is spent on public relations and not on the animals themselves. Some feel that the images of nature that are represented to the public are a manufactured corporate point of view that centers more on what the public wants than what is good for the animals. Witness the existence of numerous "Flippers" (the prototypical dolphin) and "Shamus" (the model killer whale), whose lives do not resemble even closely the lives of free-living conspecifics or relatives.

Similar questions are raised when considering research on captive animals. Certainly, information may be gathered about various aspects of their lives (e.g., maternal behavior, self-recognition, social behavior, communication, and cognitive capacities). However, research on captive animals is being increasingly carefully scrutinized by some researchers, philosophers, many universities, and various funding agencies. Some relevant questions include: is it ever permissible to keep individuals in captivity regardless of their utility, is the knowledge that is gained by studying captive individuals justified by keeping them in cages or tanks, and could more reliable data be collected under more natural conditions? Very little still is known about the life histories of most marine mammals. For many people it is the benefits that the captive individuals and other members of their (or other) species might accrue that is central, not the benefits that humans might gain. However, rarely are results used to benefit the animals other than in learning about medical treatments and husbandry to make their lives in captivity better. Rarely do wild individuals benefit from work done on captive relatives.

V. Research Ethics

In addition to questions concerned with how humans treat other animals, the study of ethics also considers questions dealing with such areas as (1) the context of research (where it is done, are local people involved when researchers "go into the field" in countries other than their own, are local customs and beliefs about native fauna respected); (2) scientific integrity (researchers' responsibility for integrity in data collection, analysis, and dissemination); (3) the ownership of data (do data "belong" to any single person or to the team that is involved in their collection, analysis, and dissemination); (4) authorship (whose names should appear on a publication and in what order); and (5) individual responsibility for the integrity of a project as a whole and for the integrity of the results. A good deal of trust is involved in all research, and questions that arise in these general areas require, and are receiving, much attention in the scientific community. Studies of marine mammals often require large teams of people, some of whom have never met, and it is important for all individuals to realize that each is responsible not only for his or her involvement, but for the composite product that is generated.

Another area of concern, some aspects of which are included in this volume, is research methodology (trapping, marking, tracking, and observing animals; experimentally manipulating social groups, food supply, and habitat). Often, human intrusions have major effects on animals' behavior even if they are unintentional. For example, the mere handling of individuals can influence their behavior and their acceptance back into a group, as can fitting individuals with various telemetric devices. Tracking or stalking animals can lead to changes in their activity patterns so that they spend more time avoiding humans than feeding or giving care. Most data come from animals other than marine mammals, and future studies of the effects of various methods are needed. Ethical considerations require that we learn about the effects of research methodologies and attempt to avoid them. In some cases the methods used may preclude collecting data relevant to the questions at hand.

VI. Ecotourism

Ecotourism (whale watching, swimming with wild dolphins, photographing animals, visiting pinniped rookeries), some as-

pects of which are discussed in this volume, also raises numerous ethical questions concerning human intrusions into the lives of other animals. When, if ever, this activity is justified requires serious debate. People often try to interact with wild marine mammals but do not attempt to pet wild zebras or lions. What principles underlie these differences in attitude?

Whether ecotourism is less intrusive on the lives of marine mammals than various research practices awaits further study. Indeed, there are observations of humans causing seal pups to stampede and being trampled and of humans striking and injuring animals with boats. It is essential to educate the public of possible negative effects of ecotourism.

VII. The Future: Being Proactive

Kellert's study of American perceptions of marine mammals and their management shows clearly that most people support the various goals of the U.S. Marine Mammal Protection Act. Most are willing to "render significant sacrifices to sustain and enhance marine mammal populations and species. . . . These findings clearly indicate that marine mammals possess considerable aesthetic, scientific, and moral support among the great majority of Americans today." (Kellert, 1999, pages iv–v)

It is in the best traditions of science to ask questions about ethics; it is not antiscience to question what we do when we interact with other animals. Ethics can enrich our views of other animals in their own worlds and in our different worlds and help us to see that their lives are worthy of respect, admiration, and appreciation. Indeed, it is out of respect, admiration, and appreciation that many humans seek out the company of whales, dolphins, polar bears, and other marine mammals.

Many ethical issues are extremely difficult to reconcile and generate highly charged and deep emotional and passionate responses. Achieving a win–win situation for animals and humans will be very difficult. However, it is clear that the increasingly detailed attention being given to various sorts of human–marine mammal interactions is showing that there are innumerable negative effects on the lives of the animals. While many negative influences have been anticipated or are not surprising, the severity of human influences has not been fully appreciated. We must be careful not to love these animals to their (or our) deaths. Humans are indeed dangerous to marine mammals and they are dangerous to us.

The study of ethics can also broaden the range of possible ways in which we interact with other animals without compromising their lives. Ethical discussions can help us see alternatives to past actions that have not served us or other animals well. Thus, the study of ethics can be enriching to other animals and to ourselves. If we believe that ethical considerations are stifling and create unnecessary hurdles over which we must jump in order to get done what we want to accomplish, then we will lose rich opportunities to learn more about other animals and also ourselves. Our greatest discoveries come when our ethical relationships with other animals are respectful and not exploitive.

Allowing human interests always to trump the interests of other animals is not the best strategy if we are to solve the numerous and complex problems at hand. We need to learn as much as we can about the lives of wild animals. Our ethical obligations also require us to learn about the innumerable ways in which we influence animals' lives when we study them in the wild and in captivity and what effects captivity has on them. As we learn more about how we influence other animals, we will be able to adopt proactive, rather than reactive, strategies.

The fragility of the natural order requires that people work harmoniously so as not to destroy nature's wholeness, goodness, and generosity. The separation of "us" (humans) from "them" (other animals) engenders a false dichotomy, the result of which is a distancing that erodes, rather than enriches, the possible numerous relationships that can develop among all animal life.

Public education is critical. To disseminate information about what is called the "human dimension," administrators of zoos, wildlife theme parks, aquariums, and areas where animals roam freely should inform visitors of how they may influence the behavior of animals they want to see. Tourism companies, nature clubs and societies, and schools can do the same. By treading lightly, humans can enjoy the company of other animals without making them pay for our interest in their fascinating lives. Our curiosity about other animals need not harm them.

Many marine mammals are closely linked to the wholeness of many ecosystems, and how they fare is tightly associated with how communities and ecosystems fare. By paying close attention to what we do to them, and why we do what we do where and when we do it, we can help maintain the health of individuals, species, populations, and ecosystems.

Acknowledgments

I thank Toni Frohoff, Robert Hofman, Dale Jamieson, Naomi Rose, and Trevor Spradlin for comments on an earlier draft of this paper. Trevor Spradlin kindly sent me voluminous material dealing with human–dolphin interactions, much of which I can only summarize here. Support for summary statements can be found, for the most part, in J. R. Twiss, Jr., and R. R. Reeves (eds.), "Conservation and Management of Marine Mammals," Smithsonian Institution Press, Washington, DC, and in other sections of this encyclopedia. Some sections of this essay are modified from my essay titled "Troubling Tursiops," in Toni Frohof and Brenda Peterson (eds.), "Dolphins: A Literary and Scientific Exploration."

Evolutionary Biology, Overview

Frank Cipriano
San Francisco State University, California

Evolutionary biology is a multidisciplinary field devoted to the study of the biological significance of evolution, as well as documentation of its effects. This branch of biology is not *just* the study of evolution, although that is one of its integral components, and may perhaps be better defined as "the work that evolutionary biologists do." This includes a focus on many different aspects of biological processes, informed by an evolutionary perspective, and addressing questions from the microscale of point mutations in DNA to the genealogy relating all living organisms on planet Earth.

I. Components of Evolutionary Biology

From its very beginning, evolutionary biology has been, by necessity, an interdisciplinary field. Four areas of biology were most important in demonstrating the existence and operation of organic evolution; studies of morphology, paleontology, genetics, and ecology have been termed the "four pillars" of evolutionary biology. However, evolution encompasses all aspects of biology, as all living things do and have evolved, and evolutionary biology thus contributes to, and is influenced by, all biological disciplines. In current practice, evolutionary biology depends on an understanding of zoology, botany, geology, physics, analytical chemistry, and biochemistry, as well as some familiarity with aspects of microbiology, physiology, embryology, cell biology, mathematics, statistics, anthropology, archaeology, SOCIOBIOLOGY, psychology, history, and philosophy. Genetics has been the most significant contributor to the development of evolutionary theory after Darwin, and its offspring, molecular biology (co-parented by cell biology), is fundamentally grounded on evolutionary mechanisms. "Biotech," a derivative of molecular biology, genetics, and the pharmaceutical industry, is clearly the most active area of biological investigation today and for the foreseeable future. The synthesis of population genetics and ecology, each also essentially rooted in evolutionary principles, led to the development of the field of population biology, which mainly deals with the interplay among gene frequencies, population demographics, and selection coefficients in a purely mathematical framework. Biological systematics (the study of the relationships among groups of living organisms) is necessarily practiced in an evolutionary framework. A new but very rapidly developing field is nicknamed "evo/devo"—essentially the study of development in an evolutionary framework, which depends on aspects of embryology, biochemistry, molecular biology, and evolution—and which will probably be the next important focus of the "biotech" industry.

Evolution itself can be considered the process (and also the result) of change in heritable aspects of biological populations over time, as observed routinely in the fossil record and in living populations alike. There is incontrovertible evidence for such changes both in the past and currently: that biological evolution happens is a well-documented fact. *Evolutionary theory* is concerned with the details: elucidation of mechanisms that cause and influence evolutionary changes, and evaluation of the relative importance of particular factors. However, what is generally meant by "the" theory of evolution (as developed by Charles Darwin and Alfred Russel Wallace) is a simple, three-part observation that describes evolution resulting from the operation of *natural selection:* (1) members of a species usually have a high reproductive capacity and thus the population will tend to increase in size and its members to compete with each other, (2) individuals of a species differ in a variety of ways,

some of which are heritable, and (3) particular individuals possessing some advantageous heritable quality, in competition with other members of their species, will survive and reproduce more often so that their offspring and the advantageous qualities they possess will be more numerous in succeeding generations. This is "a statement of what are held to be the general laws, principles, or causes of something known or observed," and thus a theory in the scientific sense. Criticisms that evolution is "only a theory" are ignoring both the proven fact of evolutionary change and the scientific meaning of *theory*.

Evolutionary biology is currently a significant discipline within the biological sciences because an understanding of evolution is important in understanding the functioning, as well as the history, of morphological structures, physiological mechanisms, cellular processes, and so on (consider, for example, the giraffe's neck or the development of antibiotic-resistant disease bacteria). A search of recent science literature shows that article titles and abstracts containing the word "evolution" account for 1% of the 10 million scientific articles in the Science Citation Index (Institute for Scientific Investigation), about the same number of references as for articles containing the words "chemistry," "physics," or "computer" (Fig. 1). This key word search probably underestimates the influence of evolutionary thought, as an understanding of the evolution of enzymes, proteins, cell-recognition mechanisms, and gene regulation is fundamental to the booming fields of molecular and cell biology and "biotech," although such a perspective may not be reflected in the titles and abstracts of articles (Fig. 1, see entries for "cell," "gene," and "molecular").

Given the fundamental influence of evolution on all living things, one might reasonably claim that *all* biology is evolutionary biology. After all, an interest in the purely mechanistic functioning of the most minor part of a single cell carries with it the implicit question of why and how that part came to be. Without going that far, it seems fair to suggest that it is the *explicit* asking of such questions that defines the evolutionary biologist: how they go about finding an answer is a matter of individual taste, possibly even of style (and hence the claim in the second sentence of this article)! An evolutionary perspective, applied to a wide variety of biological questions, defines the field (accurately if not precisely) and predicts the breadth of subject matter that is the grist to our mill.

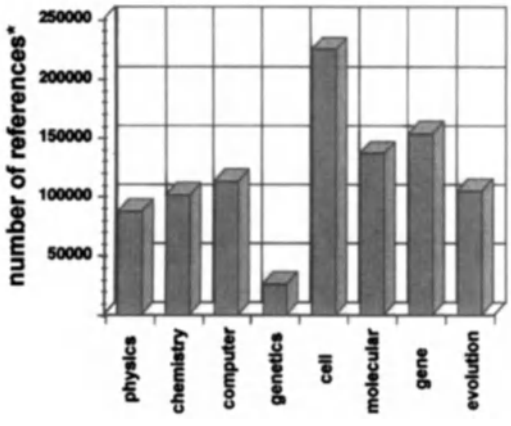

Figure 1 *Results of a literature search for certain keywords (most denoting scientific disciplines) using the online Science Citation Index (© Institute for Scientific Investigation). Bars show the number of articles found containing the key words (in the title, abstract of the article, or listed keywords) indicated along the bottom axis. *At the time of this search, the Science Citation Index (expanded) 1988–present contained 10,163,098 articles.*

II. Model Systems and the Subject Matter of Evolutionary Biology

Although it was claimed earlier that the study of evolution itself is not the only focus of evolutionary biology, it is certainly one of the most important. A glance through the table of contents of books on evolution and evolutionary biology will reveal that the main areas of interest in evolutionary studies are limited to just a few issues. These include studies of adaptation, tracing evolutionary descent, the history of biological diversity and geographic patterns thereof, debate over the source material of evolution and its causes (selection and/or chance events?), estimates of the rates and directions of evolution, and assessment of the mechanism(s) of SPECIATION. Studies in these areas have produced the body of knowledge of mechanisms that cause, influence, and constrain evolutionary changes referred to earlier as *evolutionary theory*. Such theory is developed in a back-and-forth between observation of living systems, interpretation of patterns thought to indicate the operation of evolutionary laws or principles, erection of formal theories encapsulating those laws or principles, and tests of the theories with further observation and/or experiment.

Crucial to development of our understanding in each of these subject areas is the establishment of appropriate model systems—organisms in an environmental and evolutionary context—some that provide initial data that (according to particular interpreters) illustrate the patterns and others that can be used to test the generality of the theory, for specific issues at appropriate time, distance, and evolutionary-relatedness scales. Biological model systems are analagous to what engineers call a "test bed"—strap a newly designed engine onto a 747, then take her up and see how she flies. . . . The model systems that are the test beds of evolution are often organisms that only a devoted biologist could have much fondness for: fruit flies, yeast, and roundworms. These valiant conscripts to the cause of science serve well because their size, care requirements, and rapid generation time make them ideal experimental subjects. None of these criteria characterize any marine mammal species—even the smallest dolphin is a relatively large mammal, slow-growing, reproducing late in life, and difficult, if not impossible, to breed in captivity. Marine mammals have certainly undergone some interesting evolution—invaders of an alien and difficult habitat that require extensive adaptations of mammalian morphology, physiology, sensory systems, and behavior—but have studies of marine mammals contributed much to the development of evolutionary theory?

III. Marine Mammals and Evolutionary Biology

Out of the 10 million entries in the current database of the Science Citation Index, a search for articles containing the term "evo-

lutionary biology" along with "cetacean," "pinniped," "marine mammal," "whale," "dolphin," "seal," or "sea lion" turns up exactly two articles. Not necessarily indicative, given the assertion that evolutionary biology is more a matter of evolutionary perspective applied to biological questions than an explicit focus on evolution alone. This is perhaps supported by searches for "evolutionary biology" along with "Drosophila," "human," "bacteria," or "HIV" (all of which are of major interest to evolutionary biologists), which produced just 59, 53, 8, and 4 articles containing those combinations of terms, respectively. A search for just "evolution" combined with the names of various groups of marine mammals was somewhat more successful, producing a list of several hundred articles.

The literature on marine mammals *and* evolution (not just marine mammal evolution) includes a fairly broad cross section of all the evolutionary topics outlined previously. This literature does include "purely evolutionary" discussion of the time of origin of particular marine mammal groups, from the divergence of the cetaceans from terrestrial mammals about 40 million years ago to the in-progress split between polar bears (*Ursus maritimus*) and brown bears (*U. arctos*). In addition, the divergence time of whales from land mammals is an often-used molecular landmark used to "calibrate" divergence times of other groups.

Although marine mammals are usually unsuitable for direct experimental manipulation (difficult husbandry, political issues, and so on), the analysis of "natural" experiments involving marine mammals has identified particular factors generally important in evolution. Natural experiments are often initiated by the dispersal of species or populations across a wide variety of habitats, or disruption of widely distributed species into separate regions by major environmental changes. Documentation that divergent species or populations use contrasting methods to find prey or avoid predators, find mates, or use resources differently in their particular environments is useful in identifying patterns that can be analyzed for correlation with evolutionary principles. Much attention has been spent on comparative studies made possible by natural experiments of gene evolution, social and breeding systems, morphological and developmental differences, and physiology, both within and between groups of marine mammals. For example, many comparisons have been made within and between seals and sea lions, and very many others between particular marine mammal examples and other terrestrial mammals, or vertebrates in general. Cetaceans, especially the large whales, are often used in such comparisons because both their large size and ancient divergence make them a useful yardstick for comparative studies of gene evolution, physiological adaptations, sensory system functioning, and even disease resistance. Physiologists, life history modelers, and sociobiologists alike have recognized that if they can demonstrate a consistent relationship between factors along a continuum from mice to whales, that says a lot; if particular species are above or below the mouse-to-whale line (for breeding system, brain:body size, and so on), that says a lot too.

In addition, it appears that although marine mammals may not have contributed directly to development of evolutionary theory as model systems, some evolutionary principles are exemplified beautifully by marine mammals. Just about any general biology textbook will illustrate two general principles of evolution with drawings like those shown in Fig. 2. Homology is the similarity between organisms or their parts due to derivation from a common ancestor; Fig. 2a shows that forelimbs from a variety of mammals, including whales, have the same underlying bone structure related to their common ancestry. CONVERGENT EVOLUTION is almost the opposite: similar features found in distantly related organisms; Fig. 2b shows how a common physical regime has resulted in very similar body shapes for three very distant groups of marine vertebrates.

The evolutionary origins of whales, and of pinnipeds, have been subjects of much controversy. Some datasets (and their interpreters) suggested separate origins for toothed vs baleen whales, whereas other interpretations indicated a common origin for all whales. A similar disagreement raged (some will say still rages) over the independent vs common origin of pinnipeds. Although not all proponents are yet satisfied with a resolution of the pinniped origin question, baleen and toothed whales are now generally recognized as resulting from a single origin. These controversies provide clear examples of the difficulty of disentangling homology (identity by descent) from analogy (similarities related to functional convergence), a distinction of broad evolutionary interest. The current debate over the placement of sperm whales (are they more closely related to baleen whales or to other toothed whales?) continues to underscore such difficulties. Detailed investigations of the molecular genetic methodology used to address this question have indicated the importance of certain methodological choices used in the analysis and also the effect of including data from particular, distantly related groups ("outgroups") to the results of such comparisons. Although many different types of genetic comparisons consistently conclude that whales and hippos (*Hippopotamus* spp.) are nearest relatives, morphological comparisons of fossils suggest a different (and now extinct) group of early ungulates ("hooved" mammals and their progenitors) not related to hippos were the progenitors of whales. These difficulties underscore another point important for the consideration of evolutionary biologists—morphology and molecules often do not agree—and how to handle such difficulties is a topic taking up many pages in the current issues of the scientific journals of the field.

Another prime example provided by marine mammals is for the consequences of extreme "population bottlenecks" associated with near extinctions. Northern elephant seals (*Mirounga angustirostris*) were almost completely extirpated by unregulated human hunts and their genetic diversity was greatly reduced. A closely related Southern Hemisphere "sister species" (*M. leonina*) was not depleted so severely, and a higher level of genetic diversity compared to the northern species has been maintained. Loss of genetic diversity has been predicted to result in an increased susceptibility to disease as well as problems associated with inbreeding, but so far northern elephants seals appear to be thriving. Scrutiny of their reproductive status, study of their genetic makeup, and comparisons to their southern relatives and other mammals continue. Similarly, North Atlantic right whales (*Eubalaena glacialis*) were badly depleted by unregulated whaling, and only a small population of about 300 individuals remains off the east coast of North America. Unfortunately, this population continues to decline, and there is some evidence that the low level of genetic diversity remaining is associated with reproductive problems stemming from inbreed-

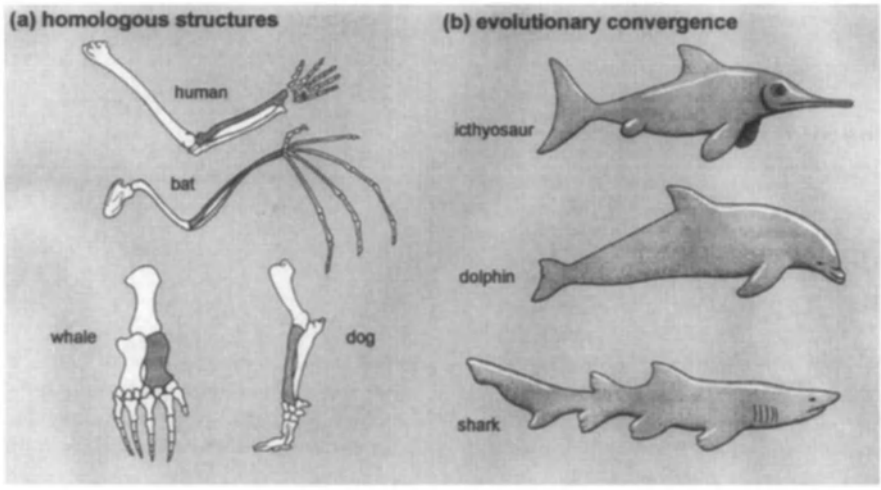

Figure 2 *(a) Mammalian forelimb bone structure showing derivation of differently shaped limbs based on the same underlying (homologous) bone structure. The dark-shaded bone in each illustration is the radius. (b) Examples of evolutionary convergence, where distantly related marine vertebrates have developed similarly streamlined body shapes with biolobed tail, dorsal fins, and pectoral flippers. The icthyosaur is an ancient, now extinct, marine reptile. Both figures redrawn from Minkoff (1983), used by permission.*

ing. Because of the many threats faced by marine mammals and their history of overexploitation by humans, the development of genetic diversity, identification of distinct population units, and conservation status of many species are under intense examination. Thus, details of speciation and molecular divergence mechanisms are being developed with studies of these groups.

Finally, the new insights brought about by evolutionary thinking are currently spurring interesting and integrative work on marine mammals. The details of these studies are starting to feed back into the evolutionary biology literature so that the contributions of marine mammals to the discipline are likely to increase as these areas are explored further.

Extinctions, Specific

DEBORAH A. DUFFIELD
Portland State University, Oregon

Extinction of species has been occurring since the dawn of life on Earth. Sometimes this process is a gradual one, with a few species disappearing over a long period of time. Occasionally, the process appears to be quite rapid and widespread; such mass extinctions often result in the disappearance of many of the flora and fauna on Earth in a relatively short period of time. Such a mass extinction is currently taking place, only this time the cause is not climactic, tectonic, or cosmic, but rather is the result of the activities of one species, *Homo sapiens* (Domning, 1999). It is well established that many species of animals have disappeared over the last 400 years because of humans, including such well-known examples as the passenger pigeon, dodo, quagga, and great auk. Many other lesser-known species of animals, along with many representatives of the plant kingdom, have also died out because of human activities. It is thought that a total of 1190 species of plants and animals have gone extinct since 1600 (Smith *et al.*, 1993). When this is combined with the countless number of fungi, protists, and bacteria that have disappeared without notice, it is easy to see why this human decimation of the Earth's living organisms may easily rank among one of the most major mass extinctions that are a part of our planet's history.

Until recently, the effect of human activities has been primarily felt by those species whose members are relatively large and conspicuous. The great Pleistocene extinctions of mammoths and horses in North America, along with the demise in more recent times of many species of large, flightless birds, are examples of this. Being relatively large, it would be expected that marine mammals would have suffered the same fate as their terrestrial counterparts. The size and remoteness of the habitat of most marine mammals, however, spared them the slaughter and resultant slide toward extinction until more recently. In the last few hundred years, technology gave humans the ability to seek out and kill these animals throughout the vast expanses of the ocean, and many marine mammal species have been brought to the verge of extinction. Lack of profitability from increased costs inherent in trying to find fewer animals, coupled with increased public awareness of and resistance to the destruction, has brought a halt to the exploitation of many of these marine mammals, and in some cases the numbers of certain species are on the rise. This fortunate development came too late for three species of marine mammal: Steller's sea cow (*Hydrodamalis gigas*), the Caribbean monk seal (*Monachus tropicalis*), and the Japanese sea lion (*Zalophus japonicus*). In addition, one population has become extinct in recent times, the Atlantic gray whale (*Eschrichtius robustus*). Direct human destruction was the primary cause of these extinctions, and in all cases the story is one of human ignorance, shortsightedness, and greed.

I. Steller's Sea Cow

In the late autumn of 1741, a Russian exploratory vessel, the *Saint Peter*, wrecked on a bleak, uninhabited island near the western end of the Aleutian chain (Ford, 1966). This island was completely isolated, save for smaller nearby Copper Island, and was over 200 miles from the nearest Russian settlement on the Kamchatka peninsula. As food supplies were practically nonexistent in the winter, it was a joyous occasion when it was discovered that the nearshore waters around the island were inhabited by huge, slow-moving, previously unknown marine mammals. These were Steller's sea cows, later named after the naturalist accompanying the voyage, Georg Wilhelm Steller. Upon killing, this animal provided large quantities of beef-like meat and almond-tasting oil. Throughout the winter, the crew members of the *Saint Peter* slaughtered sea cows. When in the summer of 1742, the men who survived the winter reached Kamchatka, they spread the word of the wealth in furs to be had in the Bering Sea and Alaska and of the huge sea cow that would provide food necessary for the required long voyages. From then on, fur traders and hunters would stop at Bering Island and Copper Island to slaughter these animals and stock their vessels with meat and oil. In addition, parties hunting fur-bearing animals would winter on these islands and dine on sea cow meat (Stejneger, 1887). By 1754, the sea cow was gone from Copper Island. With its disappearance 14 years later from Bering Island, *Hydrodamalis gigas* was extinct (Haley, 1978).

What little is known about this species comes from the observations and written accounts of Georg Steller and from bones found on Bering and Copper Islands. Members of this species were large, fusiform animals with a relatively small head and a horizontally flatted tail. Individuals grew to about 25 feet in length and probably weighed upwards of 4 tons. They had short forelimbs with no digits, a tough hide, and thick layers of fat for insulation. These characteristics permitted the animals to survive in the frigid, storm-tossed waters of the north Pacific, far from the tropical areas inhabited by their nearest living relatives, manatees and dugongs (Domning, 1978). Like other SIRENIANS, these animals were herbivorous, grazing on the large kelp beds that grew in the shallow waters around the Commander Islands. They had no teeth, but rather two flat, horny chewing plates, one in each jaw, between which the animals mashed kelp. Steller observed that they spent most of their day feeding, head down, with their backs exposed. They lived in shallow, sandy areas, preferring the mouths of running streams with their input of fresh water. They may not have been capable of diving (or if so, only near the surface), a characteristic that would have restricted them to the intertidal area outward to the seaward edge and to the surface of this zone (Reeves *et al.*, 1992).

This shallow restricted range, coupled with their slow-moving and docile habits, made Steller's sea cows easy prey for human hunters, even those with relatively primitive weapons and boats. Grazing animals could be easily approached, harpooned, dragged ashore, and butchered (Stejneger, 1936). Often a wounded animal would escape from its killers and swim out to sea. It has been estimated that only one out of every five sea cows killed was actually utilized for food. Even though this species apparently lived all along the rim of the

North Pacific into the late Pleistocene, by the early 18th century it was confined as a relict population to the shallow waters around the Commander Islands. This reduction of numbers was thought to be possibly a result of hunting by indigenous peoples (Whitmore, 1977). In 1741, the population was estimated to be no more than 2000 individuals, and relentless hunting pressure, together with the wasteful harvest method, led the complete extermination of Steller's sea cow by 1768 (Stejneger, 1887). Even though there have been reports of sightings in the North Pacific of animals reputed to be sea cows, some as recently as 1977, it is almost certain that *H. gigas* was driven to extinction over 200 years ago.

II. Caribbean Monk Seal

Nearly 300 years before the Bering expedition and almost half a world away, the demise of another species of marine mammal at the hands of Europeans began. In 1494, on his second voyage to the Caribbean, Columbus discovered the Caribbean monk seal (*Monachus tropicalis*) on the coast of Santo Domingo (Hispaniola). He ordered his men to kill eight of these "sea wolves" for food, and from that time on the killing never ceased (King, 1983). Probably confined to sandy beaches on remote islands and atolls because of centuries of aboriginal hunting on large islands and the mainland, the monk seals were sought out and ruthlessly slaughtered by fishermen, turtle hunters, buccaneers, and organized sealers. In the Bahamas, up to 100 seals per night were known to be killed (Maxwell, 1967). By the mid-19th century, many zoologists thought that the Caribbean monk seal was already extinct. However, in 1886 a small herd was discovered near the Yucatan peninsula, and because so little was known about the species, North American museums sent expeditions out to gather specimens. One of these expeditions killed 49 seals, 5 of which were pregnant females with near-term fetuses (Ward, 1887). For a species in such precarious circumstances, such activities of science were also of no help. The last confirmed sighting was reported by C. Bernard Lewis, Director of the Institute of Jamaica, who said that until 1952 a small colony existed at Seranilla Bank, halfway between Jamaica and Honduras (Rice, 1973). Since that time, although some pinnipeds have been sighted in the Caribbean (these probably being individuals of other seal or sea lion species outside of their normal range), no confirmable sighting of a monk seal in the Caribbean has been made. In 1996, the International Union for the Conservation of Nature (IUCN) declared *M. tropicalis* extinct.

Even though known to Europeans for over 400 years, little scientific information was obtained concerning the Caribbean monk seal before its disappearance. The species belongs to the family Phocidae, and with the Mediterranean monk seal (*Monachus monachus*) and the Hawaiian monk seal (*Monachus schauinslandi*) comprise the genus *Monachus*. The Caribbean species was apparently very similar to the other two monk seals, with males reaching six to seven feet in length, and females somewhat smaller. The fur of adults was brown on back with a gray tinge, and yellowish on the underside. The fur of pups was dark to black. Pupping probably peaked in December, a time different from that of the other two species (Kenyon, 1981). At the time of Columbus, the range of the seal included the shores and islands of the Caribbean Sea and Gulf of Mexico, eastward to the Bahamas and Florida Keys and westward to the Yucatan Peninsula and the Central American coast. The most primitive of all the seals, the three monk seal species probably evolved in areas remote from land predators and never learned to flee nor defend themselves from animals such as humans. In effect, they were "genetically tame" and could easily be clubbed to death by human exploiters (Kenyon, 1981). Like all monk seals, *M. tropicalis* would have been very sensitive to human disturbance, a fact that usually leads to poor reproduction and pup survival (Bonner, 1990). As humans spread through the Caribbean, these characteristics would ensure that the species declined quickly. It became so scarce by 1887 that it was referred to as an "almost mythical species" (Allen, 1887). Its persecution and demise continued, however, and sometime after 1900 the species went into its inexorable slide to extinction. Although it probably survived until the 1950s, represented mostly by old individuals past reproductive age, the species was doomed due to human slaughter and habitat destruction (Kenyon, 1977). Hoping that the species might somehow have survived in some remote area, extensive surveys were conducted of suitable monk seal habitat in both 1973 and 1984. Sadly, no evidence of the Caribbean monk seal was found, only signs of human habitation and use (LeBoeuf *et al.*, 1986). Although reports of sightings have surfaced into the last decade, the species is almost certainly extinct. As stated by biologist Karl Kenyon (1977): "My conclusion from the 1973 survey is that the Caribbean monk seal has been extinct since the early 1950s. The fact that I saw no monk seals was not as important as the fact of ubiquitous human presence. . . . Even if a few old Caribbean monk seals had survived to the 1970s, all available evidence leads me to believe that there is no hope that the species can recover. Man has now dominated its environment."

III. Japanese Sea Lion

The Japanese sea lion, formerly considered to be a subspecies of the California sea lion, has now been recognized as a separate species, *Zalophus japonicus* (Rice, 1998). Currently considered extinct by the IUCN, it is possible that a small number of Japanese sea lions may still exist in Korean waters, although the animals reported in Korea may actually be Steller sea lions (Nishiwaki, 1973). The Japanese sea lion formerly inhabited the southern sea of Japan and coastal waters of Japan from Hokkaido to Kyushu. No individuals of this species have been seen in Japanese waters for over 50 years. Little is known concerning this species, but it is felt to have been morphologically similar to its counterpart, the California sea lion (*Zalophus californianus*). The Japanese sea lion has probably disappeared due to direct hunting pressure and habitat destruction.

IV. Extinct Population

A. Atlantic Gray Whale

The gray whale (*Eschrichtius robustus*) is best known as a coastal dwelling cetacean that migrates along the western coast of North America from Alaska to Baja California. Almost

exterminated by whalers, this population has rebounded as a result of being completely protected, except for aboriginal subsistence hunting (Reilly, 1984). Another population is found in the western North Pacific, where it migrates between the Okhotsk Sea and southern South Korea. This population has been reduced to very low numbers due to overexploitation and is currently highly endangered. A third population in the western North Atlantic appears to have existed until the 17th century and was probably rendered extinct by early whaling activity (Mead and Mitchell, 1984). Accounts from this period, although somewhat confusing, describe a whale known as the "scrag" whale, which bears a strong resemblance to the gray whale. Earlier Icelandic accounts describe a "sandloegja," which is also felt to have been a gray whale (Fraser, 1970). Subfossil remains of gray whales have been found in eastern North America, and radioactive dating has shown the latest to have been from approximately 1675 A.D. (Mead and Mitchell, 1984). The population went extinct shortly thereafter. Subfossil remains of gray whales have also been found in Europe, but are apparently much older. Therefore, an eastern Atlantic population of gray whales probably also occurred in historical times, apparently going extinct sometime before 500 A.D., quite possibly at the hands of early European whalers (van Deinse and Junge, 1937).

V. Prospects for the Future

Even though few species of marine mammals have gone extinct at the hands of humans, many have come very close. Elephant seals, fur seals, monk seals, walruses, and sea otters all have narrowly escaped extinction. Among cetaceans, the great rorquals, the gray whale, and the right whales were all nearly exterminated. Some have rebounded, some appear to be slowly increasing, others apparently are not increasing and may never recover. The history of sealing and whaling makes for depressing reading. Although these industries have mostly disappeared in today's world (with some notable exceptions), some species of marine mammals are still highly endangered. The Mediterranean monk seal is down to less than 1000 individuals and is being forced into tiny pockets of habitat by an explosion of tourism. The vaquita, a small porpoise from the northern Gulf of California, exists as a small population under pressure from unintentional destruction from fisheries (Rojas-Bracho and Taylor, 1999). The baiji, the river dolphin of the Yangtze River, is the most endangered marine mammal in the world. With probably less than 100 now remaining and its river habitat being massively altered by humans, the future of this species is bleak. Many other species are also endangered, although they are not in as precarious a state as these. As much as may be desired, it will never again be possible to observe the "sea wolves" of Columbus lounging on the tropical beaches of the Caribbean or Steller's sea cow rising out of the northern mists.

False Killer Whale

Pseudorca crassidens

Robin W. Baird
Dalhousie University,
Halifax, Nova Scotia, Canada

The false killer whale (*Pseudorca crassidens*) is one of the larger members of the family Delphinidae, with adult males reaching lengths of almost 6 m and females reaching up to 5 m. The common name comes not from a similarity in external appearance to the killer whale (*Orcinus orca*), but rather similarity in skull morphology of these two species (Fig. 1). In fact, the two species do not appear to be closely related; based on genetic similarity, false killer whales appear to be most closely related to the Risso's dolphin (*Grampus griseus*), melon-headed whale (*Peponocephala electra*), pygmy killer whale (*Feresa attenuata*), and pilot whales (*Globicephala* spp.). There is some evidence of geographic variation in skull morphology, although no subspecies are currently recognized.

Largely black or dark gray in color (usually with a lighter blaze on the ventral surface between the flippers), they are easily recognizable with their rounded head, gracile shape, small falcate dorsal fin located at the midpoint of the back, and distinctive flippers (with a bulge on the leading edge). False killer whales are slightly SEXUALLY DIMORPHIC, with the melon of males protruding farther forward than in females. Their teeth are large and conical, with 7–11 in each of the upper jaws and 8–12 in each lower jaw.

False killer whales are found in all tropical and warm temperate oceans of the world, and occasional records of their presence in cold temperate waters have also been documented. Although they are typically characterized as pelagic in habits, they do approach close to shore at oceanic islands and are one of the handful of species that regularly mass strands. These oceanic habits have hindered study of this species in the wild, and most of what is known comes from stranded individuals, captive animals, and a few observations of wild groups (usually around oceanic islands). No long-term behavioral or population studies of wild individuals have been undertaken. No estimates of worldwide population size are available, and a few regional estimates based on surveys are imprecise.

False killer whales are considered to be extremely social, usually traveling in groups of 20 to 100 individuals. Details of social organizations are lacking; however, strong bonds between individuals are evident from their propensity to strand en masse (the largest number of individuals mass STRANDING was over 800) and by the affiliative behavior of stranded animals. False killer whales are active during the day, and food sharing in the wild has been recorded on several occasions. The diet of false killer whales appears to be diverse, both in terms of species and size of prey. In general they feed on a variety of oceanic squid and fish, but have also been documented FEEDING on smaller delphinids being released from tuna purse-seines in the eastern

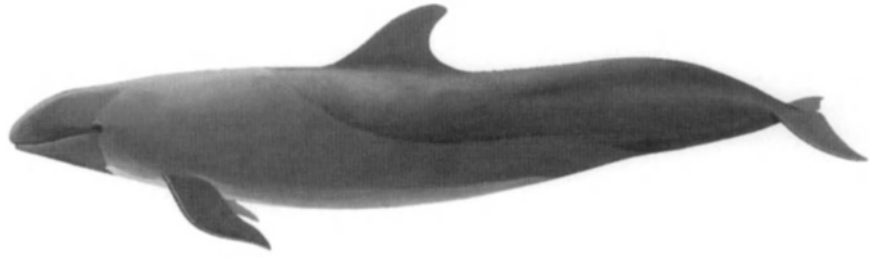

Figure 1 *The quite social false killer whale* (Pseudorca crassidens) *does not resemble the killer whale* (Orcinus orca) *in external appearance. The skulls of the two species are, nevertheless, quite similar. Pieter A. Folkens/Higher Porpoise DG.*

tropical Pacific. One case of predation on a humpback whale (*Megaptera novaeangliae*) calf has also been recorded, and they have been documented attacking sperm whales (*Physeter macrocephalus*). Nonaggressive interspecific associations with bottlenose dolphins (*Tursiops* spp.) have also been reported. Nothing is known about the DIVING BEHAVIOR of this species, and no predators of false killer whales have been reported, although large sharks likely take some individuals.

Life history information comes entirely from stranded individuals. Because the deposition rates of growth layer groups in the teeth have never been calibrated, there is some uncertainty in life history parameters. Both sexes are thought to mature between about 8 and 14 years of age, although there is some suggestion that males may mature later. Maximum longevity has been estimated at 57 years for males and 62 years for females. Calving interval for one population has been reported as almost 7 years, and calving may occur year-round, with a peak in late winter.

A number of types of interactions between humans and false killer whales have been documented. They are the only "blackfish" to regularly bowride on vessels, and in Hawaii they are regularly encountered by commercial whale- or dolphin-watching vessels. They have been maintained in captivity in a number of aquaria around the world, including Japan, the United States, the Netherlands, Hong Kong, and Australia. They have been successfully bred in captivity in several locations, and there they have produced viable interspecies hybrids with bottlenose dolphins. False killer whales are one of several species of odontocetes that occasionally steal fish from both commercial and recreational fishermen, with these types of interactions noted in Japan, Hawaii, the Indian Ocean, and the Gulf of Mexico. Such conflicts have resulted in direct killing in Japan, and small numbers have been occasionally taken in fisheries, both directly and incidentally as bycatch. They are one of a growing list of species that has been recorded ingesting discarded plastic, and high levels of toxins have been documented in tissues collected from stranded animals. It is unknown, however, whether such toxins contribute to immunosuppression in this species.

Feeding Strategies and Tactics

MICHAEL R. HEITHAUS AND LAWRENCE M. DILL
Simon Fraser University, Burnaby, British Columbia, Canada

arine mammals are found in a wide range of habitats, including the open ocean, coastal waters, rivers, lakes, and even on ice floes and land. They feed on a variety of prey species from aquatic plants to microscopic zooplankton to the largest marine mammals, and a diverse array of strategies and tactics are used to locate and capture these prey. Some marine mammals consume huge numbers of prey items at a time (batch feeding), whereas other attack and consume prey items singly (raptorial feeding). Many marine mammals forage in large groups, whereas others feed alone. This article considers the wide range of marine mammal foraging behaviors and the circumstances and habitats that led to the adoption of particular feeding strategies and tactics.

Before embarking upon a review of marine mammal foraging, it is important to make a distinction between a strategy and a tactic, terms which have specific meanings in the field of behavioral ecology. Put simply, a strategy is a genetically based decision rule (or set of rules) that results in the use of particular tactics. Tactics are used to pursue a strategy and include behaviors (Gross, 1996). Tactics may be fixed or flexible; in the latter case they depend on the condition of the individual or characteristics of the prey or environment. For example, a humpback whale's (*Megaptera novaeangliae*) strategy may be to use a tactic that will maximize energy intake at any particular time. The whale may pursue this strategy by switching between the tactics used to capture fish and those used to catch krill, depending on the relative ABUNDANCE of these two prey types.

Our understanding of marine mammal foraging is hampered by the difficulty of studying these animals. They live in an environment where observations are difficult (often beneath the surface), our presence can disturb their foraging behavior, and feeding events often occur quickly and are easy to miss. Despite this, much is known. This article begins with a review of marine mammal foraging by considering ways that marine mammals find and capture their prey, continues with a discussion of group foraging, and then concludes with a discussion of the causes of variation in feeding strategies and tactics.

I. Finding Prey

The first step in foraging is locating prey. This may be done over many temporal and spatial scales and can involve migrations of thousands of kilometers or switching between habitats separated by only a few meters to forage in prey-rich locations. Then, once a marine mammal is in a prey-rich area, it still must locate prey.

A. Habitat Use

One way that marine mammals can increase their chances of encountering prey is to spend time foraging in those habitats with high prey abundance. Evidence shows that a variety of marine mammals tend to aggregate in areas with high food concentrations. For example, the highest densities of polar bears (*Ursus maritimus*) are found along floe edges and on moving ice, habitats that contain the highest density of seals. Resident killer whales (*Orcinus orca*) are most abundant in Johnston Strait, British Columbia, when salmon migrate through the strait. Also, the distribution of humpback whales in the Gulf of Maine appears to reflect the availability of fish prey, and humpback whale distribution in southeast Alaska may partially be determined by KRILL abundance. When there are a variety of habitats available to marine mammals in a restricted area (such as nearshore environments), a theoretical model predicts that if the main concern of the animals is to maximize energy intake, they should be distributed proportional to the amount of food available in each habitat (e.g., Fretwell and Lucas, 1970). Testing this hypothesis is difficult because marine mammal prey availability is often hard to quantify. However, the distribution of bottlenose dolphins (*Tursiops aduncus*) in Shark Bay, Western Australia, conforms to this hypothesis and matches that of their fish prey in winter months. Humpback and common minke whales (*Balaenoptera acutorostrata*) do not appear to conform to this hypothesis. Instead, they appear to show a threshold response to prey availability, only using a habitat once prey density has reached a particular level. Of course, prey availability is not the only factor that might influence the habitat use of marine mammals, which will be considered in detail later.

B. Migration

When suitable habitats for a marine mammal are widely spread, movements between them are considered migrations. There is thus a continuum between habitat use decisions and migrations. Some migrations appear to be driven primarily by the variation in food availability. Unlike baleen whales, sperm whales (*Physeter macrocephalus*) cannot fast for long periods of time, and female groups use migrations up to 1100 km as part of a strategy for surviving in a variable habitat with low local food abundance and poor foraging success. In fact, this strategy may be the reason that female sperm whales are found in permanent social groups as they may benefit from the experience of old females during migrations.

Migration frequently involves trade-offs between feeding and another factor, such as reproduction. Baleen whales and some pinnipeds feed only for a relatively short period of time in high-productivity, high-latitude waters and then fast during the rest of the year while moving to, and spending time at, low-latitude breeding grounds. For example, northern elephant seals (*Mirounga angustirostris*) forage along the entire North Pacific and then migrate to a few beaches on the California coast to breed. Also, humpback whales reproduce in warm, low-productivity, Hawaiian waters and then move to the more productive waters of the North Pacific to feed during the summer months. There is some evidence that not all individuals migrate each year. Some humpback whales can be seen in the Southeast Alaska feeding grounds year-round, and individuals that do not consume enough prey during the feeding season may forego migration in order to continue feeding.

C. Searching and Diving

The way in which an animal moves through its environment can influence its encounter rate with prey, and many animals exhibit stereotyped search patterns. Marine mammals that forage on concentrated prey may patrol continually through areas where they expect to encounter concentrations. For example, leopard seals (*Hydrurga leptonyx*) will patrol along ice edges where departing and returning penguins congregate, and killer whales patrol nearshore areas in search of seals. When groups of marine mammals forage, they often spread out into widely spread subgroups and/or move forward in a line abreast formation [e.g., dusky dolphins (*Lagenorhynchus obscurus*), pilot whales (*Globicephata* spp.), Risso's dolphins (*Grampus griseus*), bottlenose dolphins (*Tursiops* spp.), killer whales (*Orcinus orca*)]. Spreading out in such fronts may either reduce foraging competition among individuals or increase the probability that prey is detected so the subgroups can converge to feed.

Once a marine mammal has selected a habitat for foraging, it must execute a strategy that will optimize its net energy intake rate, often with respect to trade-offs and constraints. For diving animals this means that it must balance the energetic costs of diving with the energetic gains from foraging. The costs of diving vary greatly among marine mammals. Polar bears, sea otters (*Enhydra lutris*), and most pinnipeds are divers: they spend most of their time above water or have long surface intervals between food-gathering dives. In contrast, most cetaceans and sirenians can best be thought of as surfacers: they spend the majority of their time submerged and make trips to the surface only to breathe.

Theoretical studies of optimal diving suggest that as the depth at which prey are located increases, both dive times and surface times should increase (Kramer, 1988), and the type of a dive a marine mammal executes will depend on the depth and distribution of prey. Some predictions of optimal diving theory are supported by several studies of marine mammals,

and both dive times and surface times increase with dive depth in pinnipeds, cetaceans, and sirenians. Because a diving individual should behave in a manner that optimizes its net energy intake (e.g., Kramer, 1988), marine mammals may exceed aerobic limits when the energetic payoff is sufficient.

There is a great deal of variation in the depths to which marine mammals dive. Some, such as sea otters, nearshore odontocetes, and otariids, tend to be shallow divers. Others, including sperm whales, elephant seals, and beaked whales, are extremely deep divers, sometimes foraging over 1000 m from the surface. Some species minimize the depths to which they must dive, and thus the costs, by modifying their diel pattern of foraging. For example, some dolphins and pinnipeds are nocturnal foragers on prey whose daily movements bring them closer to the surface at night [e.g., spinner dolphins (*Stenella longirostris*), northern fur seals (*Callorhinus ursinus*), Antarctic fur seal (*Arcotocephalus gazella*)]. The diving tactics of beluga whales (*Delphinapterus leucas*) may be influenced by competition with pinnipeds, who are superior divers. Belugas generally forage over the deepest waters and, because of their body size, are able to gain access to benthic areas that the smaller pinnipeds cannot. Although the time spent at the bottom decreases with increasing depth, belugas compensate by increasing their ascent and descent rates as dive depth increases, a result also found in narwhals.

D. Prey Detection

Marine mammals have many ways to detect their prey, including vision, various types of mechanoreception, echolocation, and hearing. Most marine mammals appear to rely on vision to at least some extent. The large, forward pointing eyes of pinnipeds suggest that vision is an important method for detecting prey. Even species that dive to extreme depths, such as elephant seals, are capable of using vision to find prey in dark waters at their foraging depth. VISION may be less important in other taxa. For example, the river dolphin (*Platanista gangetica*) of the Indian subcontinent has eyes that are greatly reduced and may be mostly blind. Sea otters can use their forepaws to find food and discriminate prey items without the aid of vision, and many pinnipeds are found in turbid waters, making vision a poor method of prey detection. However, they are able to use their vibrissae (whiskers) to detect prey through active touch or through minute water movements caused by their prey.

Odontocete cetaceans have a method of prey detection not available to other marine mammals: echolocation. In controlled situations, odontocetes can detect relatively small objects at a considerable distance. For example, a common bottlenose dolphin can detect a 7.62-cm-diameter sphere from over 100 m. However, it is still unclear how efficient echolocation is under natural conditions. It is likely to be less efficient than suggested by laboratory and controlled experiments (as has been shown for bats) and may vary greatly depending on environmental conditions such as noise. Echolocation appears to be the primary method of prey detection in some essentially blind river dolphins such as the Indian river dolphin, which inhabits murky waters.

Echolocation is not always an effective way to detect prey. While most fish cannot hear echolocation calls, clupeid fish and other marine mammals can. Therefore, odontocetes foraging on prey that can detect their echolocation may have to use tactics other than echolocation for detecting prey. This difference in the ability of potential prey to detect echolocation is reflected in the foraging behavior of fish-eating ("resident") and mammal-eating ("transient") killer whales off British Columbia. Whereas resident whales commonly use echolocation during foraging, transients do not. Also, when transients echolocate, their pulses are of low intensity and are irregular in timing, frequency, and structure, a pattern that may be difficult for prey to detect. Instead of echolocation, mammal-eating killer whales appear to use passive listening to detect their prey. Other marine mammals probably use passive listening opportunistically, especially bottlenose dolphins, which feed on a variety of noisy fish species. Elephant seals and other pinnipeds also have good hearing abilities in water and may use passive listening to find prey.

II. Capturing and Consuming Prey

A diverse array of tactics is used by marine mammals to capture and consume their prey once they have located it (Fig. 1). The most widespread tactic of raptorial predators is to simply chase down individual prey items that they have encountered. However, there are many other more unique tactics employed by marine mammals.

A. Stalking and Ambushing

Marine mammals often hunt prey that are nonsessile, fast-moving, and have good sensory abilities and, thus, could avoid predators if their approach were too obvious. For example, seals can avoid polar bears by diving back through the ice, and penguins can avoid leopard seals by hauling out, as can pinnipeds approached by killer whales near land. When hunting elusive prey, a predator must rely on either stalking or ambushing. A stalking predator attempts to conceal its identity or presence until it approaches its prey close enough for a sudden, successful attack. In contrast, an ambush predator conceals itself and lies in wait, leaving the approach to the prey.

Polar bears use both stalking and ambush methods when hunting seals hauled out on the ice near breathing holes. In terrestrial stalking, bears creep forward and use ice for cover to closely approach their intended prey. Bears also stalk seals by swimming circuitously through interconnected channels or even under the ice, occasionally surfacing through holes to breathe and monitor their prey. However, an ambushing tactic, where a bear lies, sits, or stands next to a breathing hole waiting for a seal to surface, is the most energy-efficient and most commonly used foraging tactic.

Leopard seals also use both stalking and ambush tactics when foraging. Stalking leopard seals may swim under the ice below a penguin and then break through to capture the bird, or they may swim submerged near a fur seal beach and lunge at pups when they get close enough. Alternatively, leopard seals may ambush their prey by hiding between ice flows near a penguin-landing beach. Sea otters will stalk birds by swimming underwater and grabbing them from below, a tactic similar to that used by Steller sea lions (*Eumetopias jubatus*) hunting northern fur seal pups and leopard seals stalking Adelie penguins.

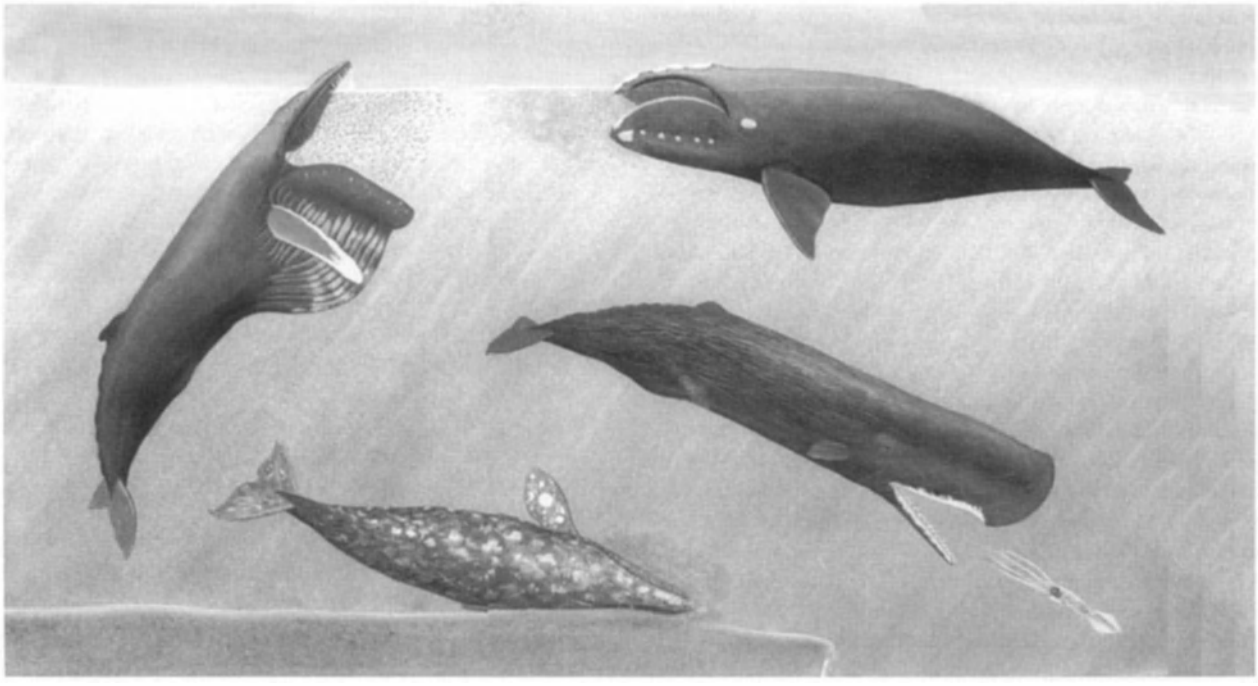

Figure 1 *Whales employ a diverse array of foraging tactics. Pieter A. Folkens/Higher Porpoise DG.*

Another behavior that could be considered stalking is wave riding and intentional beaching used to capture young pinnipeds and penguins near the water's edge. This tactic is commonly used by killer whales and occasionally by Steller sea lions and leopard seals. This may be a particularly dangerous foraging tactic, especially for young killer whales who may not be able to return to the water if they strand too high on the beach.

Some stalking predators make detours that involve moving away from the prey and potentially losing visual contact temporarily before making another approach. Polar bears will make detours from their prey while stalking aquatically, and dolphin subgroups may detour away from a school of fish to attack it from opposing sides. Weddell seals (*Leptonychotes weddellii*) have also been observed making detours when stalking cod under fast ice. These detours allow the seal to remain out of the fish's view and to attack from very close range below the fish.

B. Prey Herding and Manipulation

In order to capture them more efficiently, marine mammals may actively manipulate the behavior of their prey. In other words, marine mammals take advantage of normal prey behaviors to enhance their ability to capture them. These manipulations may help a marine mammal flush prey from hiding, capture an individual prey item, or increase the density of prey aggregations so as to increase the forager's energetic intake rate. Prey herding is a common tactic used by dolphins, porpoises, whales, and pinnipeds and may be considered prey manipulation when they take advantage of natural schooling and flight behavior of their prey. Dolphin and porpoise groups and individuals have been observed herding prey against shorelines or other barriers, reducing the number of escape routes. Dolphins use shorelines for more than herding fish. Common bottlenose dolphins inhabiting salt marshes are known to form small groups that rush at fish trapped against a mud bank. The wave created by the rapid swim causes fish to strand on the mud bank and the dolphins slide up the bank and pick fish off the mud before sliding back into the water. A similar behavior is performed by both individuals and groups of humpback dolphins (*Sousa plumbea*) foraging around sand banks off Mozambique.

Marine mammals also herd fish in open waters. When schools are at the surface, dolphins may split into groups to attack from different directions, herding the fish into a ball between subgroups. Other times, fish may be herded up from deeper waters and trapped between circling individuals and the surface. During a herding event, individuals swim around the fish school, and below it, preventing its escape. Fish herding in open waters has been reported in many dolphin species, porpoises, and sea lions. Sea lions are also found feeding on schools of fish that are herded to the surface by dusky dolphins (*Lagenorhynchus obscurus*), but it is unclear if the sea lions aid in fish herding. The tactic of herding fish is found in a variety of marine predators, and although there are no reports of prey herding for many species of pelagic dolphins, it is probably a widespread tactic employed by marine mammals feeding on schooling fish.

During a prey-herding event, many different tactics may be used to cause the fish to move into a tight ball and to capture fish in these balls. Splashing at the surface causes fish schools to compact. Dusky dolphins perform leaps at the edge of fish schools that they are herding, and Atlantic spotted dolphins (*Stenella frontalis*) have been observed tail slapping and splashing at the edge of a fish school when it started to break apart or move in a different direction, but the function of these behaviors is still unclear. Killer whales in Norway and humpback

whales in the northwest Atlantic also use tail slaps when near schools of prey. Tail flicks by humpbacks may also be used to concentrate schooling euphasid prey in Southeast Alaska, although this may simply be a hydromechanical effect.

Another tactic that marine mammals can use to herd prey is flashing light-pigmented areas of their body toward a fish school. Killer whales herding herring swim under the school and flash their white undersides to keep the school from diving, and a similar behavior has been noted in spotted dolphins. Humpback whales in Southeast Alaska may also use flashes to help concentrate prey by rotating their elongated pectoral flippers while they herd herring, thereby showing the highly visible white undersides.

Fish show strong avoidance responses to bubbles and are reluctant to cross barriers composed of them. Not surprisingly, marine mammals take advantage of this response. The use of bubbles during foraging has been observed in many odontocetes, mysticetes, and pinnipeds. Atlantic spotted dolphins use bubbles to isolate individual fish, pulling them away from the school with the water disturbance created by the passing bubble, so they can be consumed, and Weddell seals blow bubbles into ice crevices where fish are hiding to flush them out. Killer whales also use bubbles to flush prey and blow large bubbles toward rays buried in the sediment, causing them to move. However, bubbles are primarily used to concentrate and contain schools of fish. For example, killer whales blow large bubbles near the surface to keep fish in a tight ball. Humpback whales are the best-known bubble users, and bubble feeding may be conducted by individual whales or in large groups. Whales deploy bubbles in a variety of formations, including columns, curtains, nets, and clouds, with the tactic used dependent on the characteristics of the prey aggregations.

Sound and pressure waves may also be used to manipulate prey behavior. For example, bubble-netting humpback whales in Southeast Alaska produce loud "feeding calls" as they rise to the surface, presumably herding prey up into bubble nets that are meters above the herring schools. Bottlenose dolphins off Australia and Florida use tail slaps known as "kerplunks" while foraging in shallow seagrass habitats. The kerplunk displaces a significant amount of water, creates a plume of bubbles, and causes a low-frequency sound. Kerplunks may cause startle responses in fish and help the dolphin locate and flush their prey, while the bubbles may provide a barrier to contain the fish. Humpback whales in the western Atlantic may flush burrowing fish (sand lance) from the bottom by scraping the substrate with their head and then feed on the fish once they have entered the water column.

C. Prey Debilitation

Marine mammals sometimes debilitate their prey before they consume it. Killer whales attacking mysticetes often swim onto their backs when the prey tries to surface, and in some cases the victim may drown instead of dying from its wounds. While killer whales are herding herring, individuals thrash their tail through the school, stunning fish with the physical impact of their flukes; they then feed on the stunned and injured fish. The whales probably use this tactic because it is energetically more efficient than whole-body attacks. Bottlenose dolphins strike fish with their tails ("fish whacking") when foraging alone or in groups, sometimes knocking the fish through the air. Also, there is evidence that walruses (*Odobenus rosmarus*) may use their tusks to kill or stun intended seal prey. Sound may also be used to debilitate prey, and several authors have hypothesized that odontocetes may be able to use echolocation to stun or disorient fish, but this hypothesis remains largely untested.

D. Tool Use

"Tool use is the external employment of an unattached environmental object to alter more efficiently the form, position or condition of another object, another organism, or the user itself when the user holds or carries the tool during or just prior to use and is responsible for the proper and effective orientation of the tool" (Beck, 1990). Tool use by marine mammals is reviewed in detail elsewhere in this volume, but several marine mammals make extensive use of tools during foraging and deserve brief mention here.

Sea otters are the best-known marine mammal tool users and will pick up rocks from the bottom and place them on their chest to use as an anvil for crushing mussels, crabs, or urchins, or use them to smash or dislodge abalone off rocks. In some cases, the rocks are retained between foraging dives to be reused. Certain bottlenose dolphins carry sponges on their rostra, apparently as a tool to aid foraging (Fig. 2). Also, there are popular accounts of polar bears throwing blocks of ice at basking seals to injure or trap them, and polar bears in captivity are often observed throwing large objects, raising the possibility of tool use in the wild. Another behavior that might be considered tool use involves killer whales creating waves to wash hauled out seals into the water. For example, in ANTARCTICA, a group of killer whales spotted an adult crabeater seal (*Lobodon carcinophaga*) on a small ice floe. The whales made a rapid swim up to the floe and dove rapidly. The resulting wave tipped the floe and knocked the seal into the water, but predation was not observed. Finally, as described earlier, several marine mammals, including humpback whales, killer whales, bottlenose dolphins, and Atlantic spotted dolphins, use bubbles as a tool to concentrate schooling fish.

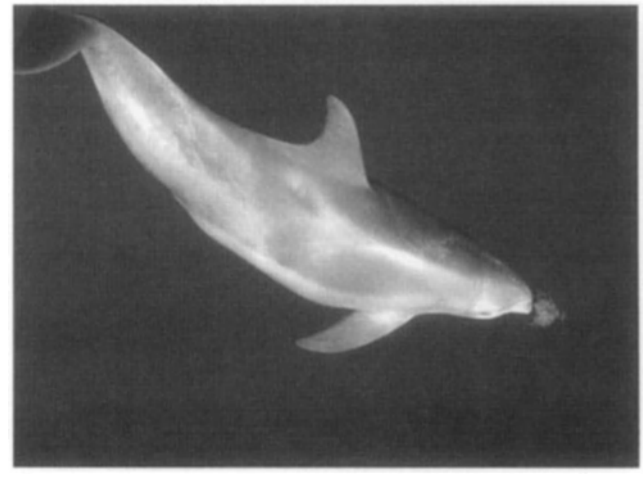

Figure 2 *Bottlenose dolphins use sponges as tools to aid in foraging. (Photograph by Michael R. Heithaus).*

E. Benthic Foraging

While most marine mammals pursue their prey in the water column, several species forage on benthic organisms. There are three basic methods that marine mammals use to obtain prey from the bottom: collecting, extracting, and engulfing. Epibenthic prey are simply collected by foraging marine mammals. For example, sea otters collect echinoderms (mostly sea urchins), crabs, and other benthic organisms using their forepaws.

Infaunal prey items must be extracted from the substrate and require the predator to excavate in some manner. Sea otters use their forepaws to dig for clams in soft-sediment areas and may produce large pits over the course of several dives, occasionally surfacing with a clam. Harbor seals (*Phoca vitulina*) dig for prey in sandy habitats with their foreflippers or snouts while narwhals (*Monodon monoceros*) and belugas use water jets to dislodge mollusks buried in the sea floor. Walruses use a combination of tactics to obtain buried bivalves, including digging with their snouts (not tusks) and hydraulic jetting. Walruses make multiple excavations on each dive and have been recorded consuming at least 34 clams on a single dive. Killer whales, in New Zealand, engage in benthic foraging on rays and have been observed pinning them to the bottom and may also be digging for them. Bottlenose dolphins in the Bahamas also dig for infaunal prey ("crater feeding"), and once a burrowing fish has been located, the dolphin will dive into the soft sand and use its flukes to drive deeper, almost up to the flippers, to catch the fish.

If many small infaunal prey items are consumed in a single feeding event, they may be engulfed while still in the sediment. Gray whales (*Eschrichtius robustus*) feeding near the bottom use suction to pull sediment and prey into their mouths and then filter the sediment and water out through their baleen.

F. Batch Feeding

Batch feeding is a tactic employed to consume a large number of prey items in a single feeding event. While mysticetes are obligate batch feeders, some pinnipeds facultatively use this tactic. There are two basic types of batch feeding: skimming and engulfing. Skimmers, most notably the right whales and bowhead whale, swim through concentrations of zooplankton, either at the surface or in the water column, with their mouths open, filtering water through their fine baleen plates, which trap prey.

Engulfers include rorquals and several pinnipeds. These species engulf large amounts of water and prey and then filter the water back through their baleen plates or teeth. Rorquals have a suite of adaptations, including expandable gular pleats and a lower jaw that can disarticulate from the upper jaw, that allow them to engulf huge volumes of water, and fish or crustacean prey, in each feeding attempt. "Lunge feeding" is one of the most common tactics of rorquals feeding near the surface and may take several forms. During a typical lunge, a whale surfaces with its mouth open to capture prey near the surface. Lunge feeding may be done singly or in groups, and in combination with many of the prey concentration tactics.

All Antarctic seals [crabeater, Weddell, Ross (*Ommatophoca rossii*), leopard seals] include zooplankton in their diet, as do some Arctic seals [ringed (*Pusa hispida*), ribbon (*Histriophoca fasciata*), harp (*Pagophilus groenlandicus*), larga (*Phoca largha*), and harbor seals]. Of these, the crabeater seal is the most specialized batch feeder, and zooplankton may comprise up to 94% of its diet. The cheek teeth of crabeater and some other seals are modified for straining krill, which are probably sucked into the mouth when the seal depresses its tongue and are then trapped against the cheek teeth as the water is expelled.

G. Ectoparasitism, Kleptoparasitism, and Scavenging

Predators kill their prey in the course of consuming it (Ricklefs, 1990). While most marine mammal foraging is predatory, there are several ways that animals may forage that do not involve killing their own prey. For example, an animal may gouge mouthfuls of flesh from a "host" without killing it (sometimes referred to as ectoparasitism). Although marine mammals fall victim to such ectoparasites (small sharks), there are no concrete examples of marine mammals using this tactic. However, killer whales may effectively ectoparasitize large whales as some attacks do not kill the victim. Kleptoparasitism (food stealing) has been observed in only otters and polar bears, but may occur within and among other species. Scavenging is a common foraging tactic, but does not appear to be widespread among marine mammals. However, it may be an important tactic for polar bears and some pinnipeds.

H. Herbivory

Sirenians (manatees, *Trichechus* spp., and dugongs, *Dugong dugon*) are the only marine mammals that routinely feed on plants, and both manatees and dugongs may be found foraging individually or in large groups. Manatee feeding appears to be more flexible than that of dugongs, as the former will consume either floating or rooted vegetation and sometimes leaves from overhanging branches or vegetation along banks. Dugongs feed almost exclusively on seagrasses, but may also intentionally consume benthic invertebrates. While manatees tend to crop vegetation, dugongs dig up rhizomes and leave large feeding trails through seagrass beds, which can have a large impact on seagrass biomass, both above and in the sediment (Fig. 3).

I. Prey Preparation and Consumption

While some marine mammal prey can be consumed immediately after capture, others require extensive handling before they are eaten, and some are only partially consumed. Sea otters remove the heads of birds that they capture and strip the muscle from the breast, neck, and legs. Many dolphins and sea lions remove the heads from large fish before consuming them, and bottlenose dolphins will strip flesh from spiny fish (Fig. 4). Head and spine removal may reduce the probability that a predator is injured while consuming prey, but it may also be a mechanism to reduce the intake of bony material that provides no nutritional value. Dolphins do not always consume their prey correctly, and sharp spines have been implicated in mortalities of bottlenose dolphins stranded in Texas and Florida.

Odontocetes cannot chew prey and must spend considerable time handling large prey items. For example, bottlenose dolphins will drag large fish along sandy bottoms until pieces

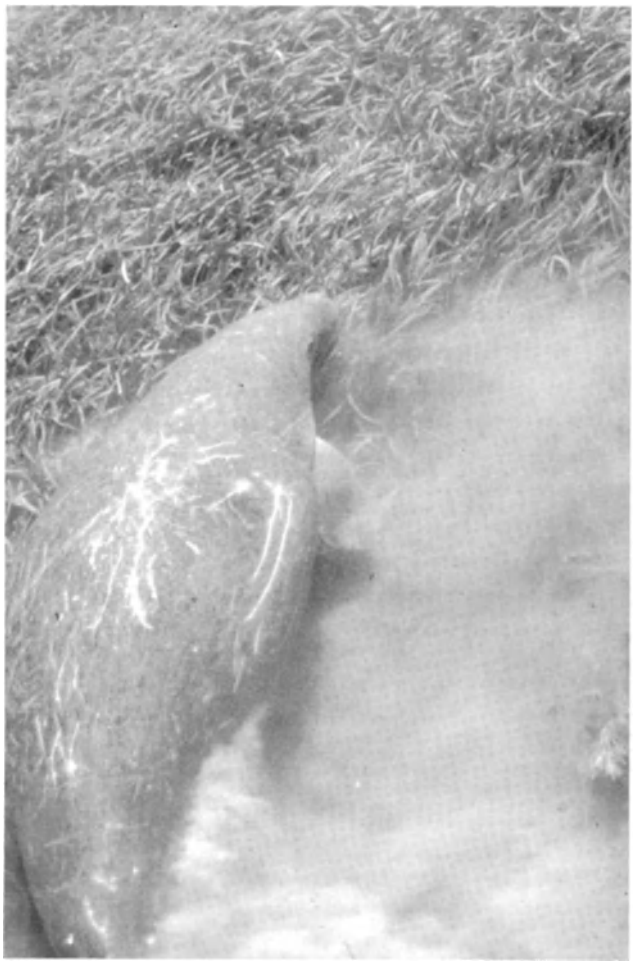

Figure 3 *Dugongs preferentially forage on below-ground portions of many seagrass species, creating a cloud of sediment during foraging activity. (Photograph by Michael R. Heithaus).*

that are small enough to swallow are broken off. Killer whales are well known for their extensive handling of prey, especially pinnipeds, after capture. Killer whales often breach upon sea lion and seal prey as well as slap them with their tails. The function of these behaviors is unclear, but they may tenderize the prey, aid in training calves in hunting techniques, or even debilitate dangerous prey. Selective feeding on energy-rich portions of prey is common in both killer whales and polar bears. Killer whales will selectively eat the blubber and tongue of whales that they kill, and polar bears prefer the blubber and muscle of seals and narwhals over the internal organs.

III. Group Foraging

Many foraging tactics are executed by groups of marine mammals. Sometimes these groups are merely aggregations of animals attracted to the same resource, and there appears to be little interaction among individuals as they pursue prey individually. Other group-foraging behaviors, such as herding of prey, appear to be highly coordinated efforts and may involve

Figure 4 *Not all prey that are captured can be consumed immediately. Large fish, like this one captured by a bottlenose dolphin, may take extensive handling before they can be consumed. (Photograph by Michael R. Heithaus).*

animals cooperating with each other to increase their net energy intake rate. It is not always easy to determine whether group-foraging marine mammals are cooperative or not. For example, the echolocation rate of an individual resident killer whale decreases as group size increases, suggesting that there may be information transfer. While this could represent cooperative information sharing, it is also possible that individual whales are parasitizing the information of others, as shown in bats. In many cases it is difficult to assess whether marine mammals are foraging cooperatively because group living may be selected for by factors other than food, and group foraging, whether cooperative or noncooperative, is therefore simply a necessary epiphenomenon. One important consideration in studies of cooperation is whether groups are kin based, as individuals in kin groups are more likely to engage in cooperative behavior to increase their inclusive fitness.

A. Cooperative Foraging, Food Sharing, and Cultivation

Cooperation can be defined as an "outcome that—despite individual costs—is 'good' in some appropriate sense for the members of the group . . . and whose achievement requires collective action" (Mesterson-Gibbons and Dugatkin, 1992). Most cooperation is achieved through a mechanism of by-product mutualism in which an individual acts selfishly to benefit itself, and its actions incidentally benefit other individuals, but not all by-product mutualisms are cooperative. A possible example of by-product mutualism involves bowhead whales (*Balaena mysticetus*) skim feeding in groups with whales staggered in an inverse "V" formation. This formation may aid a whale in prey capture by using adjacent whales as a wall to trap prey or to catch prey that have escaped from the whale in front. These groups sometimes appear to be coordinated, with whales changing direction and leadership. All individuals probably act selfishly, but their presence may benefit other whales.

The just-described definition of cooperation requires three things be shown to support the hypothesis that a group is

cooperative. First, individuals acting cooperatively must realize a short-term cost. This cost may include having to share food with other individuals or an opportunity cost by not attacking prey immediately while herding. Next, energy intake rate of individuals benefiting from cooperation must be higher than what they would have gained without cooperation. Finally, collective action must be required for the hunt to be successful. It is worth noting that in cooperative groups not all group members are required to receive equal benefits, and in groups that appear to be cooperative, a number of individuals may be noncooperative (Packer and Ruttan, 1988).

There are many possible examples of cooperative foraging in the marine mammal literature involving mysticetes, odontocetes, pinnipeds, and sirenians. However, most anecdotal accounts of possible cooperative foraging behavior do not provide enough detail to determine whether these groups were truly cooperative. For example, many dolphin species are known to break into subgroups that spread out across a large front when foraging or to travel in line abreast formation. Generally, when one subgroup finds fish, other subgroups join to feed, and this behavior has often been considered cooperative foraging. However, none of the three criteria for cooperation outlined earlier has been shown to apply to these cases. Furthermore, although some authors have assumed that joining subgroups were recruited, they may simply be converging once they determine that another group located food. Fish herding by dolphins, porpoises, whales, and sea lions has been cited as an example of cooperative foraging. In these cases, there does appear to be a cost involved as individuals do not start foraging immediately, but wait until the school has been herded to the surface ("temporary restraint"). Larger groups of dusky dolphins forage on a single fish school for longer periods of time than small groups. Some authors have suggested that this indicates an increase in individual intake and that herding requires collective action. However, it is important to measure individual intake rates because longer foraging durations of large groups may simply be the result of larger schools being herded (and increased time until school depletion) or of increased foraging interference in large groups. More studies are required to support the hypothesis that such groups are cooperative.

Deliberate prey sharing provides strong evidence for cooperative hunting, but must be viewed with caution as some apparent food sharing may represent intense competition for large prey items or kleptoparasitism (e.g., Packer and Ruttan, 1988). Prey sharing has been observed in few marine mammal species, but has been documented in many killer whale populations. Also, an apparent case of prey sharing has been documented in leopard seals when two seals killed penguins, but one individual released its penguin to be consumed by the other.

There are a few other examples of marine mammal foraging that appear to represent cooperative foraging. Leopard seals have been observed hunting in a coordinated fashion, with one seal driving penguins toward a second seal hiding behind an ice flow. The process was repeated several times, and both seals caught penguins each time, sharing prey in one instance. Collective action is required if killer whales are to capture large or swift prey and, in general, larger groups are seen when transient killer whales attack such prey. There may even be a division of labor during their hunts. Also, there is a cost as prey are divided among group members. Bubble-netting humpback whales feeding on herring in Southeast Alaska represent another potential example of cooperative foraging. In these groups, one whale deploys a bubble net, starting at a depth shallower than the herring schools. The whales then apparently drive the prey up into the bubble net and simultaneously lunge through the herring trapped against the surface. Although there are apparently costs to this behavior and coordination is probably required, no data exist on intake rates in these groups.

One study has suggested that dugongs cultivate seagrass as they forage in large groups moving among seagrass banks. Although dugong grazing changes seagrass communities to stands of more profitable species, for this type of cultivation to occur, cooperation among dugongs would be required. In general, cultivation is favored to evolve only when the individual that gardens realizes the benefits of that action (Branch *et al.*, 1992). This implies both a fixed and a defendable feeding site (Branch *et al.*, 1992). Cooperative cultivation by dugongs is unlikely, as individual dugongs that moved to a previously cultivated area, before the cultivating individuals, would benefit from reduced foraging competition. Also, there do not appear to be any mechanisms to prevent such cheating. A more likely explanation for the observed pattern of dugong foraging is "trap lining" where dugongs rotate among the most profitable seagrass meadows, and the changes in seagrass communities are an incidental byproduct of dugong foraging on rhizomes.

B. Optimal Group Size

The question of why particular group sizes are observed has been raised several times. For some species, group size has been suggested to be that which maximizes the intake rate of individuals in the group (optimal group size). However, this may not generally be the case. When it is difficult for a group to exclude joiners (e.g., when foraging on a large fish school), the observed group size will often be greater than that which maximizes the intake of each group member, as individuals will continue to join a foraging group until the average energy intake in the group approaches that of a solitary forager (stable group size; e.g., Giraldeau, 1988). Also, the benefits of defending resources may be low in large groups, as individuals that do not defend the resource will realize higher intake rates than those individuals that try to defend against joining individuals. Finally, group size is likely to be larger than that which is optimal for foraging considerations if there are other benefits of being in a group (e.g., mating opportunities, protection from predators). Therefore, it is likely that most dolphins feeding on large schools of fish are in groups larger than those that would maximize the energy intake of each group member. However, some marine mammals may be found in groups that are of optimal size for maximizing energy intake. For example, killer whales feeding on marine mammals may be able to regulate group size as individual prey items are easily defended, and groups (which are kin based) may be able to exclude other individuals before foraging commences. This may explain why the modal group size of three individuals observed in foraging transient killer whales is the group size that maximizes its members' energy intake.

IV. Variation in Feeding Strategies and Tactics

Marine mammals show a high degree of variability and flexibility in their foraging tactics. Individuals may be flexible in their foraging tactics depending on their state or circumstances, and this flexibility may lead to variation in foraging tactics among populations, individuals, and age/sex classes. A variation in feeding tactics may also arise from differences in the ways individuals solve cost–benefit trade-offs. Some of these differences among individuals may be genetically based and thus considered strategic variation.

A. Trade-offs

Evolution favors strategies that maximize fitness (usually by maximizing lifetime reproductive success). For example, animals may pursue a strategy that maximizes their expected lifetime energy intake, which may involve a trade-off between maximizing short-term energy intake and minimizing predation risk because habitats that are prey rich are often the most dangerous (e.g., Lima and Dill, 1990; Fig. 5). Therefore, marine mammals may sometimes accept lower energetic returns in order to forage in safe habitats. For example, Indian Ocean bottlenose dolphins in Shark Bay, Western Australia, match the distribution of their prey when their primary predator, the tiger shark, is absent, but shift habitats to forage mostly in low-risk, low-food habitats when sharks are abundant. Also, female polar bears with cubs may preferentially select habitats with lower food abundance to avoid adult males who might kill their cubs. Trade-offs between predation risk to calves and food availability at high latitudes may also be the reason that a strategy that includes seasonal MIGRATION with discrete periods of feeding and fasting evolved in baleen whales.

Trade-offs between feeding and predation may also result in habitat use patterns that vary with behavior. For example, spinner dolphins rest in shallow nearshore coves with sandy bottoms during the day, possibly to reduce the probability of shark attack, and then move offshore to feed on deep scattering layer organisms at night. Similarly, bottlenose dolphins in Shark Bay rest almost exclusively in safer, relatively deep waters, but will often move into higher risk but more productive shallow habitats to feed.

Trade-offs between feeding and reproduction may also influence foraging patterns. For example, most phocid females fast during lactation and must consume sufficient food before the breeding season, whereas female otariids make foraging trips of variable duration throughout lactation (for a review, see Wells *et al.*, 1999).

Prey selection can be viewed as the result of another type of trade-off. Each potential prey item differs in the energy required to capture it and the amount of energy the predator will gain from eating it. This trade-off sometimes results in selective foraging where one prey type is favored over others irrespective of its relative abundance. For example, harp seals always preferentially feed on capelin and select Arctic cod only in nearshore waters. Prey preferences have also been shown in resident killer whales. Off Alaska, resident killer whales prefer coho salmon, whereas those off British Columbia prefer chinook salmon, which are energy-rich but relatively scarce. Prey selection may also take the form of capturing a particular size of prey. For example, harbor seals in Scotland feed primarily on the most abundant fish species, but prefer fish 10–16 cm in length. Changes in the relative costs and benefits of particular prey items may lead to prey switching, which has been observed in some marine mammals.

Figure 5 *Foraging decisions made by individuals can be influenced by the presence of predators. Some individuals may forage in areas where they are more likely to be attacked by predators if the energy gain in these habitats is sufficient. (Photograph by Michael R. Heithaus).*

B. Ontogenetic Variation

There are often distinct differences in the foraging behaviors of marine mammals of different ages. Such differences may be the result of changing physiological or foraging abilities, the relative importance of energy intake and survival at different life history stages, or differences in experience if a learning period is required for the successful use of a particular foraging tactic. Diving by young seals and sea lions is constrained by physiological development and they typically make shorter and shallower dives than adults (e.g., Steller sea lions, Weddell and elephant seals, *Mirounga* spp.). During their first trip to sea, elephant seal pups make a transition from short, shallow dives to a pattern similar to that in adult seals, with longer deeper dives that show diel fluctuations. This transition appears to be related to changes in the physiology of young seals and possibly prey distribution. Young seals of different sizes may adopt different diving tactics. For example, larger yearling Weddell seals engage in relatively shallower dives to forage on benthic prey compared to small yearlings, which make deeper dives to forage on energy-rich prey. However, the cause of this variation is unclear.

Learning plays an important role in the acquisition of foraging tactics in cetaceans. For example, there is a long period of practice required for young killer whales to become adept at using the intentional stranding tactic to capture pinnipeds. This period of learning may involve calves preferentially associating with the female pod members (not necessarily their mother) that engage in this tactic most frequently.

C. Interindividual Variation

Within many marine mammal populations, substantial differences exist among individuals in the foraging tactics that they employ. Northern fur seal females perform two distinct types of foraging dives: shallow dives, which seem to be directed toward vertically migrating prey, and deep dives to feed near the bottom. Shallow dives are made only between dusk and dawn, whereas deep dives occur both at night and during daylight hours. Some individual seals specialize in one dive type or the other, whereas other individuals use a mix of tactics. Southern sea lion individuals differ in their propensity to hunt fur seal pups. In Alaska, only juvenile male Steller sea lions prey upon fur seal pups, whereas in Peru, most hunting is done by just a few adult males, and there are large differences in the success rates of different individuals. Similarly, sea otter predation on birds appears to be largely restricted to a few individuals, and a few individual sea lions have learned to wait at fish ladders and at the mouths of freshwater streams to take advantage of spawning steelhead. Leopard seals also vary in their hunting tactics. For example, a single individual was responsible for all ambushing attacks on Adelie penguins observed in Prydz Bay, Antarctica. Finally, individual variation in the prey species consumed by sea otters may be a result of differences in diving tactics as juvenile males forage further offshore and make longer dives than other age/sex classes.

Cetaceans also show individual variation in feeding tactics. In Shark Bay, many unique tactics, including kerplunking, sponge carrying, and extreme shallow water foraging, are restricted to a small number of individual bottlenose dolphins. It also appears that some dolphins forage only in deep waters, whereas others forage mainly over shallow seagrass habitats or use a mixture of shallow and deep-water tactics. Adult female killer whales perform most of the intentional strandings to catch elephant seals, and within a pod individual females differ in their use of this tactic. Most individual minke whales (*Balaenoptera acutorostrata*) around the San Juan Islands specialize in either lunge feeding or feeding in association with birds. These two tactics are usually observed in different regions with individual whales showing inter- and intraseasonal site fidelity. Individual humpback whales differ in their use of various types of lunge feeding and bubble-netting tactics, which may relate to dietary specializations on either krill or herring and to the distribution of these prey items. Finally, reproductive state may influence the foraging tactics of cetaceans, as lactating female bottlenose, common, and pantropical spotted dolphins (*Stenella attenuata*) consume different prey items than other dolphins.

Cultural transmission appears to be responsible for the acquisition, in humpback whales, of lobtail feeding where a whale slaps the water with its flukes before lunge feeding. Lobtail feeding may have originated with an increase in the importance of sand lance in the whales' diets and then spread as individuals born into the population learned the lobtail feeding tactic rather than adults learning this behavior or new animals recruiting to the area. Cultural transmission of foraging tactics may also maintain the divergence in feeding tactics of sympatric fish-eating and mammal-eating killer whale populations. Finally, sea otter tool use may be transmitted culturally from mothers to their offspring.

D. Intraindividual Variation

Individual marine mammals can switch among foraging locations and tactics depending on their age, body, condition, group size, and prey distribution and abundance. For example, pinnipeds can change their diving behavior in response to increased foraging costs as seals make shallower dives and dive at a steeper angle to maximize their time at a foraging depth. Individuals that encounter different habitats often switch among tactics depending on their location. For example, humpback whales may switch between foraging in large bubble-netting groups and engaging in individual lunges to capture krill. Sperm whale foraging behavior is linked to foraging success, and foraging is more common when prey availability is high or the energetic cost of capturing prey is relatively low. Also, sea otters change the number of prey items they collect on each foraging dive depending on the average prey size available.

The flexibility of marine mammals is highlighted by their ability to take advantage of human activities. Many odontocetes, pinnipeds, and sea otters have learned to steal fish from nets. Sea lions will even jump into encircling nets to feed or will follow fishing vessels for days to take advantage of the abundant food resources offered by fishing operations. Bottlenose dolphins are well known for foraging behind trawlers and feeding on discarded fish or fish in nets. Some individual bottlenose dolphins also have learned to take advantage of direct handouts of fish offered by people, and many species of odontocetes remove either bait or fish from fishing lines. In the Bering Sea and off southern Brazil, killer whales may damage over 20% of the fish captured by long line fisheries.

Both the diversity of habitats in which marine mammals live and the flexibility of individuals have led to the wide variety of foraging tactics exhibited by the group. However, studies of these tactics are still in their infancy. Future studies should move beyond anecdotal accounts of particular foraging behaviors to systematic investigations of the function and use of particular tactics and the circumstances in which they are employed. Only such detailed studies will improve the ability to predict influences of anthropogenic changes to marine habitats and prey availability on marine mammals and aid in efforts to conserve them.

Female Reproductive Systems

Robert E. A. Stewart
Department of Fisheries and Oceans, Winnipeg, Manitoba, Canada

Barbara E. Stewart
Sila Consultants, St. Norbert, Manitoba, Canada

The female reproductive system in marine mammals is composed of the basic mammalian reproductive organs: ovary, oviduct, uterus, cervix, vagina, clitoris, and vaginal vestibule. Under control of the endocrine system, these organs are engaged in the reproductive cycle of ovulation, fertilization, implantation, fetal growth, and parturition. Ancillary to reproduction are the mammary glands and lactation. Some variation in anatomy, morphology, and physiology of the reproductive organs, and in reproductive cycles, exists among orders of marine mammals. Species-specific differences within orders also exist, reflecting both phylogeny and the variety of environments inhabited by marine mammals. Greater variation exists in how marine mammals use their basic mammalian anatomy in different marine habitats. This article describes the gross anatomical and morphological characteristics of female reproductive systems and notes the functional adaptations.

I. Anatomy and Morphology

The ovary is the organ where eggs or ova mature and are released during ovulation. Usually, there are two functional ovaries suspended from the abdominal or pelvic cavity by a short mesentery, the mesovarium, which attaches to the dorsal side of the broad ligament. Dugong (*Dugong dugon*) ovaries are also attached to the diaphragm by peritoneal folds that form pouches in the dorsal abdominal wall.

The ovaries are surrounded by the ovarian bursa, a fold of mesosalpinx that forms a peritoneal capsule. There is considerable variation in development and in the extent to which the bursa communicates with the celomic cavity. The ovarian bursa of odontocetes develops *in utero*, whereas in mysticetes it develops after birth. In polar bears (*Ursus maritimus*) and other carnivores, the periovarian space between the ovary and the peritoneal lining of the bursa communicates with the peritoneal cavity by a narrow passage, which may become distended at estrus with fluid of unknown origins. In all marine mammals, and mammals in general, the function of the bursa is to ensure that the ova pass into the oviduct where fertilization occurs.

Marine mammal ovaries vary in size and shape. Quiescent dugong ovaries are small, flattened ovoids or spheres. Ovaries in the Amazonian manatee (*Trichechus inunguis*) are broad and flattened against a short mesovarium. Sea otters (*Enhydra lutris*) have lenticulate, compressed oval ovaries. The odontocete ovary is more or less spherical to ovoid in shape, with a smooth surface in the resting condition, whereas in mysticetes, ovaries are flat and elongated. Phocid ovaries are ovoid and smooth in the resting state. In some species of phocids (e.g., gray seals, *Halichoerus grypus*), fetal hypertrophy of the ovaries exists through hormonal influence of the pregnant female. This condition may be less pronounced in otariids.

Typically, eggs ripen and ovulate alternately between the ovaries in successive reproductive cycles and the ovaries are of similar size. However, in some odontocete cetaceans there is a prevalence of activity in the left ovary (e.g., 70% in pilot whales, *Globicephala*) and the left ovary is larger than the right (Slijper, 1996). The right ovary may become active later in life.

The mammalian ovary is covered by germinal epithelium (Fig. 1) below which lies connective tissue (tunica albuginea) of varying thickness. Germinal epithelium is often invaginated into the tunica albuginea, forming small folds, pits, or subsurface crypts. These invaginations are particularly well developed in pinnipeds and form surface fissures in sea otter ovaries. Below the tunica albuginea is a layer of follicles and corpora that are derived from them. The ovary also contains stromal and connective tissue, interstitial tissue, vascular, nervous, and lymphatic tissues, and embryological remnants. The interstitial cells of cetaceans are less numerous and less prominent than those in some other mammalian orders, such as rodents. Understanding the maturation process of the follicles and the development and subsequent regression of the luteal bodies for each species allows researchers to assess the reproductive status of females (immature, ovulating, etc.).

Follicular maturation (Fig. 1) proceeds through a series of changes characterized by two phases. In the first phase, there is a rapid increase in the size of the oocyte and a slow increase in the size of the follicle. Second, there is slow growth of the oocyte and a rapid increase in the size of the follicle, which can be seen macroscopically. In dugongs, mature follicles may be just visible as translucent bodies or they may protrude from the

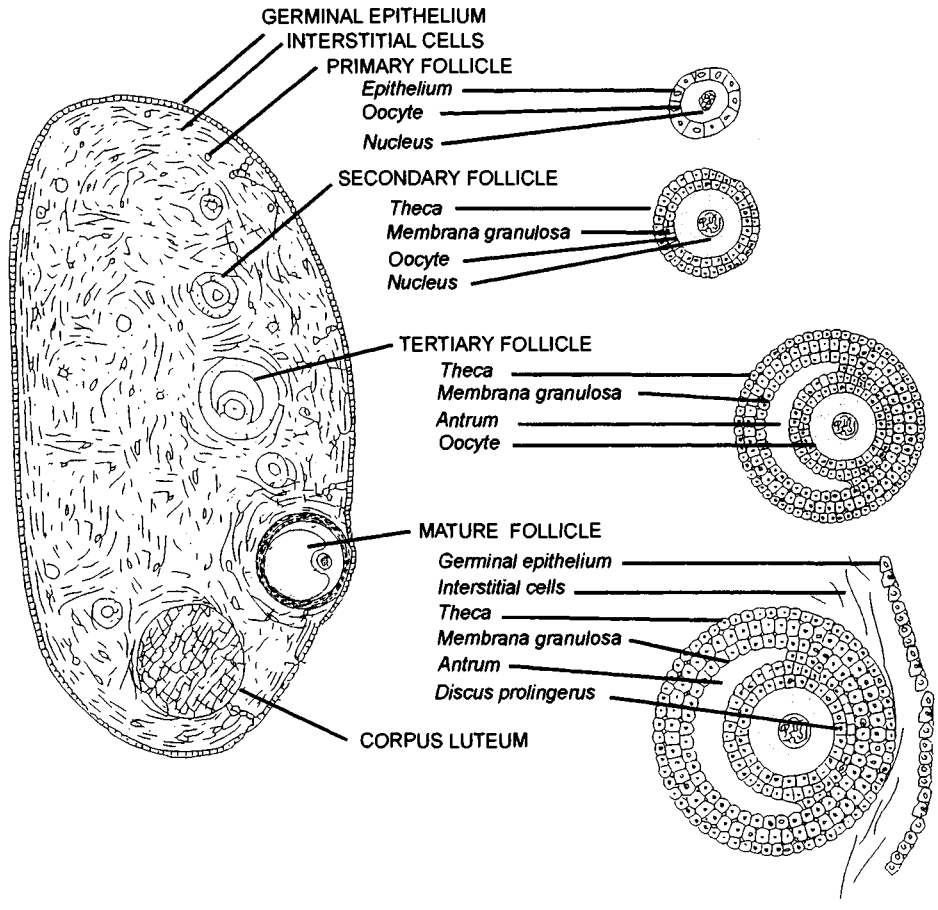

Figure 1 *Main structures of a marine mammal ovary showing stages of follicular development. Modified from Penny and Waern (1965).*

ovarian surface. In West Indian manatees (*Trichechus manatus*), mature follicles appear as large masses of bead-like spherules in the ovary. Similarly, mysticete ovaries may appear grape-like with protruding follicles. Maturing follicles of odontocetes and pinnipeds tend to be more widely dispersed in the ovary.

Oocytes develop within the ovary during fetal development but are dormant until puberty is reached. After puberty, and partly in concert with the annual reproductive cycle, they become primary follicles (Fig. 1) with a single layer of flattened epithelial cells surrounding each oocyte. These follicles lack connective tissue or thecal investment. As primary follicles increase in size they sink deeper into the cortex of the ovary toward the medulla or central area.

Secondary follicles are formed as the single layer of flattened epithelial cells around the oocyte thickens and becomes cuboidal or columnar, forming a distinct membrana granulosa (granular membrane or layer). This granulosa layer quickly becomes several layers thick while being encapsulated in an outer sheath or theca derived from the stroma. The theca divides into two layers. The inner layer, the theca interna, is glandular and well vascularized whereas the outer layer, the theca externa, is composed of connective tissue. The oocyte is now surrounded by a membrane, the zona pellucida, which is jelly-like, contains large amounts of polysaccharides, and lies between the plasma membrane of the oocyte and the granulosa cells.

Tertiary follicles rapidly increase in size due to an increased number of granulosa and thecal cells. Then, one or more cavities form in the granulosa and as the cavities enlarge they coalesce into an antrum, which fills with follicular fluid (liquor folliculi). The fluid-filled follicle is now surrounded by a wall except at the point of attachment of the oocyte.

Mature or Graafian follicles (Fig. 1) contain an oocyte that is surrounded by an irregular cluster of granulosa cells. These granulosa cells eventually form the corona radiata, which in turn is attached to cells forming the discus prolingerus or cumulus oophorus. There is mortality among developing follicles such that only a fraction of those primary follicles that start to develop will ever mature.

Under endocrine control, the mature follicle releases the ovum (ovulation). After ovulation, the corpus luteum (yellow body) develops from cellular components of the follicle. Luteinization is the process of transformation of follicular granulosa cells into luteal cells that contain carotenoid luteins (yellow pigments). There is a significant increase in cell size during luteinization. This volumetric growth is in contrast to the

accretional growth of thecal cells in tertiary follicles. The corpus luteum (CL) is considered to be a gland and several types exist, the nomenclature being based on the morphology or function of the CL. For example, a CL of pregnancy develops when ovulation is followed by fertilization; accessory corpora lutea (plural) develop by luteinization of unruptured follicles (common in cetaceans) (Perrin *et al.*, 1984).

If successful fertilization of the ovum occurs, the CL of pregnancy persists through gestation. There are several phases of development in this corpus luteum gravidatitis: a short postovulatory phase when the CL is small, poorly vascularized, and minor changes occur in the luteal cells; a phase during delayed implantation when the CL is smaller than its initial size, vascularization is still poor, and luteal cells show marked cytoplasmic vacuolation; a short phase related to implantation when vacuoles disappear, the CL enlarges with resumed glandular activity, and vascularization increases; a phase postimplantation and during early pregnancy characterized by minor cell adjustments such as fluid accumulation, more obvious intercellular spaces, appearance of small vacuoles, increase of connective tissue, and thickened walls of blood vessels; the phase of the duration of pregnancy when the corpus luteum size is maintained; and the postparturient phase as a corpus albicans (CA). In cetaceans, accessory CLs may also form in the ovary of pregnancy.

In the beluga (*Delphinapterus leucas*), the corpora lutea gravidatitis are about 3–4 cm in diameter and weigh approximately 22 g. CL diameters in blue whales (*Balaenoptera musculus*) average approximately 14 cm; in common minke whales (*B. acutorostrata*) they average about 7 cm and 160 g. In some odontocetes, such as common bottlenosed dolphins (*Tursiops truncatus*), the CL gravidatitis may protrude far out from the general outline of the ovary and is connected by a stalk (pedunculated).

The process of degeneration of the corpus luteum into the corpus albicans is similar regardless of the type of corpus luteum (CL of ovulation, pregnancy, pseudopregnancy, or lactation) that is regressing. There are four patterns of degeneration: fibrohyalin invasion, lipoid degeneration, slow necrobiosis, and fast necrobiosis. Regardless of the regression pattern, glandular elements are lost, lutein granules vanish, and the size of the body diminishes until the white or gray scar-like CA is formed.

In most mammals, corpora albicantia are assimilated either relatively quickly postpartum or after one or two reproductive cycles, as in the sea otter. In marine mammals that cycle every 2 or 3 years, such as the walrus (*Odobenus rosmarus*), the CA may persist for some time. In cetaceans, corpora albicantia are thought to persist throughout a female's lifetime (Perrin *et al.*, 1984), a consequence of the large amount of connective tissue present and its poor vascularization, leading to a slow rate of regression. Some attempts have been made to characterize various types of cetacean corpora albicantia, but a definitive way to distinguish those bodies derived from ovulation from those of pregnancy has not been established.

An ovarian structure that appears in at least some pinnipeds is the hilar rete (Boyd, 1984). These grandular cells are most abundant during delayed implantation, but their function is not clear. They also occur in a number of terrestrial mammals, including carnivores, primates, rodents, and hyraxes.

The oviduct, uterus, and vagina are all derivatives of the Müllerian duct system. The oviduct, fallopian tube, or uterine tube is generally highly convoluted and is enclosed in the ovarian bursa. The anterior end forms a funnel or infundibulum near the ovary and the posterior end of the oviduct enters the uterus. In eutherian mammals with a bicornuate uterus (e.g., cetaceans), the isthmus can be straight or convoluted but it has a thick wall and a narrow lumen. Dugong uterine tubes lack a mesosalpinx and exist as a 4-cm-long cord-like convoluted tube that lies dorsal to the peritoneum. Generally, the oviduct is lined by simple columnar epithelial that are ciliated and have occasional goblet cells. There is an inner circular layer and an outer longitudinal layer.

The uterus classification scheme in mammals is based on progressive fusion of the caudal ends of the oviducts. Four major types are recognized (Table I, Fig. 2), of which three types are represented in marine mammals; no marine mammal has a simplex uterus. All types of uteri are supported by broad ligaments, have two oviducts, and deliver into a single vagina.

The uterine wall has three layers: on the outside, the serous membrane; in the middle, the myometrium, which contains the internal circular muscle and the external longitudinal muscle separated by the vascular layer; and the inner lining of the uterus, the endometrium, composed of an epithelial lining of the lumen, a glandular layer, and some connective tissue. All uterine types exhibit changes in the layers of the uterine wall that precede implantation and development of the placenta. During the luteal phase of the follicle (postovulatory) the endometrium increases in thickness and the glands become extremely branched and convoluted.

Embryonic membranes develop before the embryo implants. The yolk sac forms first as endoderm surrounds the nutrient uterine fluid. The chorion and amnion develop as a double layer, originating from embryonic ectoderm. The innermost layer is the amnion, which forms the fluid-filled amniotic sac encompassing the fetus. The outer layer of cells of this sac wall

TABLE I
Uterine Types

Type of uterus	*Uterine horns*	*Cervix*	*Example*
Duplex	Two completely separate horns	2	Walrus
Bipartite	Two horns separated internally by a septum but sharing a small common area near the cervix	1	Phocids
Bicornuate	Two horns with no internal septum, forming a single body of the uterus	1	Cetaceans, sirenians, mustelids, ursids
Simplex	No horns, one uterine body without compartments	1	Humans

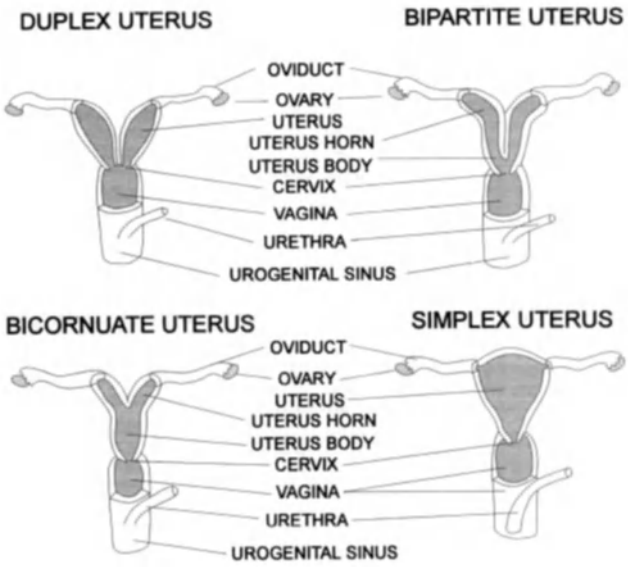

Figure 2 *Uterus types found in placental mammals. The simplex type is not found in marine mammals. Modified from Romer (1962).*

is the chorion. The allantois develops as an extension of the embryonic hindgut and forms the allantoic cavity. The allantois fuses with the chorion, forming a small round area, the allantochorion. This region becomes the placenta (Fig. 3).

The embryonic membranes persist after the placenta is fully developed. In whales, the amniotic sac and allantois extend into the contralateral uterine horn. The chorion has many folds that mesh with the uterine mucosa. In pinnipeds, the chorion extends beyond the zonary placenta. The large allantois almost completely surrounds the amnion. In sirenians, the allantois is also large and nearly fills the chorionic sac.

The placenta is composed of maternal and embryonic tissue in close union. It allows nutritional, respiratory, and excretory exchange between maternal and fetal circulatory systems by diffusion across the placental membranes. Additionally, the placenta functions as a protective barrier to bacteria and other large molecules, produces some food materials, and synthesizes hormones required to maintain the pregnancy. The umbilical cord connects the placenta to the ventral surface of the embryo and is formed of mesoderm and blood vessels. This connection is broken at birth.

There are three types of placentas seen in mammals, defined by the fetal tissue that adheres to the uterine wall. They are the chorionic placenta, the yolk-sac placenta, and the chorioallantoic placenta, which is found in all marine mammals. The chorioallantoic placenta is the most advanced placenta type in its ability to provide rapid diffusion between uterine and fetal circulatory systems. As the blastocyst implants and sinks into the uterine endometrium, chorionic villi grow quickly and push further into the endometrium. This process is accompanied by a breakdown of uterine tissue. The degraded debris is called embryotroph. The blastocyst absorbs the nourishing embryotroph until the villi are fully developed and the embryonic vascular system becomes functional.

Although all placentas are derived from both maternal and fetal tissues, the degree of separation of maternal and fetal circulatory systems is variable and is a function of the type of placenta that has developed. Chorioallantoic placentas can be further subdivided based on the fetal and maternal cell layers that are in contact. In epitheliochorial placentas (cetaceans), the epithelium of the chorion is in contact with the uterine epithelium. The villi rest in endometrial pockets. In endotheliochorial placentas (pinnipeds, mustelids, ursids), degradation of the maternal endometrium is more pronounced and the epithelium of the chorion is in contact with the endothelial lining of the uterine capillaries. Hemochorial placentation (sirenians) is characterized by destruction of the endothelium of the uterine blood vessels, allowing blood sinuses to develop in the endometrium. There is direct contact therefore between chorionic villi and maternal blood. Hemoendothelial placentas are not found in marine mammals but occur in some rodents and in lagomorphs.

Placenta shape is characterized by the pattern in which villi are distributed over the chorion. Two shapes occur in marine mammals: diffuse and zonary (Fig. 3). In the diffuse placenta (cetaceans), villi occur over the entire chorion, providing a

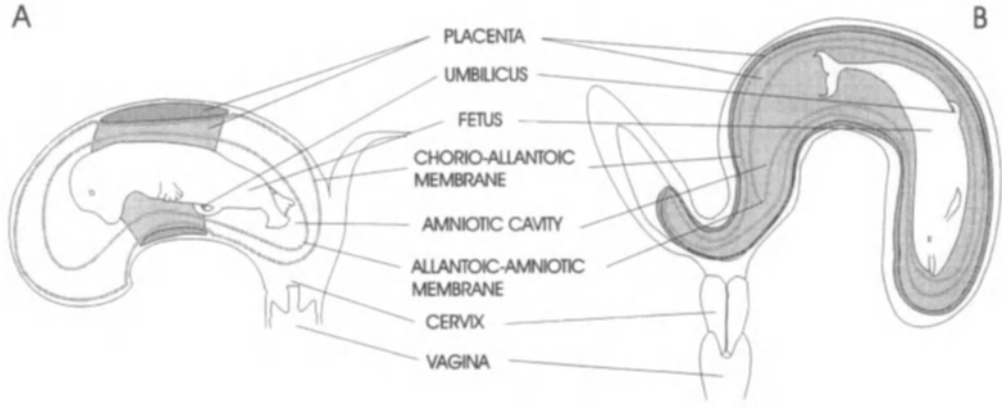

Figure 3 *Zonary (A) and diffuse (B) placentas found in marine mammals [B modified from Slijper (1966), copyright University of California Press.].*

large surface area for exchange. In a zonary placenta (all other marine mammals), there is a continuous band of villi covering the equator of the chorion. In walrus and sirenians, the zonary placenta leaves detectable scars on the uterus. Both diffuse and zonary placentas are also found in terrestrial mammals.

When the placenta is expelled from the uterus postpartum as afterbirth, a maternal component may be lost. Epitheliochorial placentas have villi that pull out of the uterine pits easily and no endometrium is pulled away. Therefore, no bleeding occurs at birth and this placenta is referred to as nondeciduous. The other types of placentas allow for closer association of maternal and fetal circulatory systems through degradation of the endometrium and extensive intermingling of uterine and chorionic tissue. At birth then, part of the uterine component of the placenta is torn away and bleeding occurs. These are termed deciduous placenta. Bleeding is arrested quickly by collapse of the uterus, contractions of the myometrium constricting blood vessels, and blood clotting. The subsequent development of uterine scars at the bleeding site can result in persistent features that can be used in the interpretation of reproductive history in a female (e.g., walrus; Fay, 1982), although their persistence is variable among species.

The cervix is a well-muscled sphincter that marks the transition between the uterus and the vagina. The West Indian manatee has a rounded cervix. In the dugong, the long, thin-walled vagina has a keratinized shield originating in the vault region. This shield surrounds the cervix and extends along the ventral wall of the vagina. In cetaceans, the cervix is long with a thick wall and a narrow, sinuous lumen. The portion of the cervix projecting into the vagina (portio vaginalis uteri) is species specific in length, e.g., very short in the narwhal (*Monodon monoceros*) but long in the harbor porpoise (*Phocoena phocoena*). Vagina length in pinnipeds equals or slightly exceeds the urogenital canal in length.

Many cetaceans have several folds in the upper part of the vagina that are not found in any other mammal. There is a valve-like arrangement to these 4–12 circular folds, which project distally and look like a chain of funnels with their mouths directed toward the cervix. This configuration may act to retain sperm, but the function of these folds is unclear. Harrison (1969) noted that the folds appeared capable, anatomically, of a pumping action and speculated that they may relate to the formation of vaginal plugs. Vaginal plugs are congealed masses of semen that occur in some mammalian orders. They are thought to assist sperm retention and discourage subsequent matings by competing males. There is some suggestion of vaginal plugs in *Tursiops* and *Delphinus* but little other evidence. Vaginal calculi are masses of organic and inorganic material that have been found in *Delphinus, Stenella,* and *Lagenorhynchus.* Calculi contain material identical in composition to mammalian bone and some contain recognizable embryonic bones (Perrin *et al.*, 1984). "Vaginal plugs" therefore may represent small or deteriorating vaginal calculi.

The remainder of the female reproductive system consists of the clitoris, urethra, and vaginal vestibule. For all pinnipeds, the presence of the os clitoridis has been recorded, but it is generally small (<1 cm) and its appearance is irregular. In cetaceans, the clitoris projects from a strand of fibrous connective tissue on the anterior border of the vulva. Dugongs possess a clitoris with a large conical glans that has prominent fissures dividing it into lobes.

The urethra also opens into the vaginal vestibule, draining the bladder, which lies ventral to the vagina. The urethra in pinnipeds opens by a large urinary papilla just caudal to the hymen. Pinnipeds have long urogenital canals compared to other mammals and there is a prominent hymenal fold, which is smaller in otariids. Dugongs have a urethra surrounded by prostate-like tissue, which also surrounds the narrow distal portion of the vagina.

In pinnipeds, the vaginal vestibule opens to the exterior just ventral to the anus in a common furrow. In cetaceans, the vulva is a slit-like aperture with labia majora and labia minora, which may be poorly developed. The slit is positioned just anterior to the anus.

Considerable variation exists in mammary gland configuration and nipple location in marine mammals. Phocids have distinct mammary glands enclosed in connective sheaths lying under the blubber layer. In otariids, the mammary glands coalesce to form a sheet-like layer under the blubber over most of the ventral surface of the body. Cetacean mammary glands are elongate, narrow, flat organs that extend in the subcutaneous connective tissue at both sides of the ventromedial line. They extend from a little posterior of the umbilicus to slightly anterior to the anus.

Cetaceans have two nipples in elongated recesses, one on either side of the midline in the urogenital slit. The nipples become protruded during nursing, and the milk is expelled under pressure, likely due to contraction of either the cutaneous muscles or the myoepithelial cells surrounding the alveoli. Sirenians have two pectoral nipples. Sea otters have only two functional teats on the lower abdomen, compared to six or more in most other mustelids. Polar bears have four teats, two on either side of the midline of the belly slightly posterior of the axillae and two about 15 cm posterior to the anterior pair. Otariids, odobenids, and two genera of phocids (*Erignathus* and *Monachus*) have four teats while the other phocids have two that correspond to the posterior pair of those in otariids. Pinniped nipples are retracted beneath the level of the body surface when a pup is not nursing and become erect during suckling.

II. Reproductive Cycle

In marine mammals, ovulation can be either spontaneous or induced. Spontaneous ovulators release an egg even in the absence of breeding (phocids, cetaceans). Induced ovulators release an egg only in response to coital stimulation (polar bear, sea otter).

The ova normally are fertilized in the oviduct within 24 hr of breeding and the zygote's first cell divisions occur there. At the 8–16 cell stage, movement to the uterus occurs with assistance of muscle contractions in the oviduct. There, further differentiation into the blastocyst and subsequent implantation take place.

Implantation of the blastocyst may be immediate (within 1–2 weeks) or after some protracted delay of several months. This delay, also know as embryonic diapause, occurs in carnivores and pinnipeds and is considered to be obligate. Its duration is species specific. Facultative delayed implantation can occur in other species of mammals if a female is nursing a large litter at the time of insemination (e.g., some marsupials, some insectivores). The length of active gestation is generally related to the body size of the female, and a delay in implantation is thought to allow the young to be born at an advantageous time. For example, harp seals (*Pagophilus groenlandicus*) have a delay of about 3 months followed by an active gestation of about 8.5 months. The delay produces a cycle that is nearly 1 year long, allowing births and breeding to occur during large spring aggregations when pack-ice conditions are suitable. There may be some flexibility in the duration of the delay, and in sea otters, this flexibility may lead to the variation seen in estimates of total gestation, ranging from 6 to 8 months.

Obligate-delayed implantation is characterized by ovulation, fertilization, and differentiation up to the blastocyst stage, which creates a hollow ball of 100–400 cells surrounding a fluid-filled cavity. Further differentiation of the blastocyst then stops and implantation in the endometrium does not occur. The blastocyst is free-floating in the uterus and is covered by a zona pellucida, a noncellular protective layer, for the period of dormancy. Resumption of blastocyst differentiation occurs prior to implantation. During delayed implantation, pregnancy is indicated, macroscopically, by the presence of a corpus luteum and an increased diameter of a uterine horn, which shows marked surface vascularization, smoothening of the endometrial folds, and development of a nidation chamber where implantation will occur.

Usually, implantation of the blastocyst occurs in the uterine horn corresponding to the active ovary (ipsilateral). However, in odontocetes with only one active ovary, there is a tendency for transuterine migration of the blastocyst, which will implant in the other (contralateral) horn. Fetal membranes project into the horn opposite the implantation site. In mysticetes, and most other mammals, there is a slight prevalence (60%) of implanted fetuses in the right horn, reflecting a similar rate of ovarian activity in the right ovary (60%) (Slijper, 1966).

Once implanted, the blastocyst begins to differentiate tissues and organs, and remains in the uterus for the duration of its fetal phase. Nourishment and protection *in utero* allow for relatively high survival rates of the fetus.

At birth, powerful and rhythmic contractions of the uterine myometrium aided by the abdominal muscles expel the fetus. Continued contractions force the placenta from the uterus and vagina. In cetaceans, birth underwater must be rapid to prevent drowning of the neonate. The newborn swims unaided or is pushed to the surface by its mother or attendants to breathe for the first time. Other birthing platforms include land-fast ice (ring seal, *Pusa hispida;* Weddell seal, *Leptonychotes weddellii*), pack ice (harp seal, crabeater seal, *Lobodon carcinophaga*), and terrestrial sites (harbor seal, *Phoca vitulina;* polar bears; otariids). Few births have been observed in sea otters and may take place both on shore and in the water. Sirenian births are also rarely seen but are thought to occur in shallow water, although there is some evidence they may also calve on low sand bars.

Cetacean and pinniped neonates have relatively large body sizes, approximately 8–10% maternal weight compared to mammals in general (Slijper, 1966; Kovacs and Lavigne, 1992), a benefit to these animals that need to swim at birth or shortly afterward and to maintain homeothermy in cold water. Most marine mammals usually give birth to a single offspring. Twin live births are exceedingly rare in pinnipeds and the sea otter, and have never been documented in cetaceans, although multiple fetuses have been observed. Some twins have been reported among sirenians. It is thought that multiple births are incompatible with the production of newborns that are large relative to maternal body size, as is found in these animals. It may also be difficult for a marine mammal mother to properly tend more than one offspring in the marine environment.

Multiple births are the norm in polar bears; however, ursids have extremely small young, relative to adult female body weight, that are born in dens and emerge with mother after considerable time when substantial postnatal growth has occurred. Most ringed seals and Baikal seals (*Pusa siberica*) are also born in dens, excavated in snow drifts from a hole scratched in the sea ice by the mother.

All marine mammals suckle their young with milk exclusively before a transition to solid food items and complete weaning is made. The period of lactation is again species specific and can be relatively short (4 days in hooded seals, *Cystophora cristata;* 10–12 days in harp seals) or more protracted (up to 2 years in sirenians, some cetaceans, walrus), although the young may start to eat solid food before weaning is completed. Marine mammal milk is typically high in fat (40–50%), high in protein (7–19%), and low in lactose (trace–5%) compared to terrestrial mammals.

Milk may be forcefully ejected from the teats or may be sucked from the teats by the neonate. In cetaceans, forceful ejection of milk is required because neonates cannot suck with their lips and must hold their breath during underwater nursing bouts. Indeed, because young *Tursiops* can only remain underwater for less than a minute, they nurse two or three times an hour over an entire 24-h period. Walruses may suckle young in water, and the teats are surrounded by sphincter-like folds of skin, which suggest that milk may be squirted into the calves' mouth. Young sea otter pups nurse while lying on the female's chest, whereas older ones lie in the water perpendicular to her. Sirenian calves nurse at the surface with their nostrils in the air or just below the surface. All other marine mammals nurse their young on ice or on land and neonates actively suck milk.

Weaning can be abrupt by abandonment (most phocids and otariids) or extend over some time (walrus, sirenians). The extended care of the young during lactation, and sometimes beyond in a period of learning, further increases survivorship of the offspring beyond the high rate of fetal survival. It also increases the efficiency of reproduction in that maternal energy expended toward young results in a high rate of offspring that reach reproductive maturity, consistent with other *K*-selected life history traits.

Age of maturation varies by species and, within a species, can be influenced by environmental factors that affect growth and fattening. Breeding success is often lower in younger breeders, but lifetime reproductive success and the number of descendants produced of those that breed young and survive can be high. Diminished reproductive frequency (reproductive senescence) has been described for some marine mammals (walrus, polar bear, some fur seals and some cetaceans). Although short-finned pilot whales (*Globicephala macrorhynchus*) of advancing age become senescent with no follicular activity, they may still lactate, nursing not only their own previous young but possibly also other young in the pod.

Filter Feeding

DONALD A. CROLL AND BERNIE R. TERSHY
University of California, Santa Cruz

I. Filter Feeding and the Marine Environment

fundamental necessity for any organism is acquiring sufficient food for maintenance, growth, and reproduction. This search for food likely drove the return of mammals to the ocean where they were able to exploit highly productive coastal waters. With their return to the sea, marine mammals evolved a number of foraging techniques. Filter feeding, found in mysticete whales and three species of pinnipeds (crabeater seals (*Carcinophaga lobodon*), leopard seals (*Hydrurga leptonyx*), and Antarctic fur seals (*Arctocephalus gazella*), is the most unique of these adaptations for feeding and is not found in any terrestrial mammals.

Filter feeding allows these marine mammals to exploit extremely abundant but small schooling fish and crustaceans by taking many individual prey items in a single feeding event. This adaptation arose in response to the unique patterns of productivity and prey availability in marine ecosystems.

Low-standing biomass and high turnover of small-sized primary producers that respond rapidly to nutrient availability characterize marine food webs. Due to spatial differences in the physical dynamics of marine ecosystems, productivity tends to be more patchy and ephemeral than in terrestrial systems. Consequently, marine grazers (e.g., schooling crustaceans and fish) often occur in extremely high densities near patches of high primary production. Most marine mammals are primary carnivores and feed on these dense, patchily distributed aggregations of schooling prey. The spatial and temporal patchiness of this prey means that marine mammals must often travel long distances to locate prey, and the larger body size of marine mammals likely plays an important role.

Initially, thermoregulatory requirements selected for larger body sizes as mammals returned to the ocean. However, once dependent on marine prey, a large body size also provided a buffer for the patchy and ephemeral distribution of marine prey. Thus, larger individuals could endure longer periods and travel longer distances between periodic feeding events on patchy prey. While adaptive for exploiting patchy prey resources, a consequence of larger body size is a higher average daily prey requirement. For marine mammals that feed on patchy and ephemeral resources, this requires individuals to take in large quantities of prey during the short periods of time it is available.

Filter feeding is a foraging strategy that allows individuals to capture and process large quantities of prey in single feeding events, thus allowing them to acquire energy at high rates when small prey are aggregated. Indeed, for mysticetes, a large body size is probably a prerequisite for attaining a sufficiently large surface area for filter feeding. Thus, the interaction of availability of prey resources, high concentrations of prey in

schools, and selection for large body size likely led to the evolution of filter feeding. Ultimately, a large body size and filter feeding allowed some marine mammals to exploit the extremely high densities of schooling prey that develop at high latitudes during the spring and summer, while fasting during the winter when these resources disappear. A large body size provided an energy store for wintering and long-distance migration without feeding.

Due to this dependency on patchy but extremely productive food resources, it is not surprising that filter-feeding whales are believed to have first evolved and radiated in the Southern Hemisphere during the Oligocene at the initiation of the Antarctic circumpolar current (ACC). It is generally agreed that the initiation of the ACC led to cooling of the southern oceans, increased nutrient availability, and thus increased productivity. This increased productivity provided a rich resource of zooplankton that could be exploited effectively through filter feeding.

Present-day filter-feeding marine mammals concentrate their foraging in polar regions and highly productive coastal upwelling regions. The Southern Ocean is still the most important foraging area for filter-feeding marine mammals. Prior to their exploitation by humans, the highest densities of mysticetes occurred in highly productive southern waters. Crabeater seals, Antarctic fur seals, and leopard seals are found primarily in the southern oceans where seasonally dense aggregations of krill develop.

II. Diet, Filter-Feeding Structures, and Prey Capture

All filter-feeding species feed on prey that form dense aggregations (primarily pelagic schooling fish and crustaceans or densely aggregated benthic amphipods). Two feeding adaptations have evolved to allow the exploitation of these dense aggregations: baleen (mysticete whales) and modified dentition (seals).

A. Seals: Diet, Feeding Morphology, and Behavior

Unlike mysticetes, pinnipeds evolved in the Northern Hemisphere where krill was not likely an important component of their DIET. As a result, adaptations for filter feeding are not nearly as extensive in pinnipeds as in mysticetes.

Only three pinniped species regularly filter feed: crabeater seals, leopard seals, and Antarctic fur seals. When filter feeding, all three species feed almost exclusively on Antarctic krill, *Euphausia superba*, in the Southern Ocean where it is abundant and forms extremely dense aggregations. Of the three pinniped species, crabeater seals are the most highly specialized, with krill comprising up to 94% of their diet, whereas krill comprises approximately 33% of the diet of leopard seals and Antarctic fur seals. The most remarkable adaptation for filter feeding in pinnipeds is found in the dentition of crabeater and leopard seals. In both species, elaborate cusps have developed on the postcanines in both the upper and the lower jaws (Fig. 1). Once the mouth closes around a small group of krill, water is filtered out through the cusps, trapping krill against the insides of the modified teeth. Little detailed information is available on the behavior used by filter-feeding pinnipeds to capture prey. However, data from Antarctic fur seals indicate that they track the diel migration of krill: shallow dives are performed during the night and deeper dives during the day.

B. Mysticetes

1. Diet and Feeding Morphology Most mysticetes feed primarily on planktonic or micronectonic crustaceans (copepods and krill) and pelagic schooling fish found in shallow waters. The gray whale diet consists primarily of benthic apeliscid amphipods, although they can forage on a wide variety of prey, including schooling mysids in some areas. Right (*Eubalaena* spp) and bowhead (*Balaena mysticetus*) whales primarily feed on copepod crustaceans of the genus *Calanus*. All of the rorquals feed on euphausiids (krill) to some extent, and blue whales (*Balaenoptera musculus*) feed almost exclusively on euphausiids. The other rorquals have a more varied diet that includes copepods (sei whales—*B. borealis*) and schooling fish (minke—*B. acutorostrata* and *B. bonaerensis*, Bryde's—*B. edeni*, humpback—*Megaptera novaeangliae*, and fin whales—*B. physalus*).

All mysticetes lack TEETH and instead have rows of baleen plates made of keratin that project ventrally from the outer edges of the palate. Similar to fingernails, the plates grow continuously from the base, but are worn by the movements of the tongue. As the edges of the plates wear, hair-like fibrous strands emerge as fringes. The outer fibers of these fringes are coarser, whereas the inner fibers form a tangled fringe that overlaps with fringes on adjacent baleen plates. Rows of baleen plates form an extended filtering surface along each side of the palate.

The coarseness of the hair-like fibrous fringes, the density of fibers (number of fibers/cm^2), the number of baleen plates, and the length of baleen plates vary among species and are related to the prey species captured in the filtering mechanism. Because gray whales (*Eschrichtius robustus*) feed primarily on sediment-dwelling benthic amphipods, they have the coarsest filtering mechanism, made up of about 100, 5–25 cm-long individual plates with very coarse fibers. This coarse filtering structure allows them to separate amphipods from bottom sediments. In contrast, right whales that feed on small copepods have a fine filtering mechanism composed of more than 350 baleen plates that can exceed 3 m in length. The fibers of right whale baleen are very fine, forming a dense mat capable of capturing copepods that are less than 5 mm long. The strong, flexible, and light characteristics of baleen plates made them commercially important in the 19th century where they served some of the roles of today's plastics.

Mysticetes have evolved three types of filter feeding: sediment straining (gray whales), skimming (right and bowhead whales), and lunging or gulping (rorquals). The morphology of mysticetes reflects these different strategies. Gray whale heads are straight and relatively short and contain short, coarse baleen and their throat regions possess only a few grooves (three to five) in the gular region that allows limited distention for taking in bottom sediment, water, and amphipods. Right and bowhead

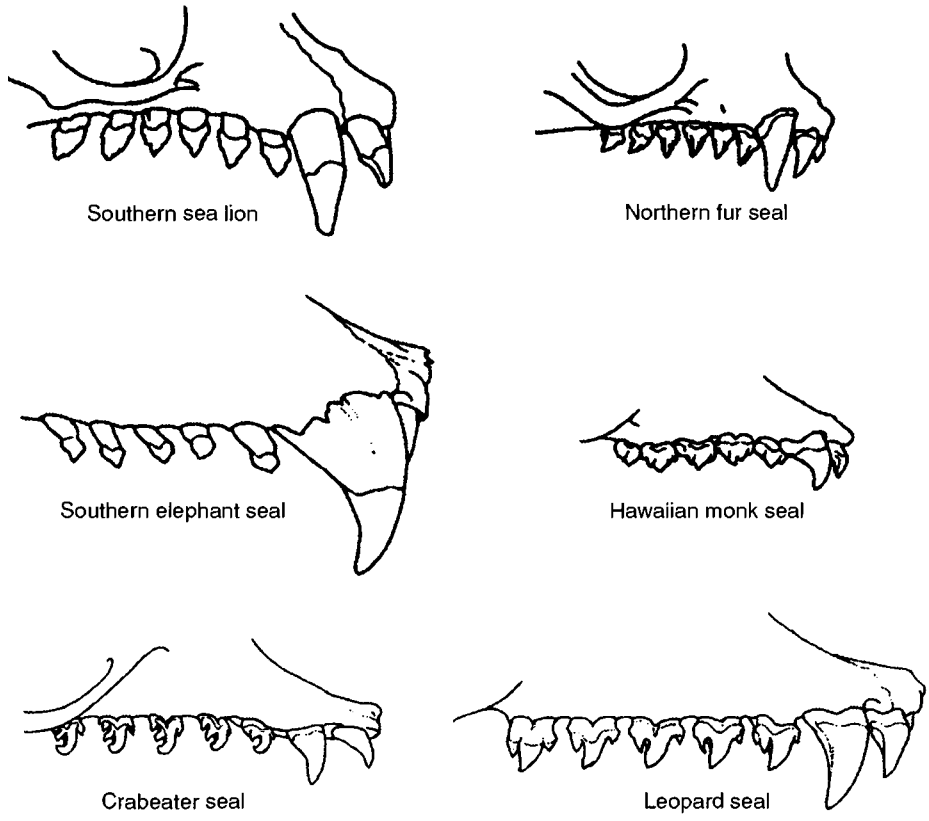

Figure 1 *Dentition patterns in pinnipeds. Note modified cusps in postcanine teeth in filter-feeding crabeater and leopard seals. From Berta and Sumich (1999).*

whale heads have a strongly arched rostrum that allows them to have very long and fine-textured baleen within a relatively blunt mouth. They have no throat grooves for distension and instead feed by swimming slowly and skimming prey from the water. Rorqual heads are large and contain enormous mouths that extend posteriorly nearly half of the total body length. Their mouths contain relatively short baleen that ranges from fine (sei whales) to medium texture (blue, fin, humpback, and minke whales). The heads and bodies of rorquals are much more streamlined than other mysticetes, allowing them to swim rapidly into a prey school to gulp large quantities of water and schooling prey. One of the most remarkable adaptations for feeding is the presence, in rorquals, of 70–80 external throat grooves. During gulping, these grooves open like pleats to allow the mouth cavity to expand up to four times in circumference, taking in a volume of water equivalent to about 70% of the animals' body weight.

2. *Feeding Behavior* Observations of feeding gray whales in the Arctic and Bering Sea have shown that the whales roll to one side and suck benthic invertebrate prey and bottom sediments, with some distension of the mouth cavity through the expansion of the throat grooves. Water and mud are expelled through the side of the mouth. A similar behavior is used by gray whales that do not migrate as far north where they feed on a variety of benthic invertebrates and schooling myscids. This benthic foraging behavior creates scrapes of about ½ m deep and 1 by 5 m in shape in the ocean floor, and several studies have shown that the disturbance is an important factor in the ecology of soft-bottom benthic communities of the Arctic and Bering Seas.

Right and bowhead whales forage by skimming with their mouths open through concentrations of crustaceans. As the whale swims, water and prey enter through the front of the mouth and water exits along the sides of the mouth while prey are trapped in the fine baleen (Fig. 2). Whereas right and bowhead whales generally feed singly, at times they may feed alongside one another—a V formation of 14 bowhead whales has been observed.

Rorqual lunge feeding has been described as the largest biomechanical event that has ever existed on earth. Rorquals capture food by swimming rapidly at a prey school and opening the mouth to gulp vast quantities of water and schooling prey (Fig. 3). To maximize the opening, the lower jaw opens to almost 90° of the body axis. This is possible because the lower jaw has a well-developed coronoid process. This process is located where the large temporalis muscle inserts and provides an anchor and mechanical advantage for control of the lower jaw while maximizing the gape for prey capture. It is not developed in other whale species, and a tendinous part of the temporalis muscle, the frontomandibular stay, enhances and strengthens the mechanical linkage between the SKULL and the lower jaw.

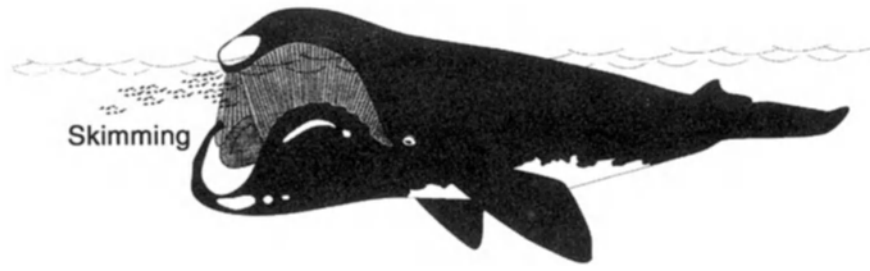

Figure 2 *Skim feeding in right and bowhead whales. From Berta and Sumich (1999).*

With the mouth open, the onrush of water and prey is accommodated by the distending ventral pleats. The tongue invaginates to form a hollow sac-like structure (cavum ventrale) that lines the inside of the gular region and the ventral pleats distend fully. After engulfing entire schools of prey, the lower jaw is closed. The muscular tongue and the elastic properties of the ventral walls of the throat act in concert to force water out through the baleen (Fig. 3).

Although the process just described is fundamentally the same in all rorquals, some species exhibit modifications and additional adaptations. Sei whales skim feed in a manner similar to right whales, as well as feeding by lunging. Fin and blue whales often feed in pairs or trios that have a consistent echelon configuration. Humpback whales have a diverse diet and a wider variety of feeding behaviors. They have been observed bottom feeding and, while feeding on schooling fishes, have been observed to produce a cloud of bubbles and feed cooperatively to assist in prey capture.

Laboratory experiments have shown schooling fish to react to bubbles by aggregating more densely. Humpback whales appear to take advantage of this, as one member of a group of foraging whales produces a net of bubbles. The bubble cloud serves to aggregate and confuse the prey. Members of the group dive below the bubble cloud and surface together—one whale immediately

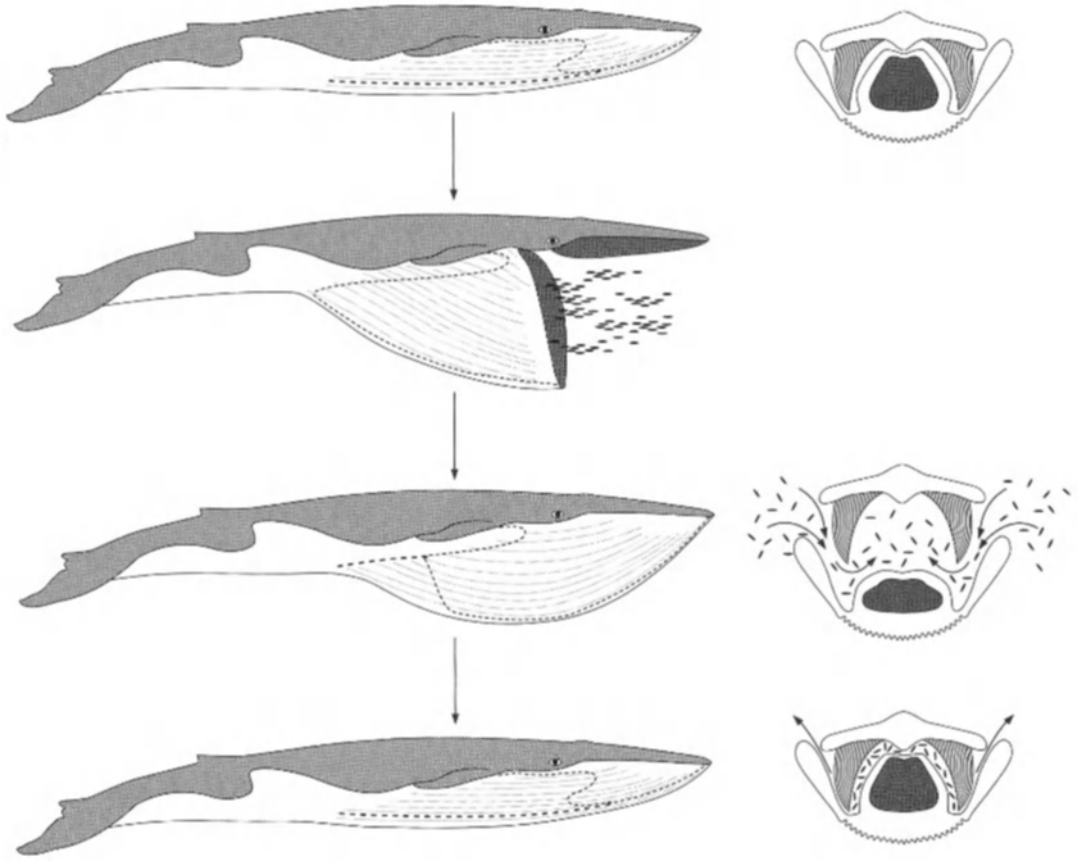

Figure 3 *Lunge feeding in rorqual whales demonstrating expansion of the throat pleats in invagination of the tongue. From Berta and Sumich (1999).*

adjacent to another. Group foraging humpbacks form long-term associations and the location of the whales in the surfacing group appears to be fairly constant through time. Humpbacks thus likely enhance prey capture success by using both bubbles and foraging cooperatively. A variation of bubble cloud feeding has been observed in humpback whales feeding on sand lance off New England. Here the bubble cloud feeding is followed by a tail slap—believed to cause the sand lance to aggregate more densely.

3. Feeding Ecology All filter-feeding whales exhibit distinct MIGRATION patterns linked to seasonal patterns in prey abundance. Seasonally dense aggregations of prey are probably necessary for successful filter feeding. For example, gray whales undergo the longest migration of any mammal: foraging during the summer and fall in the Bering Sea and Arctic Ocean when dense aggregations of benthic amphipods become available with the seasonal increase in productivity. Humpback whales seasonally migrate from breeding areas to higher latitude foraging areas where schooling fish and krill become seasonally abundant. The timing of coastal migration patterns of the California blue whale appears to be linked to annual patterns in coastal upwelling and krill development patterns.

Studies of the diving behavior and daily movement patterns of right whales have shown that they are found at dense aggregations of copepods, which in turn track oceanographic features such as fronts. Zooplankton densities in regions where right whales foraged in the southwestern Gulf of Maine were approximately three times the mean densities in the region (whale feeding densities averaged 3.1–5.9 g m^{-3}, compared to 1.1–3.6 g m^{-3} where whales were not foraging). In a related study using hydroacoustic surveys, zooplankton densities where right whales were foraging were 18–25 g m^{-3} (compared to 1–5 g m^{-3} where whales were not foraging). Whale diving behavior is related to the depth of prey aggregations. In a year when copepods did not undergo diel migrations, dive depths averaged 12 m, with no dives exceeding 30 m throughout the day and night. In contrast, in a year when copepods showed strong diel shifts in depth (near the surface at night, deeper during the day), whale dive depths were significantly longer during the day.

Rorquals also track seasonal and diel patterns in the abundance and behavior of their prey. In general, the distribution and movement patterns of most rorquals consist of a seasonal migration from high latitudes where foraging takes place to low latitudes where they mate and give birth. However, data from blue whales in the Pacific indicate that feeding also takes place at low-latitude, "upwelling-modified" waters, and data from both the Pacific and the Indian Oceans indicate that some blue whales may remain at low latitudes year-round. Fin and blue whales foraging on krill off the coast of North America concentrate their foraging effort on dense aggregations of krill that are deep (150–300 m) in the water column during the day and may cease feeding when krill become more dispersed near the surface at night.

Rorqual foraging appears to only occur in regions of exceptionally high productivity, often associated with fronts, upwelling centers, and steep topography. It has been estimated that fin whales require prey concentrations of at least 17.5 g m^{-3} to meet daily energy requirements. Krill densities where humpback whales were foraging in Southeast Alaska have been estimated at 910 individuals m^{-3}, and minimum required prey densities for humpbacks were about 50 individuals m^{-3}. Krill densities in schools where blue whales were foraging in Monterey Bay, California, were estimated at 145.3 g m^{-3} compared to an overall mean density of zooplankton of 1.3 g m^{-3} in the area.

III. Summary

Filter feeding in marine mammals is an adaptation that allows individuals to take in large quantities of prey in one mouthful. This is particularly adaptive in marine ecosystems where prey are relatively small and often densely aggregated, but patchy and ephemeral in space and time. Most filter-feeding species feed on schooling fish and crustaceans. The large body size of marine mammals, particularly mysticetes, facilitates filter feeding by providing the ability to have a large filtering area relative to body volume. In addition, a large body size likely provides an energetic buffer for animals that must move long distances between dense prey patches and endure long periods of fasting between foraging events.

Finless Porpoise

Neophocaena phocaenoides

MASAO AMANO
Otsuchi Marine Research Center, University of Tokyo, Japan

I. Diagnostic Characters and Taxonomy

The finless porpoise is a small phocoenid cetacean lacking a dorsal fin as the common name suggests (Fig. 1). Instead of a dorsal fin, a ridge runs down the middle of the back. The species has a rounded head without an apparent beak.

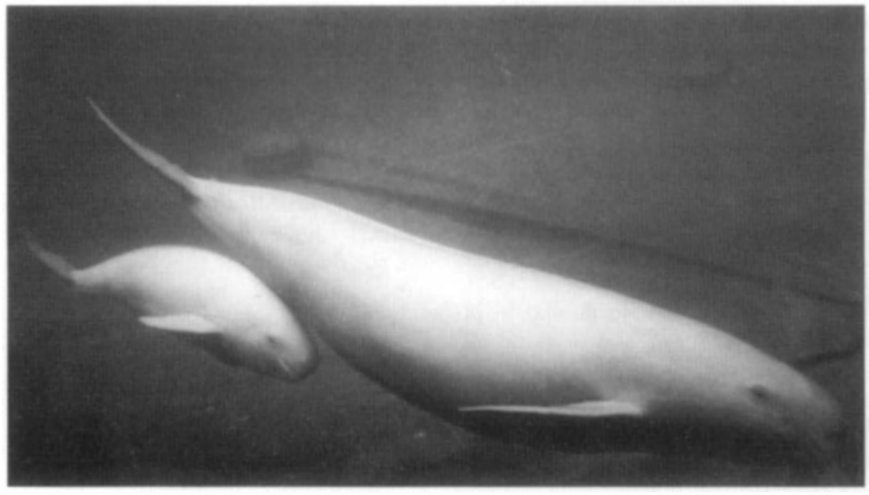

Figure 1 *Mother and calf pair of Japanese finless porpoises in captivity (courtesy of the Minamichita Beachland Aquarium).*

Its color is uniformly dark to pale gray and somewhat lighter on the ventral side. Teeth are spatulate as in other phocoenids.

The finless porpoise was originally described by G. Cuvier as *Delphinus phocaenoides* based on a skull supposedly from the Cape of Good Hope. However, there have been no further records of this species from the west coast of Africa and the true type locality is now considered to be the Indian coast. The genus names *Neomeris*, which is not valid since preoccupied by a polychaete, and *Meomeris*, which is a misspelled name and not available, were formerly used (Rice, 1999).

II. Distribution

Finless porpoises inhabit shallow coastal waters and some rivers in the Indo-Pacific region (Fig. 2). Their distributional range is from the Persian Gulf in the west, through the coasts

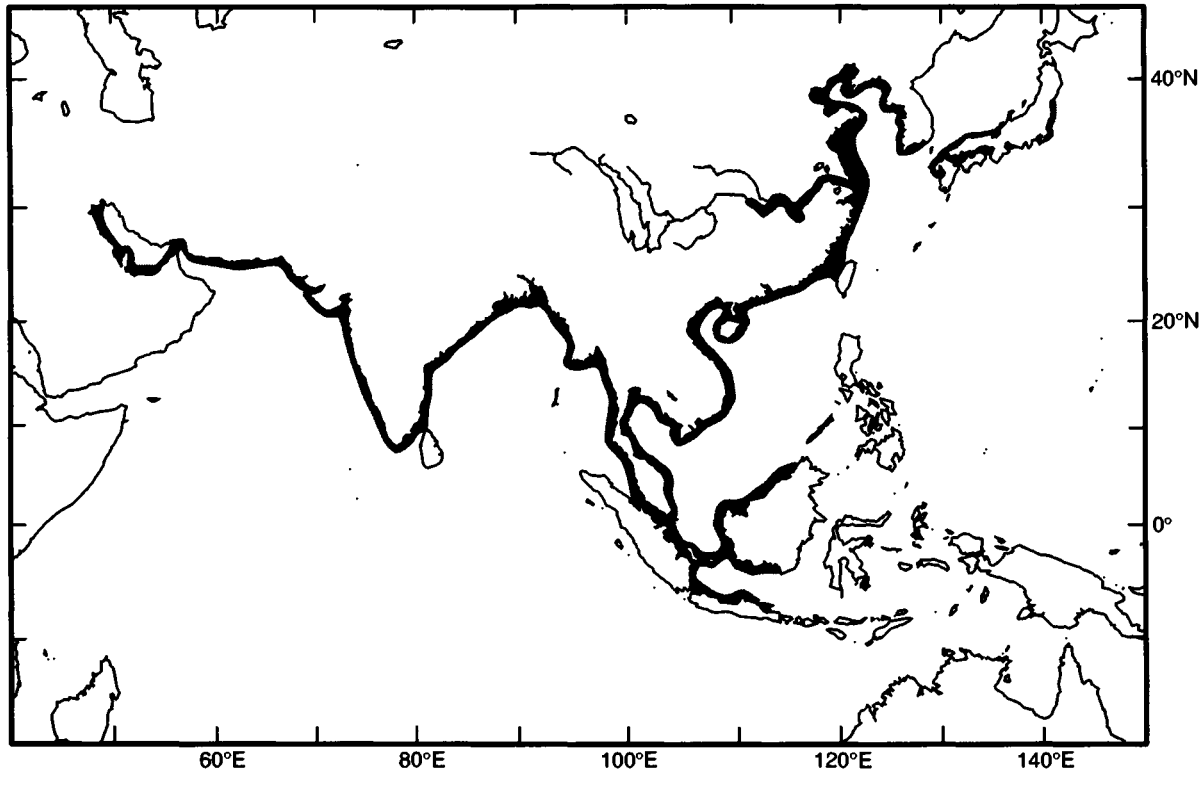

Figure 2 *Distributional range of the finless porpoise.*

of India, Indochina Peninsula, China, and Korea to northern Japan at the northern and eastern limit. The southernmost part of the range is the northern coast of Java.

III. Geographic Variation and Subspecies

The external and skull features vary geographically, and three subspecies (originally described as different species), are recognized. They are *Neophocaena phocaenoides phocaenoides* for the form in the Indian Ocean through the South China Sea, *N. p. asiaeorientalis* for the Yangtze River form, and *N. p. sunameri* for that in the East China Sea, Yellow Sea, and off the coast of Korea through Japan. Although the discrete border of each form has not been elucidated, that between *N. p. sunameri* and *N. p. phocaenoides* seems to be in the southern East China Sea, where both forms have been observed.

Five local populations are clearly identified in Japanese waters based on skull morphology and mtDNA variability. Similarly, finless porpoises are considered to live in relatively small isolated local populations in other areas.

IV. Ecology

Finless porpoises prefer the mangrove zone in tropical waters. They are also found in estuaries and large river systems such as the Indus, Brahmaputra, and Yangtze Rivers. In the Yangtze River, finless porpoises are found up to 1600 km from the sea. In Japan, the habitat of the finless porpoise is strictly defined by depth (<50 m), distance from the shore (<5 km), and sandy or soft bottom. However, other reports indicate that proximity to shore is not necessarily important in the shallow East China Sea (Reeves *et al.*, 1997).

Finless porpoises feed on various prey species from surface to bottom dwellers, including schooling fishes, squids, octopuses, shrimps and prawns, and they are considered to be opportunistic feeders. The only known predator aside from humans is the great white shark.

V. Behavior

Finless porpoises are observed year round in most localities, but seasonal fluctuation in density, suggesting some movements, has been reported in some areas.

Finless porpoises do not form large schools and are usually found in pairs. Kasuya (1999) concluded that a mother and calf or an adult pair is the basic social unit; the social structure seems to be undeveloped in this species. Usually, finless porpoises swim quietly and do not leap or make a splash. They tend to avoid vessels and do not bow ride, but they seem to be easy to observe in some areas, and commercial finless porpoise watching trips have begun in northern Kyushu, Japan.

VI. Morphology

The darkness and ontogenetic change of color pattern vary among subspecies. *N. p. phocaenoides* is born with lighter color and darkens with growth to be almost black as an adult (Parsons and Wang, 1998). However, neonates from Japan are black and lighten at 1 month after losing the fetal epidermis (Kasuya, 1999).

The dorsal ridge is also different among forms. *N. p. asiaeorientalis* and *N. p. sunameri* have a narrow and prominent ridge (a few centimeters in width), whereas the ridge of *N. p. phocaenoides* is wide and almost flat anteriorly (wider than 10 cm in adults). Horny tubercles are scattered on the ridge. Although they seem to be homologous to tubercles on the edge of the dorsal fin of other phocoenids, their function is not obvious. Some scientists have suggested that they function as an antislipping surface when mothers carry their calves on their back. It is more plausible that they serve as a sensory organ or organ for mutual contact, as many nerve endings occur in the tubercles (Kasuya, 1999).

VII. Life History

Finless porpoises grow to around 170 cm in length and 70 kg in weight, but animals over 200 cm and 100 kg have been reported. Size seems to be different geographically and generally larger in the northern population.

Information on reproduction is limited to that of porpoises from Japanese and Chinese waters. Animals from Kyushu live up to 25 years after sexual maturity at 4–9 years of age. The gestation period is estimated at around 11 months. The peak of the calving season is different among localities, i.e., April–May in the Yangtze River, May–June in the Seto Inland Sea and on the Pacific coast of Japan, and November–December in western Kyushu. Females are thought to calve every 2 years. The lactation period is estimated to be about 7 months, short as in other phocoenids.

VIII. Fossil Record

The only known fossil of *Neophocaena* is a skull raised from the bottom of the Seto Inland Sea, Japan. It is considered to be from the Late Pleistocene. There are conflicting views whether the finless porpoise is the most primitive or is derived of the phocoenids. A recent genetic study suggested that the species is the oldest lineage in the family.

IX. Interaction with Humans

Because of the nearshore habitat, the finless porpoise tends to be threatened by many human activities. Although there is no fishery that takes finless porpoises directly, incidental catches, mainly by gillnets, occur throughout the range. Habitat degradation by land reclamation and deforestation of mangrove area may be serious problems. Moreover, very high accumulation levels of toxic organochlorine and butyltin compounds have been reported from Japanese finless porpoises.

The distribution seems to be separated into relatively small local populations by unsuitable habitats of deep water or rocky bottoms. Such local populations are easily depleted, bringing about the decline of gene flow and genetic diversity of the populations.

Despite these concerns, our ability to measure the current status and population trend of the species is very limited. Rel-

atively reliable abundance estimates have been obtained for only three populations in Japan. Recent sighting and questionnaire surveys in the Seto Inland Sea, which is a major habitat of the finless porpoise in Japan, indicated a decrease in abundance of the species. It is evident that prompt and intensive research efforts on every aspect of life of the species is required.

Fin Whale

Balaenoptera physalus

ALEX AGUILAR
University of Barcelona, Spain

Fin whales were initially described by Frederik Martens in 1675 and Paul Dudley in 1725. From these descriptions, Linnaeus created his *Balaena physalus* in 1758, which was later designated by Lacépède as *Balaenoptera physalus*.

I. Taxonomy and Diagnostic Characters

The fin whale is very close to the other balaenopterids, particularly those congeneric, and shares with them the same chromosome number of $2n = 44$. It appears to be particularly close to the blue whale, from which it diverged between 3.5 and 5 million years ago, and with which several hybrids have been described. Although the hybridization rate between these two species has not been properly assessed, it may be in the range of one for every 500–1000 fin whales. At least in one case, a female hybrid was pregnant.

The fin whale is SEXUALLY DIMORPHIC, with females being about 5–10% longer than males. In the Southern Hemisphere, the average body length of adults is about 26 m for females and 25 m for males; in the Northern Hemisphere the corresponding lengths are 22.5 and 21 m. The fin whale is a slender balaenopterid, its maximum girth being between 40 and 50% of the total length. The rostrum is narrow, with a single, well-developed longitudinal ridge. BALEEN plates number 350–400 in each row and their maximum length is up to 70 cm. The dorsal fin is falcate and located at 75% of the total length; it is higher than that of blue whales, but lower than in sei whales (*B. borealis*) or Bryde's whales (*B. edeni*). The ventral grooves are numerous and extend from the chin to the umbilicus. The pigmentation of the cephalic region is strikingly asymmetrical: whereas the left side, both dorsally and ventrally, is dark slate, the right dorsal cephalic side is light gray and the right ventral side is white (Fig. 1). This asymmetry also affects baleen plates: those on the whole left side and the rear two-thirds of the right side are gray, whereas those on the front third of the right maxilla are yellowish. Particularly in adults, the skin of the flanks in the rear trunk is often covered by small round scars and stripes attributed to the attachment of lampreys and remoras. The white ventral region of whales inhabiting cold waters may have a yellowish layer produced by the infestation of diatoms.

II. Distribution and Geographical Variation

The fin whale is a cosmopolitan cetacean. It is found in most large water masses of the world, from the Equator to the polar regions (Fig. 2). However, in the most extreme latitudes it may be absent near the ice limit; thus, it has not been reported off Spitsbergen, Novaya Zemlya, or Franz Josef Land in the Northern Hemisphere or in the Weddell or Bellinghausen Seas in the Antarctic. It is also absent from the Black Sea and is very rare in the eastern Mediterranean, the Baltic Sea, the Persian Gulf, the Red Sea, and most equatorial regions. The largest concentrations are usually located in temperate and cold waters. Within these, fin whales are thought to segregate into independent breeding units, the identity of which is often a matter of discussion. Overall, fin whale density tends to be higher outside the continental slope than inside it.

Because the fin whale makes seasonal migrations (see later), which follow alternate schedules in each hemisphere, the northern and southern populations do not appear to come into contact. This has led to genetic isolation and, as a consequence, two forms, sometimes accepted as subspecies, are recognized: *B. physalus physalus* inhabiting the Northern Hemisphere and *B. physalus quoyi* in the Southern Hemisphere. In addition to the difference in body size mentioned earlier, the flippers of whales from the Northern Hemisphere are shorter and broader than those of their southern counterparts. Small variations in body proportions and coloration between fin whales from different locations in the Northern Hemisphere have also been described.

III. Ecology

The fin whale feeds on a wide variety of organisms, depending on availability; very likely, diet varies with season and locality. Preferred prey in the Northern Hemisphere seems to

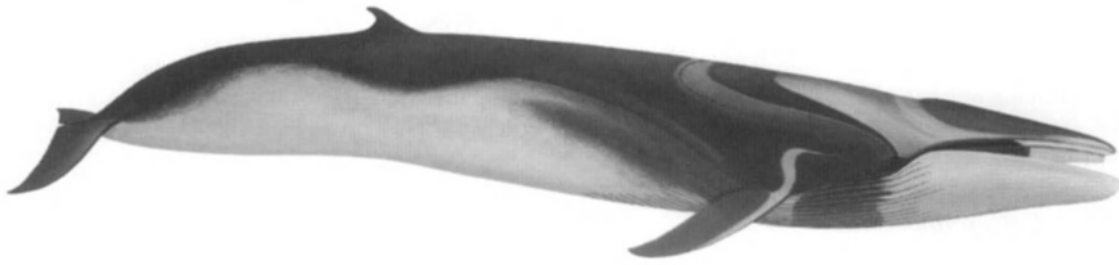

Figure 1 *Lateral view of the right side of the fin whale showing asymmetric coloration of the cephalic region. Pieter A. Folkers/Higher Porpoise DG.*

be KRILL composed of the euphausiid *Meganyctiphanes norvegica*, although other species of planktonic crustaceans (*Thysanoessa inermis*, *Calanus finmarchicus*), schooling fishes such as capelin (*Mallotus villosus*), herring (*Clupea harengus*), mackerel (*Scomber scombrus*), and blue whiting (*Micromesistius poutassou*), and even small squid are also consumed. In the Southern Hemisphere, diet is almost exclusively krill, mostly the euphausiid *Euphasia vallentini* but also other planktonic crustaceans such as *Euphasia superba*, *Parathemisto gaudichaudii*, or *Calanus tonsus* in smaller proportions. Like other balaenopterids, the fin whale feeds in summer, when an adult whale is estimated to consume up to 1 ton of euphausiids per day, and fasts in winter (see later).

Because the distribution range and the DIET of fin whales overlap with those of other balaenopterid whales, interspecific competition is likely to occur. This is especially likely in the case of the blue whale (*B. musculus*), which is often found forming mixed schools with fin whales. This association, together with the evolutionary proximity of the two species, makes blue fin hybrids relatively common (see earlier discussion).

Because they are large and swim fast, fin whales do not have significant predators, with the exception of the killer whale

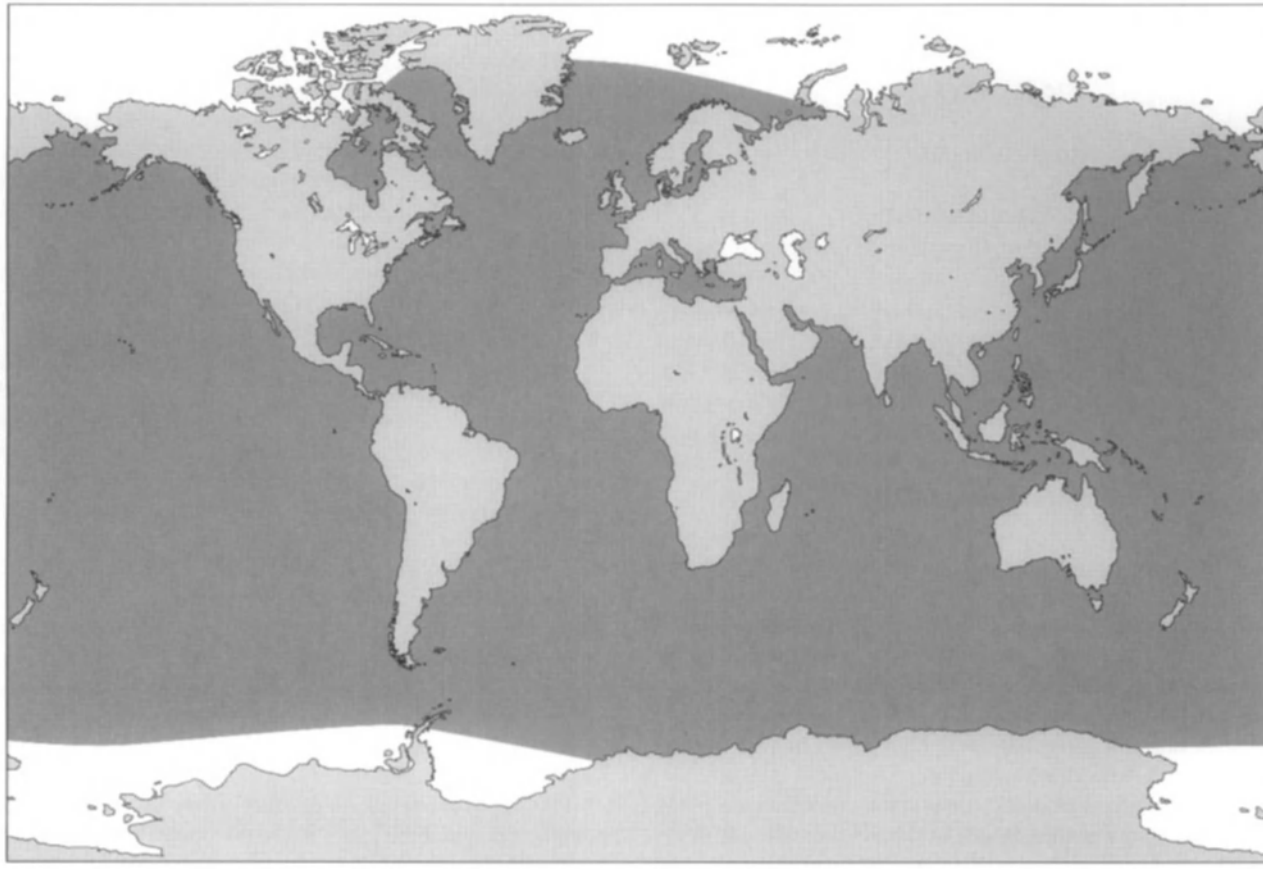

Figure 2 *Distribution of fin whales (dark shaded area).*

(*Orcinus orca*). In certain regions where this odontocete is abundant, signs of past attacks of killer whales can often be seen on the flippers, flukes, and flanks of fin whales.

IV. Behavior

In the Southern Hemisphere, fin whales engage in north–south seasonal migration, feeding in the summer and breeding and fasting in the winter. A similar latitudinal movement has been generally proposed for the Northern Hemisphere, although in many areas this pattern is not clear. For example, in the North Atlantic, although several summer grounds have been identified in medium to high latitudes (northern Morocco, Gibraltar Straits, northeastern Spain, Scotland, northern and western Norway, Newfoundland, the Faroe Islands, and Iceland), no definite wintering grounds are known. It has been suggested that in this ocean the latitudinal movements of the species are short due to the influence of the Gulf Stream, which would make the higher latitudes suitable as wintering grounds. An alternative explanation is that individuals that concentrate near the coast in the feeding season tend to disperse into open waters during the winter, therefore being more difficult to detect. Indeed, there is evidence that some whales remain in higher latitudes during the coldest months of the year. Also, fin whales may remain at lower latitudes year-round if food is available, as shown by the lack of seasonality of catches in the Gibraltar Straits (36°N).

The migration route apparently follows areas of low geomagnetic intensity and gradient and, similarly to other balaenopterids, not all components of the population move together. Pregnant females are usually the first to initiate the seasonal movement and are soon followed by adult males and resting females. Lactating females and juvenile individuals of both sexes are the last to migrate.

Compared to other large cetaceans, fin whales are relatively fast swimmers. Normal cruising speed is 5–8 knots but may increase up to 15 knots for short bursts. The SWIMMING is usually smooth, and BREACHING is very rare, except when the whale is harassed. Dives are limited to 100–200 m and usually last 3–10 min. The species is not gregarious and its only social bond appears to be that of cows with their nursing calves, a link that vanishes at weaning. School size is small; the fin whale usually swims single or in groups of two to seven, but transitory large aggregations may occur in highly productive areas.

The sounds of fin whales are simple and mostly consist of low-frequency moans and grunts and high-frequency pulses, apparently with a social function. Regional differences have been found between the Gulf of California and several Atlantic and Pacific Ocean regions. Fin whale moans are loud and can be heard for at least tens, probably hundreds of kilometers.

V. Anatomy

The body mass of adult individuals typically ranges from 40 to 50 metric tons in the Northern Hemisphere and from 60 to 80 metric tons in the Southern Hemisphere. A general formula for estimating body weight (W) from body length (L) is $W = 0.0015\ L^{3.46}$. If the girth at the level of the navel (G) is available, a more precise formula is $W = 0.0469\ G^{1.23}L^{1.45}$.

The relative mass of body tissues varies seasonally according to nutritive condition. Average mass relative to total body weight is 18.4 ± 3.3% for blubber, 45.3 ± 4.4% for muscle, 15.5 ± 2.4% for bone, and 9.8 ± 2.1% for viscera. The liver is large, usually weighing 230–600 kg. The heart is similar in relative size to that of terrestrial mammals but larger than in odontocetes and weighs 130–290 kg. Kidneys are large and weigh 50–110 kg. The right lung is about 10% heavier than the left, with each one weighing 100–160 kg. The spleen weighs 2–7 kg and sometimes has accessory bodies of smaller size.

The rostrum of the fin whale is sharply pointed, without the lateral curvature typical of blue whales. The zygomatic width is about 50–55% of the condylo-premaxillary length; the width of the rostrum at midlength is approximately 30–35% of its basal width, and the whole skull measures about 20–25% of the total body length. Ribs usually number 16 pairs, with the last pair being smaller and not attached to the vertebral column. The number of vertebrae ranges from 60 to 63, with a typical formula of C, 7; D, 15 (16); L, 14 (13–16); and Ca, 25 (24–27). The sternum is broad and variable in shape, usually in the form of a cross or a trefoil. As in other balaenopterids, scapulae are fan shaped with a convex upper margin. Flippers lack a third digit. The typical digit formula is I, 3–4; II, 6; IV, 5–6, and V, 3–4.

VI. Life History

Growth during the postnatal period is rapid, and 95% of the maximum body size is reached when whales are 9–13 years old. Males grow faster than females but stop growing sooner. Physical maturity, as determined by the degree of ossification of the vertebral column, is reached at about the age of 25 in both sexes. Longevity has not been determined precisely, but individuals of up to 80–90 years old are known.

Reproductive behavior is poorly known, but taking into account the reduced mass of their testes, their mating system probably relies on competition between males for monopolizing females and reduced sperm competition. In the Northern Hemisphere, sexual maturity is attained at an approximate length of 17.5 m in males and 18.5 m in females; corresponding figures for the Southern Hemisphere are 19 m in males and 20 m in females. These lengths typically correspond to an age of about 6–7 years in males and 7–8 years in females.

In the Northern Hemisphere, the mating period is December–February, whereas in the Southern Hemisphere it is May–July. Gestation lasts about 11 months, at the end of which a calf about 6–7 m long and weighing 1–1.5 metric tons is born. Only one calf is usually produced per pregnancy, although twinning has been reported. Weaning occurs when the calf is about 6–7 months old and measures 11–13 m long.

Weaning is followed by a 6-month resting period, at the end of which mating takes place. Therefore, the reproductive cycle is completed in about 2 years. Gross pregnancy rates (number of pregnant females in relation to that of adult females) are typically estimated at 38–49%.

VII. Interactions with Humans

Second in size after the blue whale, the fin whale has been much sought after by whalers; it was one of the target species

when modern operations started in the early 1870s, and its exploitation continued until the moratorium on commercial whaling came into force in 1985. At the beginning it was taken in large numbers off north Norway, where catches were recorded as early as 1876; overexploited, this population soon decreased in abundance and the whaling stations had to close in 1904 because of insufficient catches. The fishery then extended to other areas of the North Atlantic and, from there, to the Antarctic, the Pacific, and the Indian Oceans. Captures peaked during the period of 1935–1970, when the fin whale formed the largest part of worldwide catches, with about 30,000 individuals taken annually. In most localities, such a level of exploitation far exceeded the sustainable yield of the populations and one after another the operations collapsed.

Fortunately, however, management measures introduced by the INTERNATIONAL WHALING COMMISSION in the 1960s and 1970s prevented populations from being reduced to such a low level as its predecessor in the whale exploitation history, the blue whale. In the 1980s, when the moratorium was approved, large-scale commercial fishing of fin whales was only taking place off Iceland and northwestern Spain. Both operations ceased, the first in 1985 and the second in 1989. Today, the species is only exploited in West Greenland, where about 10–15 individuals are taken per year by the "aboriginal" whale fishery.

Apart from exploitation, no other significant conservation threats have been identified. Incidental catches in fishing gear are uncommon, and although collisions of fin whales with vessels sometime occur, they are limited to a few restricted locations where boat traffic is very intense. Moreover, given the oceanic distribution of fin whales and their lower position in the food chain, overfishing and pollution do not have a significant impact. Overall levels of contaminants are low or extremely low as compared to other marine mammals. In the North Atlantic and the Mediterranean Sea, where the highest levels of organochlorine compounds have been detected, average concentrations of DDTs in blubber ranged from 0.2 to 12 ppm and those of PCBs ranged from 0.5 to 8 ppm. In fin whales off Chile and South Africa, concentrations were much lower, often below analytical detection limits. A number of heavy metals have also been found in tissues of fin whales, although usually at low concentrations. Levels in the muscle of North Atlantic individuals are in the range of 10–90 ppb of zinc, 0.2–2 ppb of copper, 0.1–2 ppb of cadmium, and 2–3 ppm of mercury.

After the discontinuation of whaling, populations have either stopped their decline or slowly recovered from losses. Estimated population numbers in recent years are 24,000 in the Antarctic south of 30°S, 15,600 off east Greenland and Iceland, 1000 off West Greenland, 1500 off north Norway, 350 of west Norway, 700 off the Faroe Islands, 4500 off northwest Spain, 7500 in the eastern temperate North Atlantic, 3500 in the western Mediterranean, 10,800 off Nova Scotia, Newfoundland, and Labrador, and 800–900 in California coastal waters.

Fisheries, Interference with

DAGMAR FERTL
Minerals Management Service, U.S. Department of the Interior, New Orleans, Louisiana

Most marine mammal interactions with fisheries may at some time be construed as interference. Interactions may be characterized as biological (ecological) or operational (IUCN, 1981). "Biological" interactions include competition between marine mammals and fisheries for the same

prey species, as well as the transmission of parasites between marine mammals and commercial fishery resources. "Operational" interactions are those in which marine mammals take fish from fishing operations, disturb fishing, or damage fishing gear. In some areas, marine mammals are seen as a nuisance, but tolerated as part of the risks involved in fishing. In other locales, marine mammals may be detested as "pests and robbers" and there is a great demand for solutions to be found.

I. Biological Interactions

Marine mammals, particular pinnipeds, may act as intermediate hosts for certain parasites and transmit these to commercial fish species. The most readily recognized example is the codworm (*Porrocaecum decipiens*). The gray seal (*Halichoerus grypus*) is a host to this parasitic nematode, whose larvae infest the muscle tissue of many fish, particularly cod (*Gadus morhua*). The result is reduced marketability of the fish.

Ecological interactions may result directly when a marine mammal consumes one or more species targeted by commercial fisheries or indirectly if the prey serves as food for other fish species that may be exploited commercially. When commercial fish stocks are in decline and fishing interests seem threatened, conflicts with marine mammals often arise.

II. Operational Interactions

A. Depredation

Evidence from some fisheries shows that cetaceans, pinnipeds, and sirenians are attracted to fishing gear and attempt to remove bait and catches. Gear likely to have the most interactions with (and interference from) marine mammals are purse seines, trawls, gill nets, traps, and hooks and lines. Fishing operations concentrate food of interest, decreasing energy expenditure associated with foraging by marine mammals. Nursing females may especially benefit from this feeding technique. Fishing operations may perhaps permit marine mammals to select food of higher caloric value. Some food niches, not otherwise available to some marine mammals, may be opened up, making prey easier to access that might be normally more difficult (e.g., because of depth required to dive).

Feeding in association with fisheries is likely a learned behavior, with increasingly more individual marine mammals seeking out fishing gear for an easy meal. It has also been suggested that this feeding behavior is passed from generation to generation by observation and participation.

Marine mammals may cause abrasions and wounds to fish during unsuccessful capture attempts or while "playing" with fish during fishing operations, even when they are satiated. Fish that are damaged may not be useful to fishermen. It is not known how the number of injured fish relates to the total number killed.

Marine mammals may take portions of fish or the entire fish, rendering them unsaleable. Most estimates of loss vary between 1 and 8% of the total catch. There are exceptions, such as in some longline and salmon gill net fisheries. Various species of cetaceans [e.g., killer whale (*Orcinus orca*), false killer whale (*Pseudorca crassidens*), sperm whale) and pinnipeds [e.g., South American sea lion (*Otaria flavescens*), California sea lion (*Zalophus californianus*)] depredate longline-caught fish. Flesh may be torn from hooked fishes or fish may be removed completely as lines are hauled back to the fishing vessel. Estimates of lost catch per attack range from 25 to 100% of the catch (Yano and Dahleim, 1995). Depredation rates may be related to low availability of fish in the area at the time or presence of particular individual marine mammals causing problems.

B. Disturbance

When the mere presence of a marine mammal(s) can cause catches to be reduced and time wasted, fishing operations are disturbed. Cetaceans and pinnipeds may disturb fishing activity by causing fish shoals to disperse or sound (dive rapidly) and thus escape being trapped by the net. Once a marine mammal has located fishing gear, fishermen might have to move to another site or the marine mammal would continue to take substantial amounts of the catch. This disturbance results in cost to the fishermen because they have to move and relocate to fish.

Fishing operations may be impeded in other ways. Seals may be caught in the fish pump (used to remove fish from the net) and die. Fishing operations may be disrupted if live seals are brought abroad in nets or otherwise make their way onto fishing boats, especially if they manage to get below deck. Crew injuries may result from direct interactions with seals, including people being bitten and nylon burns or cut fingers from tug-of-war between a fisherman and a seal.

C. Gear Damage

When a marine mammal attempts to remove fishery catches entangled in a net's mesh or hooked on a line, holes may be torn or hooks removed. Marine mammals may become incidentally entangled during these encounters; netting and rope may be lost in trying to free live or dead animals. Damaged gear may not fish as efficiently, and a loss of catch may result. Further, repairs may be costly, and the time spent repairing fishing gear may be significant in a seasonal fishery where most of the catch is taken in a period of a few weeks.

There are numerous examples of marine mammals (particularly pinnipeds) damaging fishing gear; there are more reports of damage to static gear (e.g., fish traps, gill nets, longlines) than moving gear (e.g., trawls, purse seines). Gear damage may also result from accidental collision with fishing gear. For example, humpback whales (*Megaptera novaeangliae*) in Newfoundland in the 1970s caused several hundred thousand dollars of damage annually as a result of colliding with cod traps while feeding on capelein (*Mallosus villosus*).

Cetaceans and pinnipeds are often blamed for damage to gear or catches that should actually sometimes be attributed to other predators. For example, bottlenose dolphins (*Tursiops truncatus*) often are blamed for damage to trawl and gill nets when sharks are the real culprits. Although South African fur seals (*Arctocephalus australis*) are blamed for taking lobsters from traps, clear evidence shows that octopus are to blame. Birds may also be seen taking bait off hooks as they are cast into the water during line fishing.

III. Pinniped Interference with Fisheries

Seals, sea lions, and fur seals take caught fish from nets, hooks, trawls, seines (Fig. 1), or traps and attack fish that are

Figure 1 *California sea lions often move into a purse seine net to start feeding before the net is pursed and continue to do so until all the fish are pumped aboard the fishing vessel. Courtesy of Jon Stern.*

being raised in aquaculture pens. The impact of pinnipeds on fisheries is of particular concern through depredation and gear damage during gill netting on the west coasts of North America, Japan, Britain, Scandinavia, and Chile; through depredation, net damage, and disturbance at fish farms in Britain and Chile; and depredation from trawls, depredation and gear loss from hand lines, and disturbance of purse seining in South Africa (Wickens, 1995). Estimates of the consumption by seals from fishing operations in South Africa show it to be a minimal percentage of fishery catches and a small proportion of the total predation by seals. Preliminary calculations of overall economic losses resulting from these seals' interference show this to be small (0.3%) in comparison with the wholesale value of the catches.

Some pinnipeds converge on areas where anadromous fish stocks aggregate or where the movements of fish are constrained naturally or artificially (bottleneck or "choke points" where salmonids aggregate in response to human-made structures or natural river physiography, such as fish ladders or below falls, respectively). The most thoroughly studied pinniped/salmonid conflict is California sea lion predation on winter steelhead (*Oncorhynchus mykiss*) at Washington State's Ballard Locks. The severe decline in salmon is considered primarily a direct result of human activities (Fraker and Mate, 1999); however, much concern has been voiced that the expanding populations of seals and sea lions may be causing a further decline (or impeding the recovery) of various salmon runs in the Pacific Northwest.

IV. Cetacean Interference with Fisheries

Like pinnipeds, cetaceans interact with a diversity of fisheries. Cetaceans may feed on a fishery's target species, such as killer whales feeding on sablefish (black cod *Anoplopoma fimbria*) in the North Pacific longline fishery, or on fish that are ancillary to the catch, as in the case of bottlenose dolphins feeding on bycatch from trawl fisheries for shrimp and prawn (Fig. 2). Whales and dolphins may interfere with traps or pots, preying on target species, as well as bait. Long-finned pilot whales (*Globicephala melas*) in Newfoundland frequent traps to remove the target species squid. Bottlenose dolphins in Belize have been observed retrieving fish from local, homemade fish traps, whereas this species in the Indian River Lagoon in Florida interacts with the crab pot fishery, apparently to steal bait fish. Bottlenose dolphins and "blackfish" (e.g., killer whales, false killer whales, pilot whales) are notorious fish stealers, and there are widespread reports of catch and gear damage by these species (Fig. 3).

V. Sirenian Interference with Fisheries

Fishermen in Jamaica and Sierra Leone have complained about damage caused to gill nets by "net-robbing" West Indian and West African manatees (*Trichechus manatus* and *T. senegalensis*), respectively. Manatees have been described as stripping the flesh off fish entangled in gill nets and leaving the bones.

VI. Toward Solutions

Fishermen use various means to deter marine mammals in an attempt to safeguard their catches and gear. Lethal methods have been attempted, including shooting at or killing the marine mammal with a variety of objects and methods, sometimes involving poison. Sometimes these practices are illegal. Seals have been persecuted much more intensely than cetaceans.

Culls or control programs for marine mammals have been carried out with the expectation that they will increase fishery yields by reducing marine mammal predation on fish stocks (Earle, 1996). One of the best-known culls occurred at Iki Island in Japan between 1976 and 1982. Thousands of bottlenose dolphins and hundreds of Pacific white-sided dolphins

Figure 2 *Bottlenose dolphins pluck fish from the meshes of shrimp trawl nets. Mesh from nets may be damaged in the process. Courtesy of Dagmar C. Fertl.*

Figure 3 *Killer whales depredate longline fisheries around the world. This killer whale is feeding on a longline-caught bluenose* (Hyperoglyphe antarchia) *in New Zealand. Courtesy of Ingrid Visser.*

(*Lagenorhynchus obliquidens*) false killer whales, and Risso's dolphins (*Grampus griseus*) were killed in response to declines in catches of yellowtail (*Seriola dorsalis*). The annual Canadian commercial hunt for harp seals (*Pagophilus groenlandicus*) and hooded seals (*Cystophora cristata*) in the Gulf of St. Lawrence and Newfoundland is conducted to boost the recovery of overfished cod stocks. Scientific evaluation of a proposal to cull marine mammals for the purpose of benefiting commercial fisheries needs to consider the complexity of ecological interactions among the marine mammal population(s), the relevant fish stocks, and the fishery/fisheries that catch them.

Lethal methods have not been found to be a consistently effective means of keeping pinnipeds from interacting with fishing operations. The idea is that if problems are caused by a few rogue seals, then removal of these animals should eliminate the problem. However, this method removes individuals that are then often replaced by others.

A diversity of nonlethal methods has been attempted (Jefferson and Curry, 1996). At the most basic level, fishermen throw stones or bait to distract the predator. Other methods used include firing gunshots, using explosives (such as firecrackers and seal bombs), biological sounds (vocalizations from a predator, killer whale), gear modifications (such as mechanical and electronic sound generators), vessel chase, tactile harassment (e.g., rubber bullets), visual signals, and taste aversion (baiting fish using a chemical to induce vomiting). Acoustic "harassment" devices (AHDs) have been widely used to attempt to reduce depredation on fish, especially by pinnipeds (Reeves *et al.*, 1996). Pinnipeds are difficult to deter by acoustic methods, and the acoustic signal of the AHDs over time was a "dinner bell" effect, alerting animals to the presence of a fish pen or trap. New high-intensity AHDs appear to be effective, but have a greater potential for causing hearing damage, as well as affecting nontarget species. In some cases, a problem may be eased by changing the location of the fishing effort. The most successful mitigation measures appear to be changes to fishing gears or fishing methods where a particular change may reduce or exclude problems, thereby resulting in a permanent solution. Implementation of antipredator cages around fish farms, physical barriers at the entrance of fish ladders, and the change to synthetic twine in gill nets are some examples.

Capture and relocation of "problem" pinnipeds has proven ineffective, with the animals returning to the problem area. California sea lions have been captured at the Ballard Locks and placed in temporary captivity and released after the steelhead run. This proved ineffective in the long term, as did permanent captivity, which eliminates the "problem" sea lions without having to kill them but is limited by the availability of facilities that can hold the sea lions and the costs involved in capturing and holding the animals.

Past efforts have been unsuccessful in finding effective, long-term, nonlethal approaches to eliminating or reducing marine mammal–fishery conflicts. Some nonlethal deterrence measures appear to be effective initially or effective on "new" animals, but become ineffective over time or when used on "new" animals in the presence of "repeat" animals that do not react to deterrence. Further research on the development of new technologies and techniques is needed.

Fishing Industry, Effects of

SIMON NORTHRIDGE
University of St. Andrews, Scotland, United Kingdom

The fishing industry probably represents the single area of human activity that has the most profound effects on marine mammals. These effects can be categorized broadly as "operational effects" and "biological effects."

Operational effects include the accidental capture of marine mammals in fishing gear, a problem that has brought more than one marine mammal population to the brink of extinction. Although accidental capture usually results in the death of the animal concerned, there are also instances where marine mammals are injured or affected in some way during fishing operations so that their survival probability or reproductive potential is compromised. Not all operational interactions have a negative effect on marine mammals. In some cases the effect of the fishing operations may be positive for the marine mammal where, for example, they feed on discarded fish or take fish that have been caught before these can be retrieved onto the fishing vessel. In a few cases there are even mutually beneficial collaborative efforts between fishermen and marine mammals, with marine mammals assisting in fish capture and being rewarded with a portion of the catch.

Biological effects encompass all the consequences of the large-scale removal of animal biomass from the marine ecosystem through fishing activities, including, although not limited to, possible competition for resources between fisheries and marine mammals. Competitive interactions can be direct or indirect. Direct competition occurs where the mammal and the fishery are both taking the same kind of fish. Indirect competition includes situations where the fishery and the marine mammal population are taking two different types of fish, but where the removal of one of these fish influences the availability of the other through some competitive or predatory link. Indirect interactions need not be competitive, and sometimes the effect of the fishing industry may be to increase the abundance of marine mammal prey items through indirect ecological interactions. Sometimes fisheries may physically alter a habitat and so change the composition and abundance of the fish community to the detriment or advantage of marine mammals and other predators.

I. Operational Effects

Operational effects cover interactions between fisheries and marine mammals that relate to the mechanical process of fishing. Several fisheries have well-documented problems with unwanted entrapment of marine mammals. In some cases the numbers of animals involved are large enough to seriously endanger the marine mammal populations concerned, and in one or two instances, species have been brought to the verge of extinction through such accidental effects. Examples considered cover gill net fisheries, pelagic trawls, and purse seine fisheries.

A. Gill Net Fisheries

Gill nets are a widely used fishing gear with a long history of use in many parts of the world. Their use has become more widespread since the 1950s or 1960s with the introduction of nylon as a netting material during the 1950s. They represent a fuel-efficient means of fishing and, when set on the seabed, provide a fishing method that can be used to exploit areas of rough ground that cannot be fished easily by towed gear. When used in surface waters, they are usually left to drift with the wind and tide and are effective in targeting dispersed fish schools. They are usually left to fish unattended, and fishing times may range from a few hours to several weeks, but 24 hours would be a typical soak time. It has been suggested that in contrast to the traditional nets that were made of cotton and other natural fibres, the use of stronger nylon twines has contributed to an increased rate of marine mammal ENTANGLEMENT. This, coupled with a dramatic increase in their usage since the 1950s, has led to some serious conservation and animal welfare problems with respect to marine mammals.

Small cetaceans, such as porpoises (Phocoenidae), and some species of seals seem especially prone to becoming entangled in gill nets. In some instances, this does not present a conservation problem. In Britain, for example, gray seals (*Halichoerus grypus*) are frequently caught and drowned accidentally in gill net and tangle net fisheries (see Fig. 1). In a seal tagging program run by the Sea Mammal Research Unit in the North Sea, over 20,000 gray seals have been tagged soon after birth since the 1950s. Returns of tags by fishermen indicate that at least 10% of known subsequent mortalities are due to net entanglement, and at least 1.5% of all pups tagged were recovered dead in fishing nets. Tag loss over the months and years after tagging and failure to return tags from entangled seals are two reasons why this latter figure must be an underestimate of total mortality rates due to entanglement. Despite such mortality in fishing gear, gray seal numbers are increasing in British waters.

In other cases, accidental catches in fishing gear can lead to conservation problems. Concerns have been expressed over the numbers of harbor porpoises (*Phocoena phocoena*) that become entangled in gill nets throughout much of this species' range. Numbers are known to have declined in some areas such as the Baltic Sea, possibly as a result of entanglements. In other areas, including the North Sea, the Celtic Sea, and the Gulf of Maine, the total numbers of porpoises entangled an-

Figure 1 *Young gray seal caught and drowned in a skate tangle net set in the English North Sea. Photo by Dave Sanderson, SMRU.*

nually are thought to be unsustainable and are likely to result in long-term population declines.

A close relative of the harbor porpoise, the vaquita (*Phocoena sinus*), is threatened with extinction through accidental catches in gill nets. In this case, the species has a restricted range, in the upper Gulf of California in Mexico, where there are large numbers of small boats using gill nets and tangle nets to catch a wide variety of fishes. Although the population may number no more than about 600, one estimate suggests that at least 40 animals drown in gill nets every year. This is clearly an unsustainable rate of mortality and this species' future therefore seems bleak.

The North Atlantic right whale (*Eubalaena glacialis*), once one of the more commonly seen whales in the North Atlantic, is now reduced to a population of around 300 animals in that area. The population is declining and it is estimated that at current rates it will be extinct within 200 years. Most of this population migrate along the eastern seaboard of the United States every year, where they too are vulnerable to entanglement in gill nets and also in lobster pot lines. Lobster pots are usually set in "strings" of several pots in a line, with each end of the string marked by a surface-floating buoy attached by a line to the pot string on the seabed. Although only three right whale deaths have been attributed directly to this cause since 1970, evidence of entanglement-related scars on live animals has been identified in around 60% of the population. It has been suggested that some entangled whales die and are dragged to the seabed without being recovered, others may suffer injuries that lead to subsequent death by other causes, while at least two right whales, encumbered with fishing gear, have been fatally wounded in collisions with ships. These high levels of entanglement may therefore be a major factor in the decline in this population of right whales, even though the vast majority of the entanglements are not immediately fatal.

Marine mammal entanglements in gill nets may occur for a variety of possible reasons. Some people maintain that the animals do not detect the netting and swim into it before realizing it is there. It may be that the animals do detect the netting but that they do not recognize it as something dangerous and attempt to swim through it as though it were some natural obstacle, such as seaweed. Another possibility is that the animals are fully aware of the netting, and the danger it poses, but they simply make mistakes and become entangled while feeding close to the net due to inattention.

There has been much attention given to means of reducing the numbers of marine mammals that become caught in gill nets and tangle nets because of the conservation problems that such entanglements represent. So far, the only effective means of reducing bycatch that has been found is the use of pingers. Pingers are small battery-powered devices that emit a brief high-pitched noise every few seconds. They are attached to the float line or lead line of the gill net and are of similar size and shape as a net float so as to avoid tangling the net when it is being set or hauled. They are effective in reducing the entanglement rates of several marine mammal species in gill nets, although exactly why they work is not clear. They have been developed in collaboration with the fishing industry and are currently being used in several major gill net fisheries around the world.

B. Pelagic Trawls

Pelagic trawling is another fishing method that has increased enormously in recent decades. Although trawling dates back for more than a century, this was initially performed with low-opening nets dragged along the seabed. As various aspects of technology have improved, so trawling techniques have been refined, and trawls have been used to catch fish above the seabed and even near the surface of the water. The development in the 1950s of acoustic fish finders and net sounders that enable the skipper to control the position of the net with respect to that of a fish school has been a key technological development.

Initially, during the 1950s, pelagic trawls were used to catch fish like herring that form dense schools. Typical nets might have had an opening of around 2000 m^2, perhaps 50 m wide and 40 m high. Since then, both nets and trawlers have grown in size, as other pelagic fish species have been targeted, some of which may form much more dispersed schools. Net openings at least 10 times this are now common, with horizontal and vertical openings of up to 200 m. There are numerous records of marine mammals becoming caught in pelagic trawls, sometimes in large enough numbers to present a conservation problem, although the nature and scale of the problem remain obscure in most fishing areas.

Hooker's sea lion (*Phocarctos hookeri*) is endemic to the sub-Antarctic islands of New Zealand, around which a pelagic trawl fishery for squid developed in the 1980s. Observations of fishing activity between 1988 and 1995 suggested annual mortalities of between 20 and 140 Hooker's sea lions, at a rate of about 1 animal every 340 trawl tows. The total population of this species was only around 13,000 animals in the mid-1990s,

and the accidental catches were therefore considered significant. There is currently a quota system in operation in this fishery to limit accidental catches.

Dolphins have also been reported caught in pelagic trawl fisheries in several areas, including the United States, Europe, and New Zealand. The capture of dolphins in pelagic trawls appears to be very variable, depending on the area and probably the type of trawl being used. In one U.S. pair-trawl fishery common bottlenose (*Tursiops truncatus*), short-beaked common (*Delphinus delphis*), and Risso's dolphins (*Grampus griseus*) were observed accidentally caught in an average of one in every 5 trawl tows, although this fishery has subsequently been closed. In one New Zealand midwater trawl fishery, rates of common and bottlenose dolphin catches averaged about one animal in every 9 trawl tows observed. In European Atlantic waters, one study recorded common and Atlantic white-sided dolphins (*Lagenorhynchus acutus*) caught in sea bass (*Dicentrarchus labrax*) and albacore tuna (*Thunnus alalunga*) pelagic trawl fisheries at a rate of one in every 10 to one in every 15 trawl tows. In other pelagic trawl fisheries for anchovy (*Engraulus encrasicolus*), pilchard (*Sardina pilchardus*), and mackerel (*Scomber scombrus*) in the same area, no dolphin deaths were recorded.

The reasons why some pelagic trawl fisheries have relatively high levels of accidental dolphin catches and others have low or zero levels are not yet clear. It is probable that such factors as the dimensions of the net, the towing speed and duration, and the foraging activity of dolphins around the nets are important. There are several accounts of dolphins taking advantage of trawling activity by FEEDING on fish escaping through the meshes of the trawl. Such behavior may increase chances of dolphin entanglement. The trend toward increasing net sizes may also have increased the numbers of dolphins caught in some pelagic trawl fisheries in the past few decades, but these interactions remain relatively poorly investigated.

C. Tuna Purse Seine Fisheries

As with gill nets and pelagic trawls, technical innovations during the 1950s enabled the development and expansion of purse seine fisheries around the world. Purse seines are used to catch pelagic fish and work by first encircling a school of fish with a long net, hanging from the surface down to depths sometimes of several hundred meters. The bottom edge of the net can be pursed so as to prevent any escape under the netting once it has been set in a circle. The major technical innovations that allowed this fishery to develop globally were the introduction of nylon as a netting material, enabling much larger and stronger nets to be constructed, and the development of the power block, with which large amounts of netting could be hoisted up out of the water.

American fishermen working in the eastern tropical Pacific Ocean during the late 1950s worked out a way of using dolphin schools in conjunction with purse seine nets to catch yellowfin tuna (*Thunnus albacares*). They discovered that tuna would aggregate under dolphin schools, even if the dolphins were chased. This meant that by using speedboats to corral dolphins they could exploit this behavioral characteristic of the fish to round up tuna schools that would otherwise be invisible below the surface. By corralling a dolphin school and setting a purse seine net around it, a school of tuna would normally also be encircled. The dolphins were not intentionally killed in this activity, but many died as nets were being hauled in and fish were being brought on board. The scale of the fishery meant that in some years hundreds of thousands of dolphins drowned as a result of this fishing activity.

The eastern spinner dolphin stock (*Stenella longirostris orientalis*) was depleted to 44% of its original (pre-1959) level, whereas an offshore pantropical spotted dolphin stock (*Stenella attenuata*) was reduced to about 20% of its pre-exploitation level. From the 1970s onward, in the face of public concerns over the issue, the fishery developed and implemented means of reducing this toll. By encouraging the dolphins out of the net before trying to remove the fish, annual mortalities were reduced to a few thousand per year.

D. Other Types of Fishing Activity

Although tuna purse seines, pelagic trawls, and gill nets have been highlighted as fishing methods where operational interactions have been a cause for concern, many other fishing methods can, under the wrong circumstances, have an impact on marine mammals. Marine mammals have been reported ensnared in the most unlikely types of fishing gear, including the lobster pot lines referred to earlier. In most cases, such interactions occur rarely and the number of animals involved is so small that there is no cause for concern over unsustainable levels of catch. Occasionally, however, circumstances may conspire to cause a problem. At other times the use of certain types of fishing gear may even result in a benefit to the marine mammals and cause a loss to the fishery.

In several parts of the world cetaceans, often killer whales (*Orcinus orca*) and false killer whales (*Pseudorca crassidens*), have been reported to remove fish from hooks during long line fishing operations. This can make fishing in certain areas with long lines unprofitable, and many methods have been tried to eliminate such behavior. There has been remarkably little success reported in trying to prevent such predation, and sometimes the boats involved have had to switch gear or move to other areas.

Normally, interactions between marine mammals and hook and line fisheries have few negative impacts on the marine mammals. In the case of the baiji or Chinese river dolphin (*Lipotes vexillifer*), however, the situation is different. The baiji is endemic to the Yangtze River system in China; the population probably numbers no more than a hundred and is in decline. One of the most important causes of mortality is due to animals becoming ensnared in "rolling hooks." This type of fishing involves using many sharp unbaited hooks on a line set on the bottom of the river to snag bottom-dwelling fish. Dolphins foraging near such hooks sometimes become snagged too, occasionally causing death. Over 50% of recovered river dolphin carcasses had died as a result of such entanglements. The small population size and the restricted distribution of this species mean that even uncommon occurrences such as these can have a highly significant impact on a species.

Other types of fishery where marine mammals actively benefit from fishing activities include trawling, purse seining, and

lobster potting. Several species, including bottlenose and white-beaked dolphins (*Lagenorhynchus albirostris*), gray seals, and South African fur seals (*Arctocephalus pusillus*), have been reported to remove fish from fishing gear. Dolphins typically take undersized fish as they come through the cod end of a trawl. Fur seals swim into purse seine nets by climbing over the float line once a school of fish has been encircled and make a meal of the trapped fish. Gray seals have been observed removing bait from baited lobster pots. There are numerous other examples of marine mammals taking advantage of fishing activities in similar ways, often taking marketable fish, which may provoke considerable resentment on the part of the fishing crews.

In a few places in the world, including Burma (Myanmar), Mauritania, and Brazil, fishermen and dolphins have learned to collaborate in the capture of fish, usually by dolphins driving fish toward fishermen waiting with nets. Some of the catch is then given back to the dolphins as a reward.

II. Biological Effects

The more widespread but less well-understood interactions between fisheries and marine mammals are ecosystem-level effects, where fisheries may cause fundamental changes to the species composition of the marine environment.

Every year the fishing industry removes about over 90 million ton of fish and other marine organisms from the world's oceans. Another 20–30 million ton of unwanted animal biomass may be caught but discarded prior to landing every year. It has been suggested that fisheries may account for 8% of the global primary productivity of the oceans, and in some of the more heavily exploited areas as much as 35% of local primary productivity may be required to sustain fishery catch levels. It is clear that such levels of fishing activity are likely to have profound effects on marine ecosystems, especially on the top predators, such as marine mammals, as fish populations are reduced and restructured on a very large scale. In theory, therefore, fisheries may compete with marine mammals by depleting their food.

There is of course another side to this concern. Whereas fisheries may cause a depletion of the food resource for marine mammals, marine mammals are often accused by fishery bodies of consuming large amounts of fish, thereby reducing the amount of food available for people to eat. As a result of this latter concern, in some parts of the world there are frequent calls for marine mammals to be culled as unwanted competitors.

In both cases, however, it has proved extremely difficult to demonstrate any clear competitive interaction between marine mammals and fisheries. This is mainly because of the complexities of the marine ecosystem, which make it very hard to predict how changes in one fish stock will effect either their predators or their prey. Some brief examples will illustrate this point.

A. Increased Food Availability

The North Sea and adjacent areas are among the most heavily fished sea areas of the world, with annual landings of all species of around 2.5 million metric tons. One of the most numerous marine mammals in this region is the gray seal (*Halichoerus grypus*), which feeds on a range of fish species, including Atlantic cod, haddock, whiting, saithe, sandeels, sole, plaice, Atlantic herring, and sprats (*Gadus morhua, Melanogrammus aeglefinus, Merlangius merlangus, Pollachius virens, Ammodytes* spp., *Solea solea, Pleuronectes platessa, Clupea harengus*, and *Sprattus sprattus*). Fisheries also target all of these species, and most of the fish stocks concerned are designated as fully exploited or overexploited. Despite these facts, the gray seal population has expanded at an apparently steady rate over several decades during which fishing pressure in the region has been intense, to reach 108,500 animals in 1994. There are at least two good reasons for this apparent paradox.

First, the most important food of the gray seal is the sand eel (or "sandlance" in the United States). The sand eel fishery takes over 1 million metric tons of sand eels per year and is the single largest fishery (in terms of the amount landed) in the North Sea. Despite fishing pressure, sand eels are still extremely abundant and appear to have increased in abundance since the 1950s. The proposed reason for this is that sand eel numbers have increased in response to massive declines in the abundance of Atlantic herring and mackerel as a result of intense herring and mackerel fishing, especially in the 1960s and 1970s. Although sand eels are an oily fish (and well suited to the seal's diet), unlike herring they are not considered useful for human consumption, and those that are fished are generally reduced to fishmeal. This means that they are a low-value species and have so far escaped the intense levels of fishing pressure applied to others stocks. Being a fairly sedentary species that spends much of its time buried in the sand, they also appear to be well suited to gray seal foraging habits.

Alongside this, although gray seals and fisheries consume other more marketable species in common, gray seals typically consume smaller-sized individuals of around 15 to 20 cm in length, whereas commercial fisheries generally concentrate on fish of 30 cm and larger. As commercial fishing pressure intensifies, larger fish have become scarcer, but smaller fish of the same species may not be affected (or at least not until there are two few large fish left to generate sufficient eggs to replenish the stock). Indeed, in many of the commercially useful gadid (cod family) fishes, small fish are consumed in large numbers by bigger fish of the same species. A reduction of the numbers of larger fish may actually boost the numbers of smaller fish.

It would seem that although gray seals are feeding in an area that is very heavily fished because they exploit a niche that is not directly in competition with fisheries, they are able to thrive. Indeed their population expansion may have been assisted by fishery-induced changes to the species and size structure of the system they inhabit.

B. Decreased Food Availability

Although pinniped numbers may have increased with increasing fishing pressure in one area, this is by no means the norm. In the Gulf of Alaska and the Bering Sea, several pinniped populations have undergone dramatic declines over periods when fishing activity has been increasing. The Pribilof population of Northern fur seals (*Callorhinus ursinus*) declined from 1.25 million animals in 1974 to around 877,000 animals in 1983. At around the same time, harbor seal (*Phoca vitulina richardii*) numbers in the Gulf of Alaska and southeastern

Bering Sea declined, with one major haul-out site at Tugidak Island recording an 85% reduction in numbers between 1976 and 1988. Populations of both of these species now seem to be stable or increasing, but numbers of Steller sea lions (*Eumatopias jubatus*) in western Alaska started to decline in the 1970s and numbers are still declining. Declines of up to 80% have been recorded in some areas.

The reasons for the declines of these three species over much the same time period are not known, but there is general agreement that food availability, especially for younger animals, seems to be a key issue. For all of these three species, Alaska pollock (*Theragra chalcogramma*) is an important prey item. Alaska pollock is also the target of one of the largest single species fisheries in the world. The fishery for Alaska pollock increased greatly during the 1970s with over a million tons being landed annually from the eastern Bering Sea alone throughout most of the 1980s and 1990s.

An obvious explanation is that the fishery has deprived the pinnipeds of their food. A closer inspection, however, reveals that the situation is more complex. Overall, the pollock biomass has stayed remarkably buoyant throughout this time period. Numbers of pollock, especially numbers of the larger or older age classes that are the target of the fishery, have not declined until relatively recently. Smaller pollock are consumed by the pinnipeds and are not targeted by the fishery, but are cannibalized by the larger fish. Numbers of smaller pollock have declined. Furthermore, for Steller sea lions at least, pollock does not appear to be a favored food item. In other parts of the Steller sea lion's range, such as southeastern Alaska, where the population is not in decline, pollock makes a smaller contribution to the diet, after oily fish such as herring.

It may be that the three pinniped species have all suffered from some change in the relative abundance of their preferred diet items. It has not yet been possible to determine whether such ecosystem level changes have been the result of long-term oscillations in oceanographic conditions or whether the pollock fishery has in some way altered the abundance of the pinniped's preferred prey items through the cascading effects of restructuring the pollock population.

C. Other Effects

The effects of fisheries on marine mammals do not necessarily have to be mediated through changes in their food supply. Changes to predation on marine mammals could also arise through the effects of fishing. On the Atlantic coast of Canada, also a heavily fished region, gray seal numbers have also been increasing steadily for more than two decades for unknown reasons. One suggested reason has been that fisheries may have greatly reduced the number of large sharks in coastal waters of Atlantic Canada, and as gray seals are known to be subject to predation by certain sharks, such a reduction might be one of the factors contributing to the increase in gray seal numbers.

Conversely, recent increases in predation on sea otters (*Enhydra lutris*) in the Aleutian Islands have been attributed to behavior changes in killer whales in the region, some of which now seem to be preying more heavily on sea otters than in previous decades. The possibility has been raised that this change in behavior has been caused by a decline in other more favored food items, such as sea lions. Such declines could, as has been suggested earlier, be at least partly due to the effects of fishing on sea lion food items.

All of these hypotheses demonstrate the complex ways in which fishery-induced changes to the marine ecosystem may affect marine mammals, although none has yet proved testable. In almost all cases where some form of competition is perceived, any closer scrutiny of the situation reveals that the complex predatory interrelations of the marine ecosystem make it extremely difficult to predict the results of any proposed management action. The extent to which the fishing industry competes with marine mammals is therefore still very much an open question.

Fluking

Bernd Würsig
Texas A&M University, Galveston

Fluking is the act of a whale, dolphin, or porpoise (very rarely, a manatee or dugong) raising its tail, or flukes, above the surface of the water during the beginning of a dive. Usually, whales fluke when diving steeply in water

deeper than at least two of their own lengths, although fluking can also occur during shallow submergences. There is great variability in fluking behavior by species: humpback (*Megaptera novaeangliae*) and sperm whales (*Physeter macrocephalus*) almost always fluke (Fig. 1) or "fluke out" during the dive; minke whales (*Balaenoptera acutorostrata*) and fin whales (*B. physalus*) do so rarely (Leatherwood and Reeves, 1983). Right (*Eubalaena* spp.), bowhead (*Balaena mysticetus*), and gray whales (*Eschrichtius robustus*) are known to vary the amount and type of fluking depending on whether they are feeding near the surface (no fluking), at moderate depth (occasional fluking), or at depths of 60 m or more ("always" fluking). These species also generally fluke on MIGRATION, during the final dive after a series of "near-surface" dives between respirations. Even smaller toothed whales, such as bottlenose dolphins (*Tursiops truncatus*) and pilot whales (*Globicephala* spp.), at times fluke during deep or at least steeply angled dives (Carwardine *et al.*, 1998).

Large whales fluke as a part of bending their bodies as they angle downward, and the fluke out becomes a natural extension of the animal "rolling" forward and down. In smaller delphinids, however, fluking probably has a distinct advantage during the initiation of the dive: the tail and tailstock (or caudal peduncle) held above the surface provide in-air weight to the body and help propel it downward. The effect of this action is quite similar to human skin divers kicking their feet and legs out of water while bending at the waist as they initiate a dive.

Bowhead whales about to dive steeply often stretch their entire bodies so that head and flukes are at the surface, and the belly or midpart of the body hangs much further below. The spine, in other words, is curved downward. Such a "pre-dive flex" takes about 2 sec and occurs just before the last blow before a dive. The pre-dive flex is almost always predictive of a fluke-out dive, and it and the flukes out indicate steep, generally deep, diving for feeding or migrating (Würsig and Clark, 1993).

While fluking is the term properly reserved for the smooth lifting of the flukes above water during the initial stages of a dive, whales and dolphins lift their flukes out of water in other ways as well. A common form is tail slapping (often termed lobtailing when performed by large whales), consisting of forcefully and often repeatedly slapping the tail onto the surface of the water. This action makes a loud in-air and underwater percussive sound and may well be used to communicate with conspecifics. Tail slapping and breaching often beget more such aerial activities by others, especially when wind and sea states rise; these observations indicate COMMUNICATION and perhaps a social facilitation function of all animals of the area coordinating their states of alertness. Tail slapping may also be used to repel danger as an agonistic display against a conspecific nearby and even to help contain and corral prey near the surface. In humpback whales, tail slapping can be a sign of frustration or anger, as it and breaches are often performed after one male appears to lose during an interactive battle with another one. It is believed that similar evidence of "frustration" has been seen in bowhead, right, and gray whales apparently repulsed by a female. Repeated tail slapping can also be performed "for the fun of it" or as a form of play; in spinner

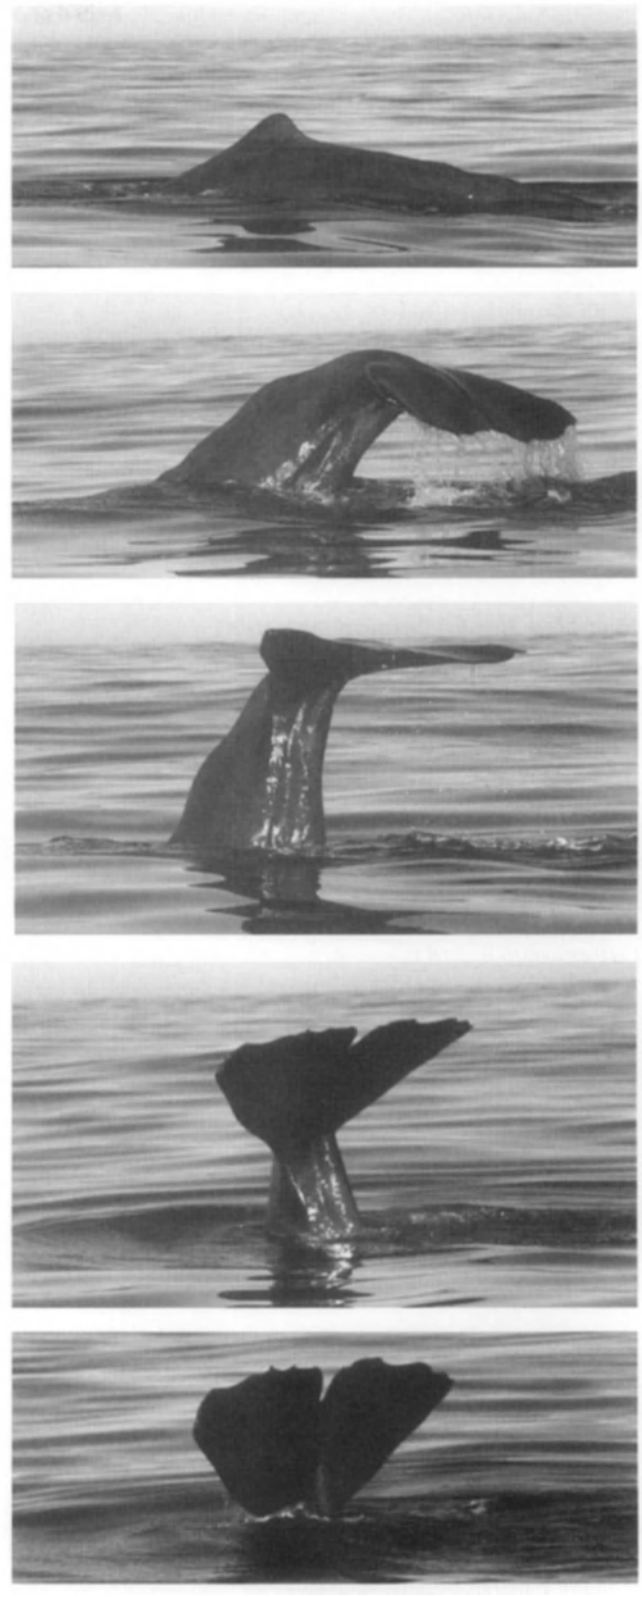

Figure 1 *A sperm whale (New Zealand) in the act of diving and fluking. Initiation of the dive (top), as the back curves just before lifting the flukes. This fluking sequence shows a particularly high "fluke out" before a fully vertical descent.*

(*Stenella longirostris*), dusky (*Lagenorhynchus obscurus*), and probably other dolphins, this appears to be its main function.

A final form of "flukes out" consists of raising the flukes above water and keeping them there for some time. Dolphins wave their flukes about for at times over 1 min, "headstanding" in apparent play; right, bowhead, and gray whales do so for at times over 10 min. It has been suggested that southern right whales are purposefully sailing by holding their large tails in air during a stiff breeze, but this recreational use of their tails has not been substantiated (Payne, 1995).

Flukes of whales and dolphins have thin trailing edges (similar to the trailing edges of dorsal fins) and are therefore easily tattered or marked by conspecific interactions, getting entangled in lines, or touching other objects. These marks make individual recognition of the flukes possible in those species that habitually fluke out, and fluke-based photographic identification is being practiced for sperm, humpback, and gray whales. In the latter two species, an additional bonus is variable spot or mottling patterns on the flukes (Hammond *et al.*, 1990).

Folklore and Legends

ROCHELLE CONSTANTINE
University of Auckland, New Zealand

Folklore and legends are usually traditional stories popularly regarded as the telling of historical events. When in the form of myths, they often involve some form of the supernatural. They have been with us for thousands of years and, because of this, folklore and legends form the basis of many religious beliefs, value systems, and the way we perceive our place in the world and our interaction with other animals. Man has long revered whales and dolphins in legends. For thousands of years they have been aligned with the gods, mythologized, and celebrated in art.

I. Ancient Greece

Some of the earliest legends about dolphins were told in Greek mythology, where it was believed the sun god Apollo assumed the form of a dolphin when he founded his oracle at Delphi on the edge of Mount Parnassus. The ancient Greeks also believed Orion was carried into the sky riding on the back of a dolphin and was gifted three stars by the gods. This constellation is now known as Orion's Belt.

Many cultures, both ancient and recent, revered dolphins and believed them to be messengers from the gods. The pre-Hellenic Cretans appeared to have honored dolphins, and the ancient Greek, Oppian (ca. A.D. 180) wrote of godly intervention in the dolphins' move to the sea. It was believed that by the devising of Dionysus, the Greek god of wine, dolphins exchanged their life on land for life at sea and took on the form of fishes. Even though they changed form, it was believed that they retained the righteous spirit of man and, because of this, they preserved their human thoughts and deeds. Oppian also wrote of dolphins stranding themselves to die so mortals could bury them and thereby remember the dolphin's gentle friendship. This was seen as an example of how magnificent dolphins were.

The close alignment with man meant ancient Greeks held dolphins in extremely high regard and that killing a dolphin was tantamount to killing a person. Both crimes were punishable by death.

II. Romans

Pliny the Elder (A.D. 23–79), a Roman philosopher, told the story of a peasant boy in the Mediterranean Sea who developed a relationship with a solitary dolphin he named Simo. The legend tells of a boy who fed a dolphin and, in return, the dolphin gave him rides across the bay on its back. The boy became ill and died and, according to local knowledge, the dolphin returned to their meeting place for many days until it was believed that it died of a broken heart. Many of the Roman legends involved close human/dolphin contact and may seem fanciful, but in more recent times these bonds between solitary dolphins and humans have been well documented.

III. Art

Drawings carved into rocks in northern Norway of killer whales and other local animals are the earliest known art work portraying dolphins. These drawings have been estimated at 9000 years old. The most detailed and colorful ancient art work was done by the ancient Greek and Minoan (Crete 3000–1500 B.C.) people. Dolphins were portrayed on frescoes, mosaic floors, coins, vases, and in sculpture. One of the earliest known pieces is a dolphin fresco painted ca. 1600 B.C. on the wall of the queen's bathroom in the Minoan palace of Knossos. The Dionysus cup dated 540 B.C. shows the Greek wine god with dolphins and grapes. Coins portraying dolphins have been found in Syracuse, Greece, ca. 480 B.C. and the Romans also had dolphin coins in 2nd-century B.C.

IV. Whales

It appears in many legends that the great whales were not necessarily held in such high regard as the dolphins. Whales

were typically described as monsters of the sea, their great size to be feared by all. Oppian (ca. A.D. 180) told of the hunt of a whale; its monstrous size and unapproachable limbs a terrible sight to behold. In biblical times, the story of Jonah and the whale was well known, and it is popular even today. The story tells of Jonah who fled from the lord by boat to Tarshish. When the ship was underway, the lord caused a great storm. In fear of their lives, Jonah asked the mariners to cast him into the sea so the lord would again make the sea calm and spare the mariners lives. Once Jonah was in the sea, however, the lord prepared a "great fish" to swallow him. He was in the belly of the whale for 3 days and 3 nights where he prayed and vowed salvation to the lord. Upon his vow the lord spoke to the whale and it vomited Jonah onto dry land and spared his life. Although today we know that it is unlikely that this event truly occurred, the story displayed the power of the lord and what he was capable of doing to those who defied him.

In his 1851 novel "Moby Dick," Herman Melville described a white sperm whale (*Physeter macrocephalus*) of uncommon magnitude, capable of great ferocity, cunning, and malice. Melville's novel summarized the fears of Yankee whalers that the tables would be turned and the whale would become the attacker.

Not all folklore portrays whales as fearsome beasts. Maori folklore of the Ngati Porou people tells of their ancestors being carried safely across the Pacific to New Zealand on the back of a whale. The Ngai Tahu people consider the sperm whales off the coast of the South Island as taonga (treasures). If a whale strands, prayers are said in order to return its spirit to Tangaroa, the Maori god of the sea. After this, the lower jawbone is removed for ceremonial carving and placement on the marae (the tribes' traditional meeting grounds).

The north Alaska Inuit people have for over 1000 years relied on whale products for their survival. As with many traditional HUNTING societies, ceremonies accompany the hunt that assure good luck, and many hunters take charms or amulets to ensure their luck and safety. Some believe the skull of the dead whale must be returned to the sea in order to assure the immortality and reincarnation of the whale, thereby protecting the future hunting success.

V. Legends and Folklore around the World

A. Haida

The Haida people of northwestern North America tell of an evil ocean people who used killer whales (*Orcinus orca*) as canoes. The Haida turned a chief into a killer whale and they believe that this whale now protects them from attacks by the ocean people.

B. Tlingit

The Tlingit (pronounced "Kling-kit") people of southeastern Alaska immortalize killer whales in their beliefs and folklore. Images of killer whales appear in many of their masks, carvings, totems, and blankets. At gatherings, the Tlingit tell stories, including one about the origin of killer whales. They believe a man from the Seal people carved many killer whales from wood but only the one carved from yellow cedar would swim. The legend says he carved many more from cedar and they swam up the inlet where he taught them how to hunt and what to hunt for. He also taught them not to hurt people. The Tlingit in return do not hunt killer whales and they believe that because of this the killer whales look after them (Fig. 1).

C. Australian Aborigines

On Mornington Island in the Gulf of Carpentaria, northern Australia, a tribe of Aborigines have been in direct communication with Indian Ocean bottlenose dolphins (*Tursiops aduncus*) for thousands of years. They have a medicine man who calls the dolphins and "speaks" to them telepathically. By these communications he assures that the tribes' fortunes and happiness are maintained.

D. Amazonians

Many people who live on the banks of the Amazon River believe that river dolphins or botos (*Inia geoffrensis*) have the ability to transform themselves into handsome young men in order to woo women during fiestas and times of ceremony. So strong is this belief that some children are believed to have been fathered by these dolphins.

E. Japan

A Japanese legend tells of a gigantic whale who challenges a sea slug to a race after boasting that he is the greatest animal in the sea. The sea slug accepts and arranges for his friends to wait at different beaches along the chosen course. On the day of the race, the whale surges ahead, but when he arrives at the first beach he is astonished to find the sea slug already there. So he challenges it to another race, only to have the sea slug win again. This happens many times until the whale admits defeat. This legend is analogous to the European legend of the tortoise and the hare but shows the Japanese peoples close relation to the sea and its inhabitants and their use in teaching moral lessons.

Perhaps such legends and folklore serve the purpose of helping people understand their past or to help society learn

Figure 1 *Killer whale images on the front of a Tlingit house. Photograph courtesy of Alaska State Library.*

valuable lessons. In many societies today we revere whales and dolphins, and this will continue to develop our folklore into the future.

Forensic Genetics

C. SCOTT BAKER AND GINA M. LENTO
University of Auckland, New Zealand

Molecular genetics provides a powerful new tool for the CONSERVATION and management of marine mammals: the forensic identification of products derived from hunting, strandings, and fisheries bycatch. Such products include soft tissue such as meat, organs, BLUBBER, skin, and blood, as well as teeth, bone, baleen, and hair. Although the species origins of these products may be impossible to determine on the basis of appearance, they contain DNA that can be sequenced and compared to sequences from known specimens. With a complete library of reference sequences, a product of unknown origin can be attributed in most cases to 1 of the (approximately) 80 cetacean species or 40 pinniped species or subspecies. If a comprehensive archive of tissue is maintained as part of a regulated hunt, it is possible to trace the origins of a product to a specific individual.

The molecular methods used in marine mammal forensic genetics have their origins in efforts to isolate and amplify DNA from ancient biological material (Pääbo, 1988). With the advent of the polymerase chain reaction (PCR) and "universal" primers (Kocher *et al.*, 1989), DNA can now be recovered from almost any biological source, even products that have been preserved, cooked, or canned. The interpretation of DNA sequences for the identification of species and geographic origins, however, is also dependent on basic research in species-level phylogenetic relationships and on the genetic structure of populations (Baker and Palumbi, 1995). The application of forensic genetics to marine mammals has, in turn, highlighted inadequacies in the basic taxonomy of cetaceans and pinnipeds and the recognition or definition of subspecies and management units (i.e., "stocks") below the species level (see later).

The forensic use of molecular genetic methods is of particular interest to the INTERNATIONAL WHALING COMMISSION (IWC), as it attempts to develop a revised management scheme for the regulation of any future commercial whaling, and to the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), as it attempts to implement a verifiable system for controlling trade in cetacean products. Progress in the molecular monitoring of commercial markets in whale products is described later as an example of this application. Other applications of forensic genetics to marine mammals include identifying strandings and fisheries bycatch, particularly for poorly described species such as beaked whales (Dalebout *et al.*, 1998; Henshaw *et al.*, 1997), and monitoring of trade in pinniped penises marketed as aphrodisiacs (Malik *et al.*, 1997). These methods are finding similar applications in the conservation and management of other taxa, most notably the HUNTING and bycatch of turtles (Bowen, 1995) and international trade in caviar (DeSalle and Birstein, 1996).

I. Phylogenetic Identification

Species-level identification of marine mammals has relied primarily on the phylogenetic reconstruction of DNA sequences from the control region or cytochrome *b* gene of the mitochondrial (mt) genome. In general, mtDNA offers two important advantages over traditional genetic markers such as allozymes. First, because of its maternal inheritance and absence of recombination, the phylogenetic relationship of mtDNA sequences reflects the history of maternal lineages within a population or species. (If hybridization is encountered, nuclear markers are required to identify the paternal species; see later.) Second, all else being equal, the effective population size of mtDNA genomes is one-fourth that of autosomal nuclear genes and its rate of random genetic drift is proportionately greater. This results in more rapid differentiation of mtDNA lineages among populations, compared to nuclear genes, and consequently greater sensitivity in the detection of recent historical demographic or speciation events. The ability to detect population differentiation is also enhanced by the rapid pace of mtDNA evolution, which is generally estimated to be 5 to 10 times faster than nuclear coding DNA in most species of mammals. The control region of the mtDNA does not code for a protein or RNA and, in the absence of these constraints, accumulates mutational substitutions more rapidly than other regions. For this reason, it has become the marker of choice for most studies of the population structure of cetaceans and pinnipeds. The cytochrome *b* gene, a protein region of the mtDNA, has also been used widely in species-level systematics and, in some cases, for the population structure of marine mammals (Lento *et al.*, 1997). Because of the large number of reference sequences available on public databases such as GenBank and EMBL, both loci have been used for species-level identification of marine mammals.

The basic steps involved in the phylogenetic identification of an unknown specimen or product are illustrated in Fig. 1. First, mtDNA is extracted from the product in question, such as a flensed piece of skin and blubber from a commercial market. Second, a fragment of the mtDNA control region is amplified from the product via PCR: a cyclic, *in vitro* enzymatic reaction

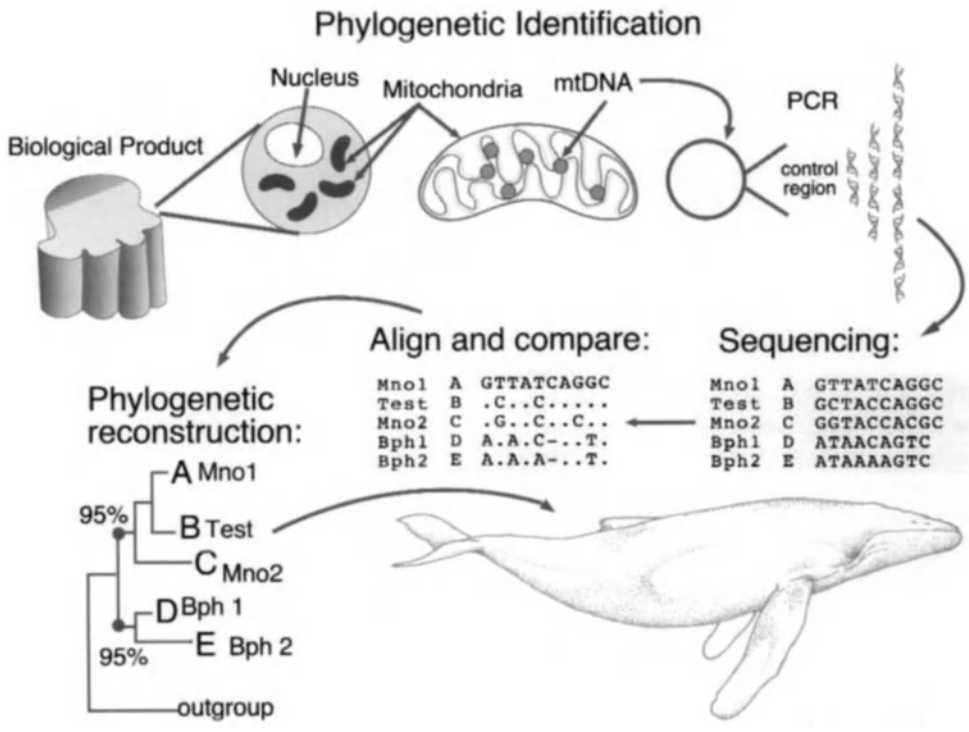

Figure 1 *The basic steps involved in the phylogenetic identification of a whale product using nucleotide sequences amplified by PCR from the mtDNA control region.*

that results in the exponential replication of a small targeted fragment of DNA (usually less than 1000 bp). Third, the exact nucleotide sequence of the amplified fragment is determined using a dideoxy-terminator sequencing reaction, followed by electrophoresis through an acrylamide gel. In many laboratories, this step is now automated with a computer-assisted, laser scanner. Fourth, the sequence of the product, now referred to as the "test sequence," is aligned to and compared with the sequences from reference samples. Finally, the sequence from the product is grouped, by phylogenetic reconstruction, with the most closely related reference sequences. The reconstruction is usually represented as a "tree," with closely related sequences forming neighboring branches. This allows a hierarchical comparison to establish, first, the suborder and family derivation using a small number of reference sequences from a large number of species. A close relationship or match with a "reference" sequence provides evidence for identification of the species origin of the product. One or more "outgroups" (i.e., distantly related species) are used to protect against a misclassification error. The strength of support for an identification or phylogenetic grouping is evaluated by "bootstrap" resampling of sequence data. The relative support for a grouping or branch in the tree is shown as the percentage agreement from a large number (>500) of bootstrap simulations.

As a conservative approach to forensic identification, a species identification should be considered "confirmed" only if the test sequence is "nested" within the range of type sequences for a given species. This is necessary because the molecular systematics of some marine mammals, particularly cetaceans, are not fully described (see later). If a test sequence is intermediate between two groups of reference sequences, rather than nested within one or the other, it could be a related species or subspecies not included in the reference database.

When a large set of reference sequences is available from the range of a single species, it is possible to use "intraspecific" variation to evaluate the geographic origin of a sample. In many cases, the MANAGEMENT of marine mammals is based on geographic populations or "stocks" (Dizon *et al.*, 1992). Catch quotas and limits of incidental mortality from fisheries bycatch are usually set according to such stock definitions, as well as according to species. Hunting may be allowed in an abundant stock but prohibited in another stock of the same species that is depleted from past exploitation. However, the ability to identify or estimate the stock origins of a specimen or product is determined by the genetic distinctiveness of the recognized stocks, as well as by the comprehensiveness of the reference samples. For some (but not all) species of baleen whales and a few pinnipeds, it is possible to identify the origin of a product to oceanic population and to geographic stock within oceans (see later).

An alternative to the phylogenetic identification of an unknown specimen or product is individual identification by DNA "fingerprinting" or "profiling" using nuclear markers. This is only possible for the control of whale products originating from a regulated hunt or bycatch. As in human forensic genetics, a combination of highly variable nuclear markers can be used to establish individual identity with high probability (or to exclude identity with certainty). The DNA profiles of each individual

whale can be stored on a searchable electronic database, forming a "register" of all products intended for the market. If the register is comprehensive (fully diagnostic), a match with a market product would confirm the legality of the product. A product that did not have a match in the register would be illegal. Further genetic investigation would be required to determine the species and geographic origin of illegal products.

II. "Portable Polymerase Chain Reaction"

In some cases, the application of forensic genetics to international conservation problems has involved an additional technical step required by international law. Under the requirements of the CITES, it is illegal to transport native products derived from most marine mammals without both importation and exportation permits from the respective countries of origin and destination. The processing of such permits is a lengthy affair in many countries, and for politically sensitive requests either nation can deny a permit, effectively terminating the research. However, CITES regulations do not apply to "synthetic" DNA created during amplification by PCR, assuming that all "native" product has been removed (Jones, 1994). To comply with these regulations, it has been necessary to assemble a portable PCR laboratory and conduct the initial PCR amplifications from whale products on site in the Japan and South Korea (Baker and Palumbi, 1994). Once the amplified DNA was isolated from the native product, it could be transported internationally for sequencing and final analysis. In this way, the "portable PCR" has become an important tool for international conservation genetics.

III. Monitoring Commercial Markets in Whale, Dolphin, and Porpoise Products

In recognition of historic patterns of overexploitation, the IWC voted in 1982 to impose a global moratorium on commercial whaling. Although the moratorium took effect in 1986, whaling never actually stopped. IWC member nations continue to hunt some species of whales for scientific research or for aboriginal and subsistence use. Whales killed for scientific research can legally be sold to domestic consumers and traded to other member nations of the IWC, thereby sustaining a commercial market for meat, skin, blubber, and other whale products. Small cetaceans are also hunted or taken as fisheries bycatch and sold for consumption in many parts of the world. Although the IWC regulates only hunting of large whales, international trade in all cetaceans is subject to CITES. When some species are protected by an international prohibition against hunting or trade but similar species are not, it is crucial to identify the origin of products that are actually sold in retail markets.

In an effort to monitor the sale and trade of cetaceans products, molecular methods have been used to identify the species and geographic derivation of products sold in two countries with active commercial markets: Japan and the Republic of (South) Korea. Whale meat is widely available in retail markets of both countries despite the international moratorium on commercial whaling. In 1995, high-quality whale meat sold for up to $30/kg in Korea and $460/kg in Japan (Chan *et al.*, 1995). Japan sustains a legal market for whale products by killing several hundred minke whales in the Southern Hemisphere and 100 minke whales in the North Pacific Ocean each year under an exemption to the moratorium for scientific research. South Korea has no program for scientific hunting but reports a substantial fisheries bycatch of cetaceans each year, including up to 128 minke whales from coastal waters (Mills *et al.*, 1997). It is assumed that products from this unregulated incidental mortality are sold in local markets, but their international trade is prohibited by CITES.

IV. Species, Stock, and Individual Identification

At least 11 independent reports have been published or formally presented to the IWC documenting the molecular genetic identification of nearly 1000 products from commercial markets (Dizon *et al.*, 2000). About 50% of all products were identified as Antarctic minke whale (*Balaenoptera bonaerensis*), the target of scientific hunting by Japan in the Antarctic. About 20% were identified as North Pacific minke whale (*Balaenoptera acutorostrata scammoni*), the target of Japanese scientific hunting in the North Pacific. The remainder were found to be small cetaceans (including porpoises, family Phocoenidae; and a variety of dolphins, family Delphinidae), beaked whales (family Ziphiidae), sperm whales (family Physeteridae/Kogiidae), and other protected baleen whales. The latter group included fin (*B. physalus*), blue (*B. musculus*) or blue/fin hybrids, Bryde's (*B. edeni*), sei (*B. borealis*), and humpback whales (*Megaptera novaeangliae*). A few products sold as "whale" were found to be sheep or horse.

Detailed comparisons of mtDNA sequences have provided information on the stock derivation of some commercial products. For example, the North Pacific minke whale forms at least two stocks with marked genetic differences (Goto and Pastene, 1997): the "J" stock found in the Sea of Japan/East Sea and the "O" stock found in the North Pacific to the east of Japan. Although the "O" stock is subject to legal scientific hunting by Japan and is reported to be relatively abundant, the "J" stock was depleted by commercial hunting before 1986 and is considered a "protection stock" by the IWC. Using molecular methods, market surveys from 1993 to 1999 showed that a large proportion of products from Korea and a substantial proportion from Japan were derived from the protected "J" stock (Baker *et al.*, 2000). Although one source of these products is fisheries bycatch, the possibility of illegal hunting of this stock cannot be excluded.

The detailed analysis of a Japanese market product identified initially as a blue whale shows the importance of maintaining archived tissue from a regulated hunt for verification of trade records. The mtDNA sequence for this product matched closely with the published sequence of a blue/fin hybrid killed during a scientific whaling program by Iceland. Because mtDNA is inherited maternally, it cannot, by itself, identify a product as a hybrid. Subsequent comparison of variable nuclear DNA markers from tissue archived during the Icelandic

whaling program confirmed that this product was derived from this hybrid individual (Cipriano and Palumbi, 1999).

V. Taxonomic Uncertainties

A final, and critical, consideration in using phylogenetic methods for species identification is the assumption that the taxonomy of the group in question is complete. If this basic biological information is lacking, questions about the adequacy of a reference database and the genetic distinctiveness of recognized species cannot be answered. Surprisingly, taxonomic uncertainties remain a problem among the baleen whales, even though this group includes only a handful of widely distributed, formerly abundant species. For example, two products purchased on Korean markets in 1994 grouped with reference sequences from both the sei and Bryde's whales but did not group closely with either of these two recognized species (Baker *et al.*, 1996). As a result, it seems likely that these products originated from an unrecognized species or subspecies of Bryde's whales. To be fully confident in all identifications, worldwide surveys are needed for nuclear and mtDNA variation among each of the 11 recognized species of baleen whales, particularly the Bryde's/sei complex and minke whales. Such surveys would provide the basis for an objective evaluation of current distinctions among species, subspecies, morphological forms, and populations or stocks.

Fossil Record

R. Ewan Fordyce
University of Otago, Dunedin, New Zealand

The fossil record of marine mammals extends back more than 50 million (M) years (Fig. 1). Hundreds of species are known, with Cetacea numerically and taxonomically dominant and globally widespread, followed by Sirenia in mainly warm settings. Seals, sea lions, and relatives (Pinnipedia) are locally abundant, but other marine carnivores (otters, amphicyonids) are rare and a marine sloth unique. Fossils occur in marine strata from nearshore to deep-ocean settings and, occasionally, freshwater habitats. Remains vary from near-complete skeletons through skulls and teeth to single and usually undiagnostic bones. The taxonomic framework, although not always firm, is adequate to review the diversity and spatiotemporal distribution of fossil marine mammals. Standard zoological techniques are used in taxonomy, classification, and analysis of function, whereas routine geological techniques are used to date fossils in terms of relative and absolute time scales and to interpret sedimentary environments. The fossil record

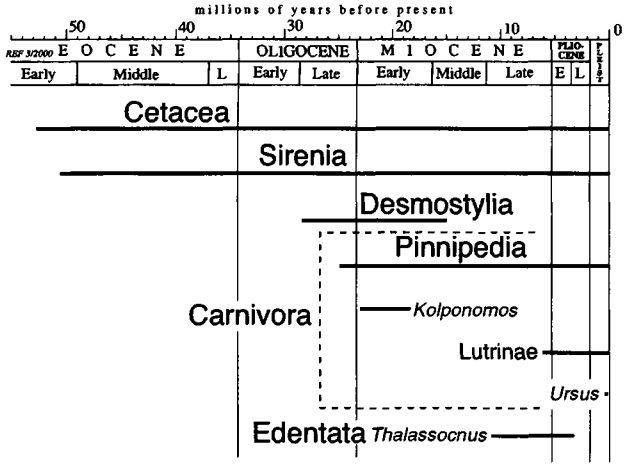

Figure 1 *Summary of geological age ranges for the main groups of fossil marine mammals.*

shows patterns of evolution and extinction that link strongly with environmental change in the oceans.

I. Occurrence, Environment, and Age

Fossil marine mammals occur in sedimentary rocks. Originally, remains accumulated in mud, silt, sand, or gravel, which, as flesh decayed, was buried and turned to rock through compaction and/or deposition of cementing minerals. Sedimentary rocks are recognized as discrete formations (genetically unified bodies of strata) and are named formally, e.g., the Calvert Formation, Maryland. Marine mammals come from strata including sandstone, mudstone, limestone, greensand, and phosphorite, most of which are marine rocks now exposed on land. Rare fossils have been recovered from the sea floor. Because broadly similar rock types may form at different times and places, sedimentary rocks must be dated to establish their time relationships.

Two correlated time scales, relative and absolute, are used in discussing the fossil record. The relative time scale has named intervals (epochs; Fig. 1) in an agreed international sequence: Eocene, Oligocene, Miocene, Pliocene, and Pleistocene. These epochs are usually subdivided into early, middle, and late. Stages (e.g., Aquitanian of Fig. 2) may provide finer subdivision. Typically, time intervals are recognized by a distinct suite of age-diagnostic fossils. The most reliable dates are based on oceanic microfossils with short time ranges, such as foraminifera, to allow correlation between ocean basins. Because of compounded errors of long-distance correlation, ages are rarely accurate to within 1 M years and many fossils can be placed only roughly within a stage. Beyond the relative time scale, absolute dates in millions of years are needed to understand rates of processes. Absolute dates are obtained usually from radiometric analysis of grains of volcanic rock interbedded with strata that also contain age-diagnostic fossils.

II. Taxonomic Framework

Fossil marine mammals are classified on the evidence of skeletons. No other useful body parts preserve, and fossils have not yet produced biomolecules useful in molecular taxonomy. SKULLS are by far the most versatile and thus important elements in classification, but teeth are taxonomically useful in most groups, and other bones (vertebrae, limb elements) have been used at times.

III. Cetacea

Fossils show that cetacean history extends back over 50 M years (Fig. 2). The earliest cetaceans—Archaeoceti—were small amphibious species that lived in fresh and brackish waters in the warm subtropical Tethys seaway between Eurasia, India, and Africa. By about 40 million years before the present (Ma), archaeocetes included large and fully marine species that had spread to temperate latitudes. The earliest modern or crown group whales, species in the filter-feeding group Mysticeti, appeared at about the Eocene/Oligocene boundary, ~34–35 Ma. Odontocetes—echolocating toothed whales and dolphins—probably radiated about the same time. Odontocetes diversified dramatically to become the most speciose group of marine mammals. Most extant cetacean families were established before the end of the Miocene, 5–10 Ma, but no living species has a history clearly longer than 2 M years.

A. Archaeoceti

Knowledge of basal whales has expanded dramatically since the early 1980s, giving new insights into cetacean phylogeny, ecology, and distribution. As noted in Kellogg's classic monograph, for many years, basal archaeocetes were known only from *Protocetus atavus* (Mokattam Formation, Middle Eocene, ~46.0 Ma; Egypt-Tethys), which was represented by a skull and uncertainly related postcranial skeleton. Since the 1980s, new finds by Gingerich, Thewissen, and others, especially in the eastern Tethys, have greatly increased diversity at the level of species, genus, and family. Basal archaeocetes are placed in the Pakicetidae, typified by the small *Pakicetus inachus*, from nonmarine red beds of the Kuldana Formation (~49–49.5 Ma), Pakistan. Skull structure (Fig. 3B) indicates limited underwater hearing capabilities, and the teeth are more simple than those of many later forms. *Pakicetus* has been cited as evidence that the earliest cetaceans radiated slowly in productive shallow waters of the Tethys seaway between Asia and India. The pakicetid (and cetacean) record has been extended back to ~53.5 Ma, based on a fragmentary jaw of *Himalayacetus subathuensis* from India. Oxygen isotopes from *Himalayacetus* indicate marine rather than nonmarine habits. Other pakicetids include species of *Ichthyolestes* and *Nalacetus*, also from the eastern Tethys.

The family Protocetidae, now expanded beyond *Protocetus*, is an Early to Middle Eocene grade for species in which the skull has an enlarged supraorbital shield, the mandible has a large mandibular foramen, and hindlimbs are reduced; they lack the complex teeth and pterygoid sinuses of younger cetaceans. Some protocetids occur in the western Tethys to western central Atlantic, including the large protocetid *Eocetus* (Egypt, North Carolina), *Pappocetus* (Nigeria; possibly North Carolina), *Natchitochia* (Louisiana), and apparently *Protocetus* (Texas). Protocetids have a high diversity in the eastern Tethys, judging from the range of teeth from Pakistan and India, although few skulls are known. *Babiacetus* (~43.5 Ma) is known

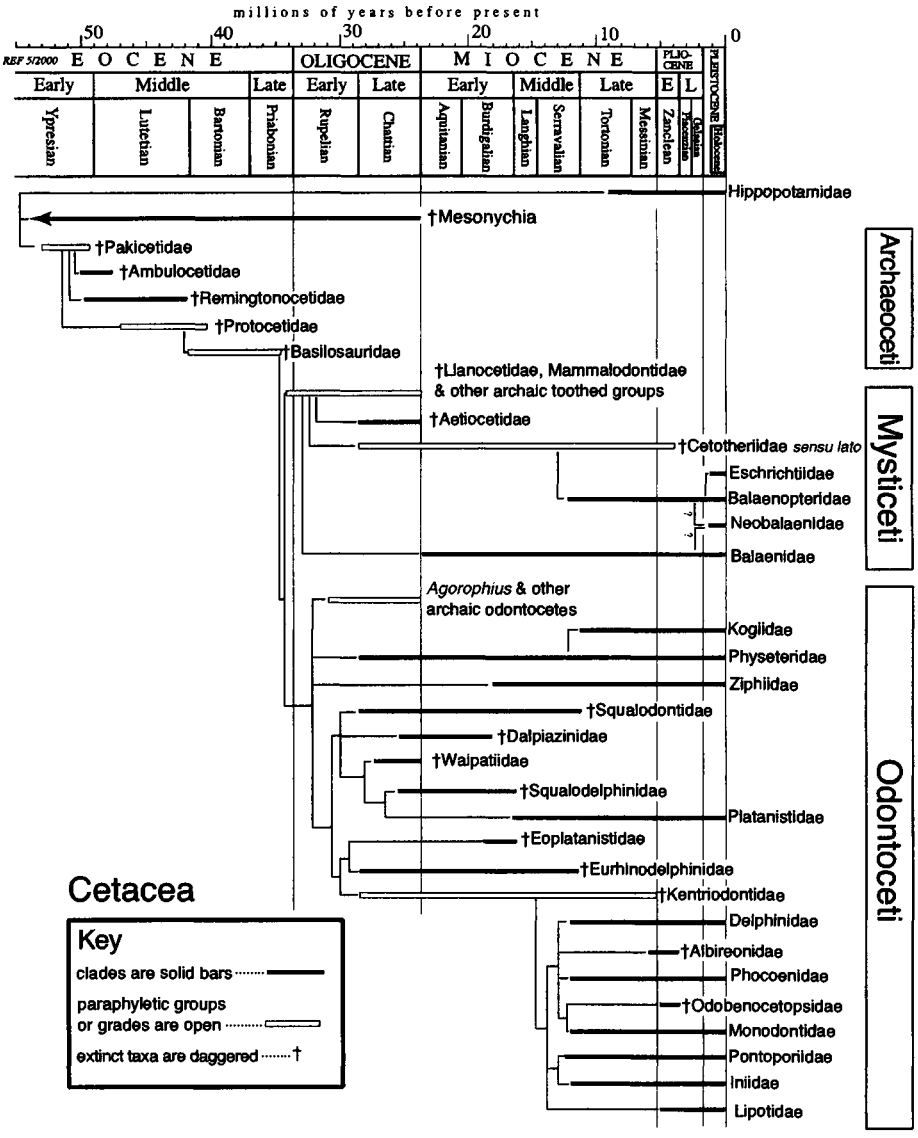

Figure 2 *Geological age ranges of major groups of Cetacea. Time scale shows absolute time, Epochs (e.g., Eocene, Oligocene) and their subdivisions (e.g., early, middle), and stages (e.g., Priabonian, Rupelian). Bars show age ranges for family level cetacean taxa, either clades or, where cladistic classification is lacking, grades. Accuracy of ranges varies between different groups and different time intervals. Inferred relationships follow Uhen and others for archaeocetes, and Muizon, Fordyce and Muizon, Barnes, Heyning, and Waddell* et al. *for odontocetes and mysticetes. From Fordyce, R. E. (2000). Cetacea. In "Encyclopedia of Life Sciences." Nature Publishing Group, London. www.els.net*

from teeth and jaws, whereas the slightly older (45.5–46 Ma) *Gaviacetus, Takracetus,* and *Indocetus* are represented by partial skulls. More complete is *Rodhocetus kasrani* (Domanda Formation, 46–46.5 Ma; Pakistan), in which the skeleton is strikingly intermediate between that of mesonychians (the terrestrial putative ancestors of cetaceans) and later whales. Cetacean features include the short neck vertebrae and more posterior vertebrae adapted for dorsoventral oscillation, but *Rhodocetus* retains a femur and sacrum. *Rodhocetus kasrani* is from deep rather than shallow water deposits, implying early colonization of offshore habitats. Another reputed protocetid, *Georgiacetus vogtlensis* (McBean Formation, 40–41 Ma: Georgia), has somewhat elaborate cheek teeth, a pterygoid sinus in the skull base, and a reduced link between sacrum and pelvis; because there are otherwise basilosaurid features, *Georgiacetus* is perhaps better placed in the Basilosauridae.

Two other archaeocete families are reported only from the Early and Middle Eocene of the eastern Tethys. First,

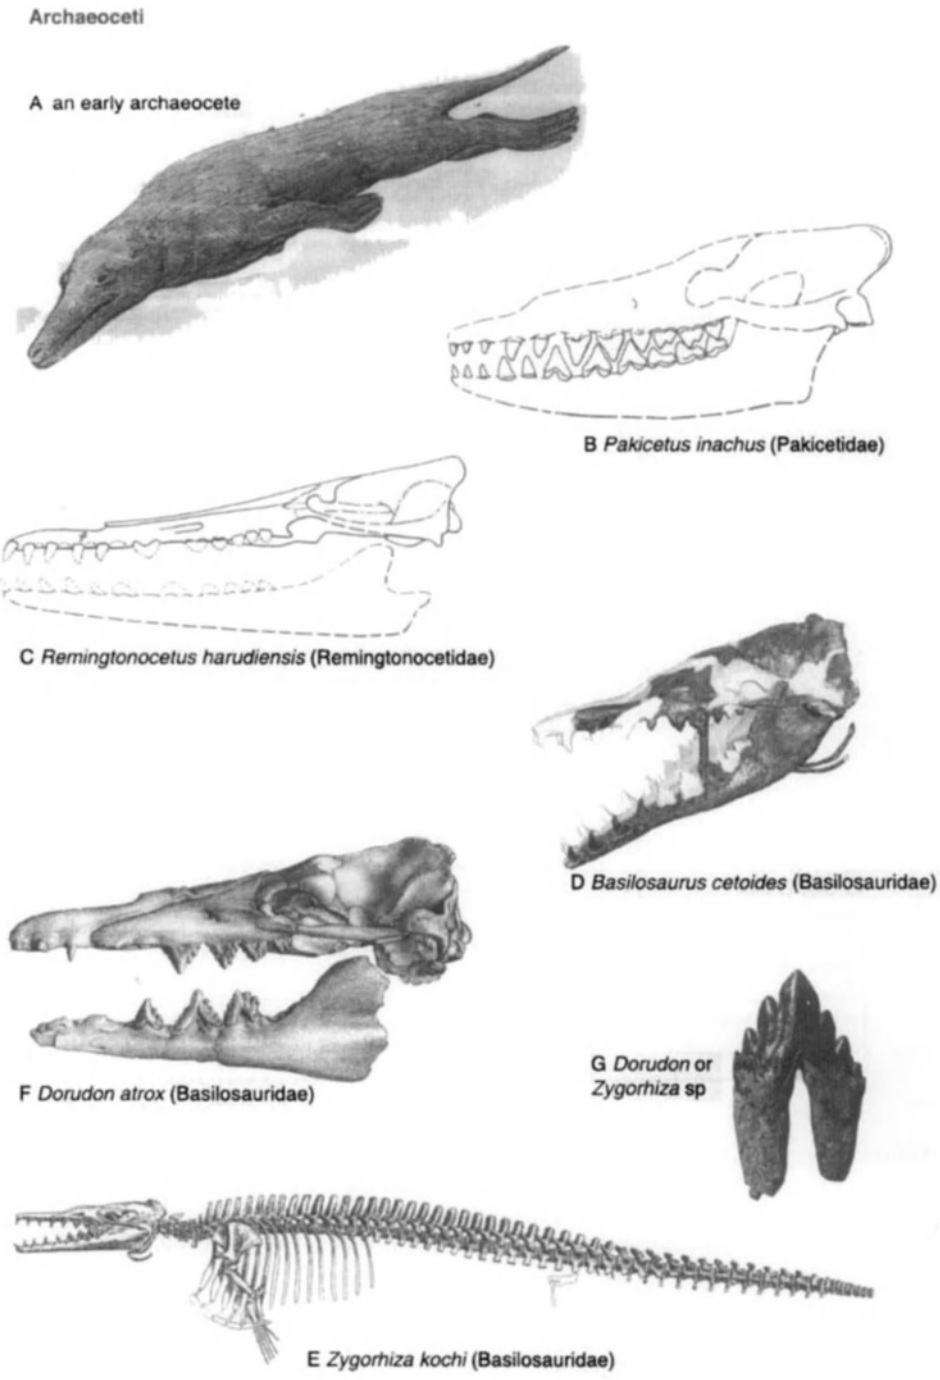

Figure 3 *Archaeocete cetaceans. (A) Reconstruction of a pakicetid-grade archaeocete, by C. Gaskin, from the Geology Museum, University of Otago. (B) Skull and mandibles of* Pakicetus inachus *(Eocene, Pakistan), lateral view, after Gingerich and Russell. (C) Skull and mandibles of* Remingtonocetus harudiensis *(Eocene, India), lateral view, after Kumar and Sahni; mandibular form is speculative. (D) Skull and mandibles of* Basilosaurus cetoides *(Eocene, Alabama), oblique lateral view of specimen in the U.S. National Museum of Natural History. (E) Skeleton of* Zygorhiza kochi *(Eocene, Alabama and Mississippi), reconstruction based on composite specimens, from Kellogg (1936); (F) Skull and mandible of* Dorudon atrox *(Eocene, Egypt), lateral view, slightly modified from Andrews. (G) Tooth of* Dorudon *or* Zygorhiza *species indeterminate (Eocene, New Zealand), medial view.*

Ambulocetus natans (Kuldana Formation, 48.0–49.0 Ma; Ambulocetidae) includes a substantially complete skeleton with a long-snouted skull and well-developed fore- and hindlimbs. *Ambulocetus* perhaps swam using pelvic paddling and dorsoventral undulations of the tail, comparable in style to some modern otters. A crocodile-like mode of predation in water is possible, but locomotion on land was probably clumsy. Second, the family Remingtonocetidae encompasses specialized long-snouted Middle Eocene species of *Remingtonocetus* (Fig. 3C), *Andrewsiphius*, and allies, known from at least partial skulls (~43.5–45 Ma). Despite previous suggestions, remingtonocetids seem unrelated to the later radiation of odontocetes.

Basilosaurids, from the later Middle and Late Eocene, are the oldest cetaceans known beyond the Tethys. They are typified by the 15-m-long *Basilosaurus cetoides* (Fig. 3D), first described and named as a fossil reptile from Louisiana (Jackson Formation, Late Eocene, ~36–39 Ma; western North Atlantic). The large size of *Basilosaurus* and its elongate vertebrae are specialized features used to recognize a subfamily Basilosaurinae. The latter include *Basilosaurus isis* (~39 Ma; Egypt, central Tethys), which has small but functional hindlimbs of ungulate-like character. Large later Eocene archaeocetes, presumably basilosaurines, have been reported from scattered localities worldwide (e.g., Northeastern Atlantic, proto-Southern Ocean, Southwest Pacific), indicating an expanding range for Cetacea.

The second subfamily of basilosaurids, the Dorudontinae, is a grade that includes smaller, more generalized, and somewhat dolphin-like species of *Dorudon*, *Pontogeneus*, *Zygorhiza* (Fig. 3E), *Saghacetus*, *Ancalecetus*, and perhaps *Georgiacetus*. These genera are rather similar to one another and are diagnosed on size, tooth form, and limb form. *Dorudon* is known from two species, the others one each. The typical species *D. serratus* is fragmentary, but others include some magnificent fossils (e.g., *Dorudon atrox*, Birket Qarun Formation, 39–40 Ma: Egypt; Fig. 3F). These formally named species are from the Tethys and western Central Atlantic, but tantalizing referred specimens (Fig. 3G) occur in other widely separated localities pointing, as for basilosaurines, to an early geographic spread.

Basilosaurids differ from more basal archaeocetes in having cheek TEETH with complex denticles and expanded basicranial air sinuses. These features, which indicate more sophisticated feeding and hearing capacities, link basilosaurids closely with early odontocetes and mysticetes. Several dorudontines are equally plausible sister taxa to the Odontoceti + Mysticeti, but basilosaurines seem too specialized, in terms of large size and elongate vertebral bodies, to be directly ancestral to living cetaceans. No positively identified archaeocetes are known from Oligocene or younger rocks.

B. Mysticeti

Since the 1960s, the fossil record of mysticetes has expanded to reveal diverse toothed and toothless Oligocene species, which effectively "bridge the gap" between archaeocetes and baleen-bearing mysticetes such as cetotheres, balaenopterids, and right whales. Pivotal here is *Aetiocetus cotylalveus* (Aetiocetidae; Yaquina Formation, Late Oligocene; Fig. 4A) from Oregon. Initially, this small cetacean was identified as an archaeocete because it has teeth, but other features, including the flattened triangular rostrum, indicate that it is an archaic mysticete. Aetiocetids are moderately diverse in their known range (North Pacific) and include species of *Chonecetus* and *Morawanocetus* from Japan. Because aetiocetids are Late Oligocene only, they are probably relict basal mysticetes that persisted after more crown-ward baleen-bearing mysticetes had appeared.

Older archaic toothed fossil mysticetes are more problematic. The enigmatic *Llanocetus denticrenatus* (Llanocetidae) was based on a fragmentary large toothed jaw and a brain cast from the La Meseta Formation, Eocene–Oligocene boundary (~35 Ma) of Seymour Island, Antarctica (Fig. 4B). Fragments of unnamed small toothed mysticetes have been described from the basal Oligocene of New Zealand (Southwest Pacific–marginal proto-Southern Ocean) (Fig. 4C). Also from the margins of the proto-Southern Ocean are two other notable toothed species: the specialized short-snouted *Mammalodon colliveri* (latest Oligocene or earliest Miocene, ~23–24 Ma, Australia; Mammalodontidae) and the enigmatic large *Kekenodon onamata* (Late Oligocene, ~27–28 Ma, New Zealand; Kekenodontidae). Other toothed Cetacea formerly identified as archaeocetes and odontocetes from New Zealand, Australia, and France probably also belong in the Aetiocetidae, Llanocetidae, Mammalodontidae, and Kekenodontidae. Most are archaeocete-like, with broad-based rostra and otherwise subtle mysticete characters, and they are more widespread and diverse than previously suspected. Their teeth were probably used in filter feeding, perhaps supplemented by baleen of which no trace has been reported. These fossils represent early branches in mysticete evolution, some of which persisted as relict taxa.

Remains of toothless and baleen-bearing mysticetes are relatively abundant in Miocene and younger strata worldwide, and some fossils (e.g., species of *Mauicetus* and *Cetotheriopsis*) occur in Late Oligocene sequences back to 29–30 Ma. Many of the fossils, particularly those older than Late Miocene (~12 Ma), lack the distinguishing skull features of right whales, balaenopterids, and gray whales and have been placed in the family Cetotheriidae. As commonly used, the Cetotheriidae is a grade or "waste basket" family (paraphyletic and probably polyphyletic), including several different lineages of archaic mysticetes. More than 20 genera have variously been placed in the group. Some Miocene cetotheres are clearly close to balaenopterids, differing mainly in the more primitive structure of the frontal bone over the eye, and these fossils may indeed be on the lineage leading to rorquals. A few of the latter, e.g., *Idiocetus* and *Plesiocetus*, have been classified alternatively in the Cetotheriidae or Balaenopteridae.

Strictly, cetotheres are typified by the Middle Miocene (12–13 Ma) *Cetotherium rathkii* from Ukraine (Paratethys), which is known only from an incomplete skull rather different in structure from those of living mysticetes (Fig. 4D). For example, the upper jaw (rostrum) thrusts back into bones of the braincase with a sharp narrow triangular apex, almost obscuring the nasal bones. The Pliocene *Herpetocetus* from the Yushima Formation of Japan shows a similar structure. Eventually, the

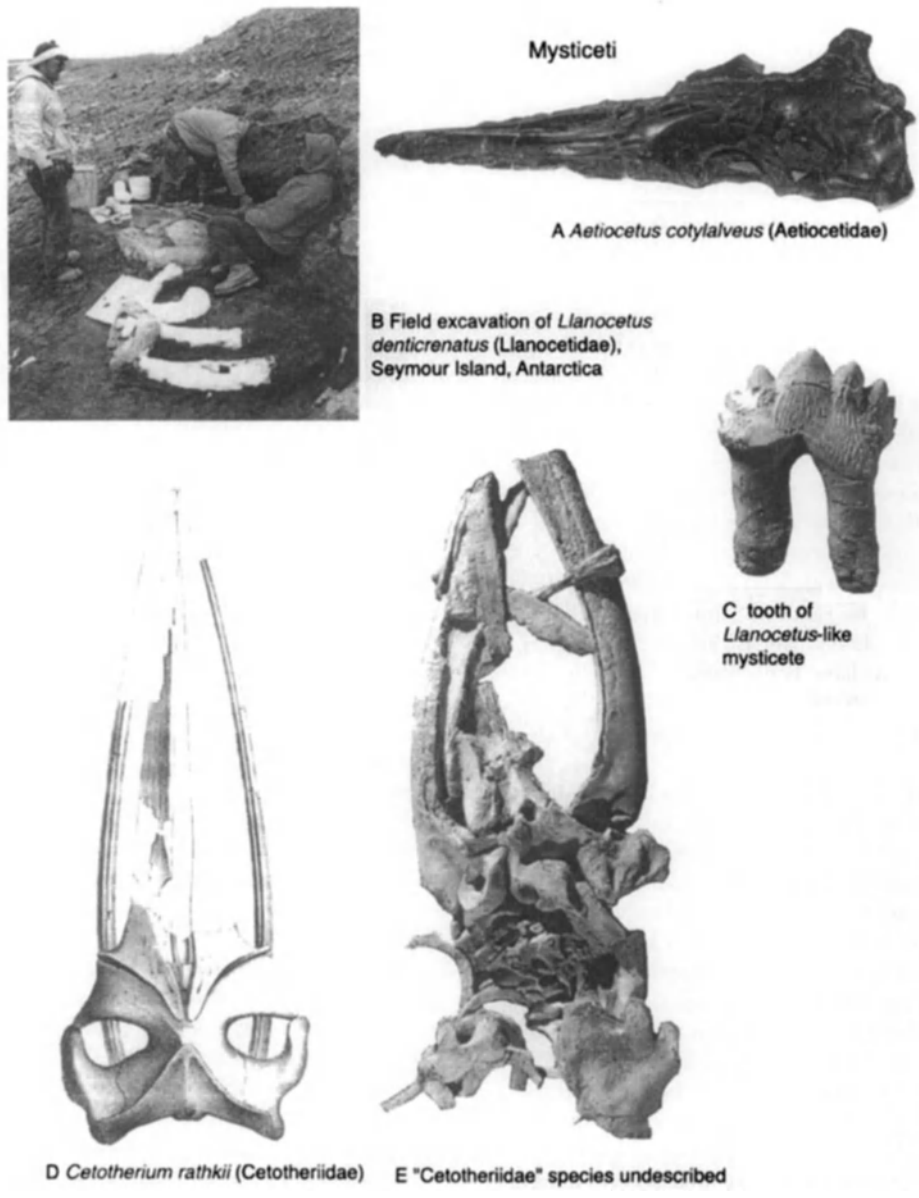

Figure 4 *Mysticete cetaceans. (A) Skull of* Aetiocetus cotylalveus *(Oligocene, Oregon), oblique dorsolateral view of holotype. (B) Field site showing excavation of ribs of the archaic mysticete* Llanocetus denticrenatus *(Eocene/Oligocene boundary, Antarctica). (C) Tooth of* Llanocetus*-like archaic mysticete (?Llanocetidae) (Oligocene, New Zealand), from Fordyce. (D) Skull and mandibles of* Cetotherium rathkii *(Miocene, Ukraine), dorsal view, holotype skull and uncertainly associated mandibles, from Van Beneden and Gervais. (E) Broken skull, mandibles, and associated elements of an undescribed* Mauicetus*-like "cetothere" (Oligocene, New Zealand), dorsal view; specimen in Geology Museum, University of Otago.*

Cetotheriidae will be defined as a clade for *Cetotherium rathkii* and its close relatives, although this will leave many other archaic mysticetes (e.g., Fig. 4E) uncertainly placed. This matter, the exact family level identity of many fossil mysticetes, is a key problem area in cetacean phylogeny.

Fossil balaenopterids, like their living relatives, have a distinctive skull structure in which the frontal bone above the eye is depressed to house the large muscles that close the lower jaw. Fossils such as *Megaptera miocaena* (Sisquoc Formation, California, northeast Pacific) indicate that *Megaptera* (subfamily Megapterinae, humpback whales) had diverged from the *Balaenoptera* lineage (subfamily Balaenopterinae, rorquals) by the Late Miocene (~12 Ma). Other Late Miocene and younger records of *Megaptera*, such as *M. hubachi* (Figs. 5A and 5B), are known. Although

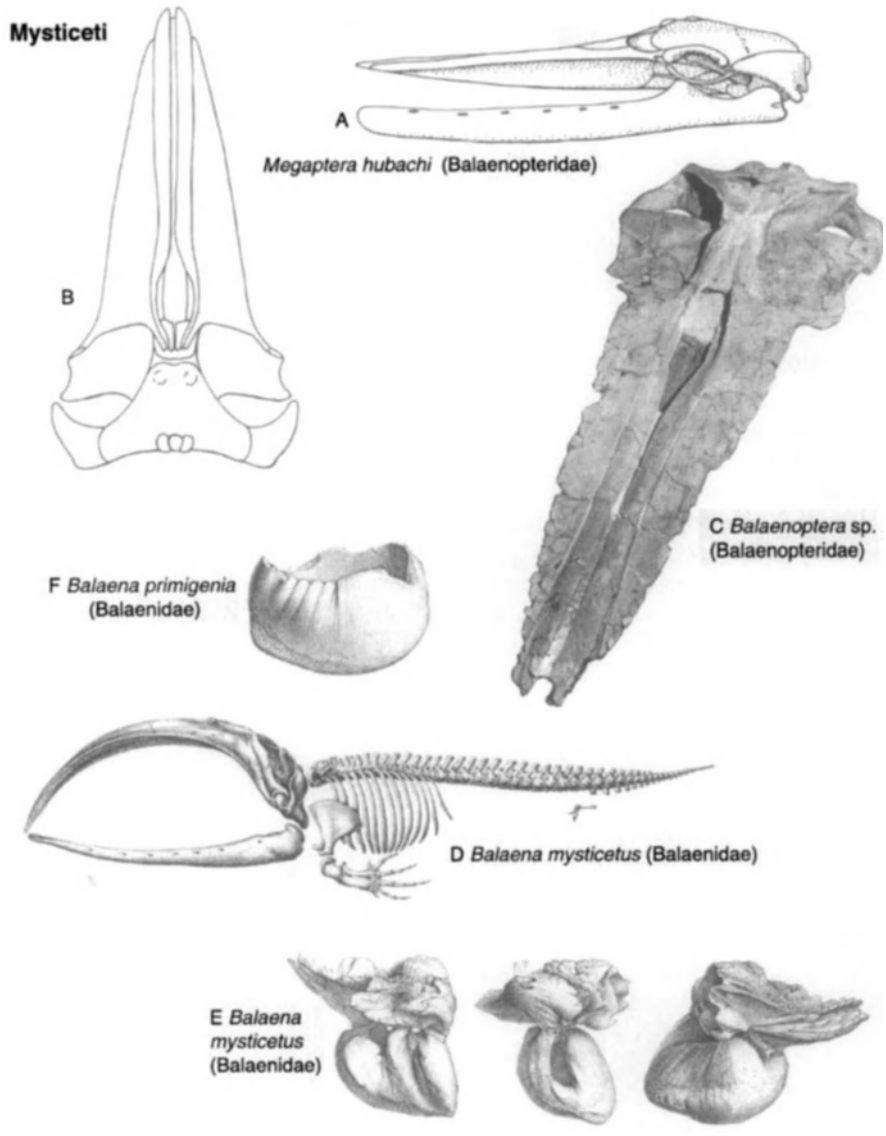

Figure 5 *Mysticete cetaceans. Skull and mandibles of* Megaptera hubachi *(Pliocene, Chile), after Dathe (1983,* Zeitschrift für geologische Wissenschaften *11): (A) skull, dorsal view; and (B) skull and mandibles, lateral view. (C) skull of an undescribed species of* Balaenoptera *(Pliocene, New Zealand), oblique dorsal view; specimen in Museum of New Zealand. Skeleton and ear bones of* Balaena mysticetus *(extant, Arctic), from Van Beneden and Gervais (1868–1880). (D) lateral view of skeleton and (E) lateral (left), anterior (middle), and internal (right) views of ear bones, with periotic above and tympanic bulla below. (F) isolated tympanic bulla of ?*Balaena primigenia *(Pleistocene?, Britain), internal view, from Van Beneden and Gervais.*

Megaptera is rather divergent from *Balaenoptera*, this does not necessitate a much older split between these two groups. For *Balaenoptera* and close relatives, the oldest described fossils are also Late Miocene (~12 Ma), with less certain Middle Miocene records. There are many records of later Miocene, Pliocene, and Pleistocene *Balaenoptera* fossils (Fig. 5C).

The oldest fossil gray whale, from the Pleistocene (~0.5 Ma), gives no obvious clue to the origins of *Eschrichtius robustus*. Fossils do not support the notion of links between the gray whale and cetotheres; equally, they do not discount relationships with *Balaenoptera*. Geologically young gray whale fossils indicate that these animals occurred in the North Atlantic.

Mysticetes diversified greatly in the Oligocene, before about 25 Ma, yet the earliest described right whale (Balaenidae) is the Early Miocene *Morenocetus parvus* (~20 Ma) from Patagonia. *Morenocetus* anchors the Balaenidae (represented by living *Balaena* and *Eubalaena*; Figs. 5D and 5E) as the oldest family of living mysticetes. Jaws are not known for *Morenoce-*

tus, but other aspects of the skull fit the balaenid pattern well. The later Miocene record of right whales is patchy, with only fragmentary fossils reported, but better Pliocene (2–5 Ma) and Pleistocene (<2 Ma) records include many nominal species (e.g., *B. primigenia*, Fig. 5F) and other published records of partial skeletons. A nearly complete skeleton of a large Early Pliocene (4–5 Ma) balaenid close to *Balaena mysticetus* is known from the Yorktown Formation, Atlantic Coastal Plain. There is no published fossil record of Neobalaenidae to indicate the origins of the pygmy right whale, *Caperea marginata*, from its presumed balaenid ancestors.

C. Odontoceti

Odontocetes are much more diverse in terms of taxa and structure than mysticetes. The oldest named species that are well dated are Late Oligocene (<30 Ma). Reportedly older species (Early Oligocene, ~30–34 Ma) are undescribed or of less certain age. The most archaic described odontocete is *Archaeodelphis patrius*, based on a fragmentary skull of uncertain origin and possible Oligocene age. Uniquely, this enigmatic species barely shows evidence of nasofacial muscles, which, in other odontocetes, are implicated in echolocation. Despite its reputedly ancestral position, because its skull base is somewhat specialized, *Archaeodelphis* is perhaps not directly on a lineage leading to living species. Almost as archaic is *Xenorophus*, a bizarre Late Oligocene genus containing one or two species with specialized facial structures superimposed on a rather primitive skull (Fig. 6A).

There is not yet consensus about the widely discussed Agorophiidae, a group previously linked with the squalodontids. Strictly, the family includes only the type species of *Agorophius* (*Agorophius pygmaeus*; Cooper Marl, Late Oligocene, >24 Ma, South Carolina), for which most of the holotype skull (Fig. 6B) is lost. Some paleocetologists prefer a grade family Agorophiidae, including *Archaeodelphis*, *Xenorophus*, and varied fragmentary archaic odontocetes. There is no evidence at present to regard the Agorophiidae as a basal clade of odontocetes.

Among living odontocetes, sperm whales (*Physeter macrocephalus*, Figure 7A-B; and *Kogia* spp.) represent a basal radiation, yet sperm whales have a poor early fossil record. The fragmentary *Ferecetotherium kelloggi* is reportedly Late Oligocene (23+ Ma; Maikop? Formation), providing the earliest record for a living family of odontocetes. Early Miocene sperm whales, such as *Diaphorocetus* and *Idiorophus* (Figs. 7D and 7E) from the South Atlantic, show the characteristic basined facial bones of later sperm whales, but retain a more primitive braincase, which links them firmly with other odontocetes. Many named species of fossil sperm whales are based on isolated teeth (e.g., species of *Scaldicetus*; Fig. 7C), which, however, reveal little about the actual animal. The oldest Kogiidae are later Miocene species from the eastern Pacific, including *Praekogia* from Isla Cedros (Almejas Formation, ~6 Ma), and the large narrow-skulled *Scaphokogia* from the Pisco Formation of Peru.

Beaked whales, Ziphiidae, have a disappointing early record based on isolated and worn rostra ("beaks" or upper jaws) but few diagnostic skull remains. The oldest reported ziphiid is *Squaloziphius emlongi* (Clallam Formation, latest Oligocene or earliest Miocene, ~23 Ma, Washington), which, equally, may be a eurhinodelphinid. Other supposed ziphiids actually represent the platanistoid dolphin group Squalodelphinidae. Most of the described ziphiid fossils are resistant isolated rostra of Middle Miocene age or younger (<16 Ma). Many of these are named, mostly as species of *Belemnoziphius*, *Choneziphius* (Fig. 7E), and *Mesoplodon*, despite the problem of determining exactly what sort of ziphiid they are. Ziphiid beaks and ear bones (e.g., Figs. 7H–7J) are common cetacean fossils at unconformities and among deep sea dredgings. Perhaps the most

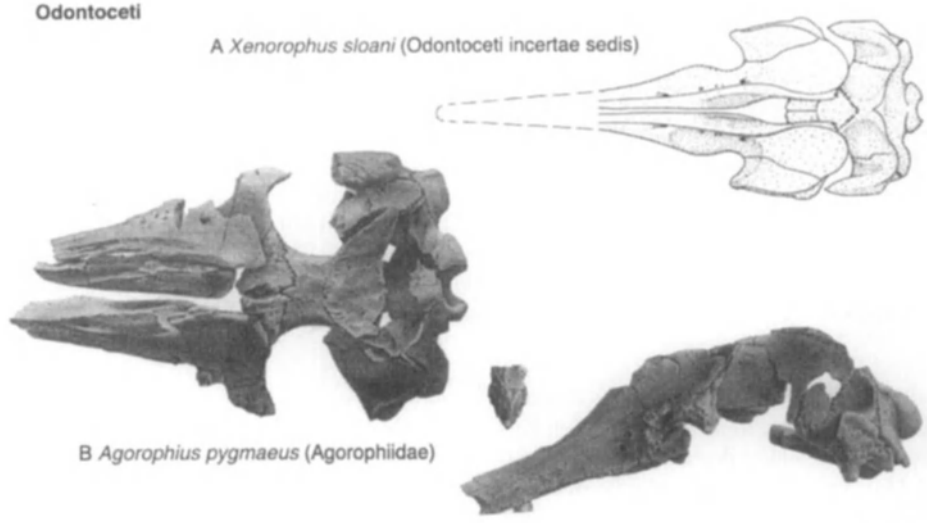

Figure 6 *Odontocete cetaceans. (A) Skull of* Xenorophus sloani *(Oligocene, South Carolina), dorsal view, after Kellogg (1923) and after Whitmore and Sanders (1977,* Systematic zoology *25). unusual occurrence of a fossil cetacean is that of a large ziphiid in freshwater Miocene strata of Kenya.

Living platanistids are known only from one species of *Platanista* from rivers in India and Pakistan, but fossil relatives are diverse. Some extinct long-beaked marine dolphins from the western North Atlantic, including *Zarhachis* (Early–Middle Miocene, ~14–16+ Ma) and *Pomatodelphis* (Late Miocene, 6–9 Ma), have facial crests, which place them close to *Platanista* in the Platanistidae. The marine *Allodelphis* (Jewett Sand, Early Miocene, ~20 Ma; California) is a more archaic possible platanistid that lacks facial crests. Clearly, platanistids invaded freshwater late in their history.

Related to the platanistids is the extinct and more archaic family Squalodelphinidae, which is based on the long-beaked *Squalodelphis* (Early Miocene, Mediterranean). Southern squalodelphinids include several species of *Notocetus* (Fig. 8A) from the latest Oligocene and Early Miocene (~18–24 Ma; New Zealand and Patagonia) bordering the Southern Ocean; formerly, some were identified wrongly as beaked whales.

A small heterodont dolphin with a slightly asymmetrical skull, *Waipatia maerewhenua* (Late Oligocene, ~25–26 Ma; New Zealand), typifies a family Waipatiidae. *Waipatia* (Figs. 8B and 8C) shows skull features that indicate an ability to echolocate. Other previously enigmatic odontocetes, such as *Sulakocetus* and *Microcetus* from the Tethys-North Atlantic, may also be waipatiids. These animals probably lie close to the base of the platanistoids.

Probably the best known of the platanistoids are the shark-toothed dolphins, Squalodontidae, which are geographically widespread medium to large odontocetes with long rostra and conspicuous, robust, triangular heterodont teeth (Figs. 8D and 8E). Squalodontids were long implicated in the phylogeny of

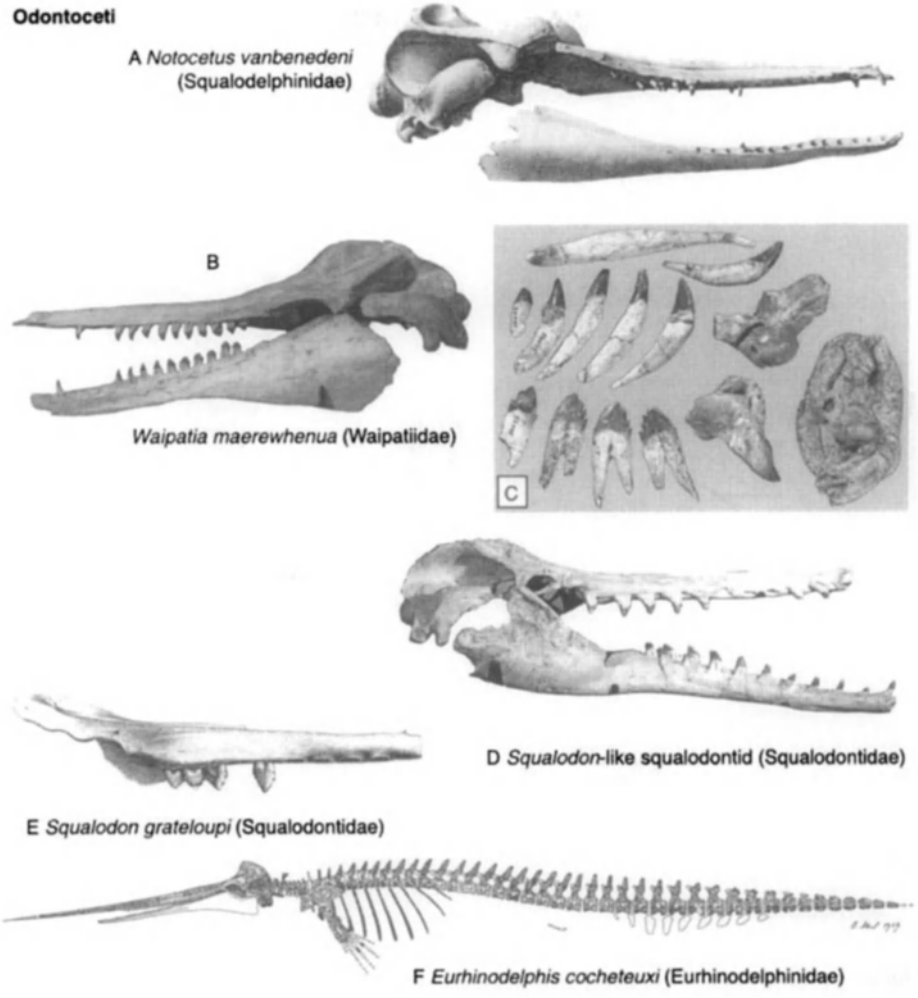

Figure 8 *Odontocete cetaceans. (A) Skull and mandibles of* Notocetus vanbenedeni *(Miocene, Patagonia), from Lydekker.* Waipatia maerewhenua *(Oligocene, New Zealand): (B) skull, lateral view; and (C) teeth and ear bones. living odontocetes, but recently have been included among the platanistoids. Squalodontids are based on *Squalodon gratelupi* (Early Miocene, ~20 Ma, eastern North Atlantic; Fig. 8E) and other clearly related species. Other supposed species of *Squalodon*, which were named from fragments, apparently represent other families of odontocetes or even mysticetes. Probably, the squalodontids include only *Squalodon*, *Kelloggia*, *Eosqualodon*, and *Phoberodon*. The broad-beaked *Prosqualodon* (latest Oligocene–Early Miocene, ~18–~24 Ma, marginal Southern Ocean) may represent a related separate family, Prosqualodontidae.

Species in the extinct family Eurhinodelphinidae (sometimes called Rhabdosteidae) have dramatically long rostra and quite specialized skulls. The early record is patchy, with Oligocene forms restricted and poorly known. This, and problems of interpreting skull bones, means that relationships are obscure; they could lie with delphinoids or, equally, platanistoids. Early and Middle Miocene eurhinodelphinids such as *Eurhinodelphis* (Fig. 8F) and *Agyrocetus* are widespread. One Late Oligocene species occurs in freshwater strata of central Australia. Eurhinodelphids are related to another extinct group, the Early Miocene Eoplatanistidae.

Early true dolphins represent the grade family Kentriodontidae (Delphinoidea). Kentriodontids are geographically widespread small to medium-sized animals with largely symmetrical skulls, including *Kentriodon* (Fig. 9A) and *Hadrodelphis* (both Calvert Formation, Early to Middle Miocene, 14–16+ Ma). Rare Late Oligocene (>23 Ma) kentriodontids indicate ancient origins for the lineage leading to delphinids. The geologically youngest kentriodontids were contemporaneous with early delphinids from the Late Miocene (~10–12 Ma), animals characterized particularly by markedly asymmetrical skulls.

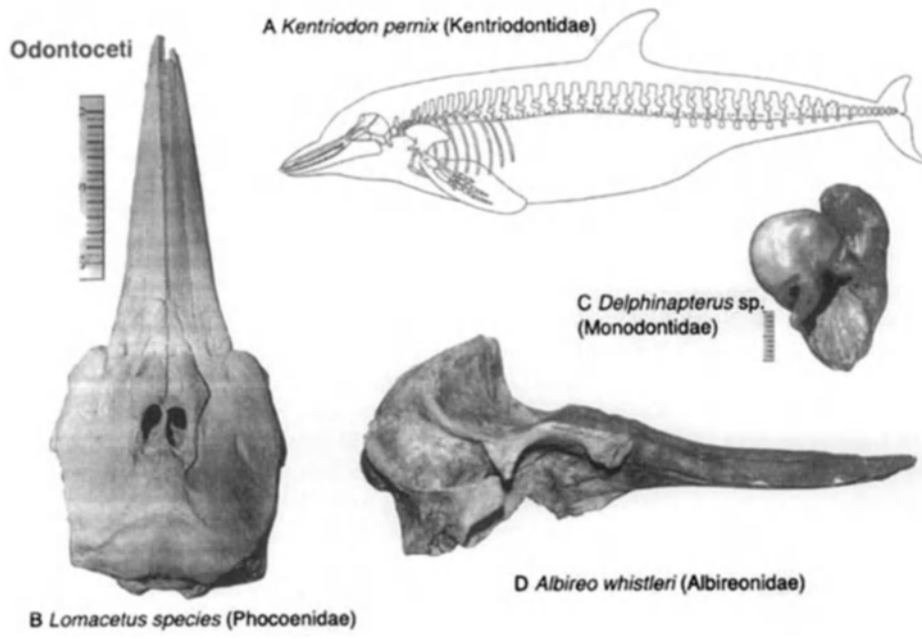

Figure 9 *Odontocete cetaceans. (A) Skeleton of* Kentriodon pernix *(Miocene, Maryland), lateral view of speculative reconstruction, from Kellogg (1927). (B) Skull of* Lomacetus ginsburgi *(Miocene, Peru), dorsal view. (C) Periotic of* Delphinapterus *sp. (Pliocene, North Carolina), ventral view. (D) Skull of* Albireo whistleri *(Miocene, Isla Cedros), lateral view.*

(Supposedly older records of delphinids, >12 Ma, appear incorrect). Delphinids are important components of, especially, Pliocene assemblages (2–5 Ma). For example, fossils from northern Italy include skulls, teeth, and ear bones referred to species of *Stenella*, *Tursiops*, *Orcinus*, the *Tursiops*-like *Hemisyntrachelus*, and the extinct *Astadelphis*.

Like delphinids, porpoises (Phocoenidae) and white whales (Monodontidae) range back to the Late Miocene, although no clear ancestors have been identified. The record of porpoises is better than that of monodontids, originating with *Salumiphocaena stocktoni* from the eastern North Pacific (Monterey Formation, 10–11 Ma; California). Fossil ear bones and skulls indicate a high diversity for phocoenids in the latest Miocene and earlier Pliocene of the eastern Pacific (e.g., *Lomacetus* and *Piscolithax* spp.; Fig. 9B). A more sparse record of monodontids reveals that this group was also important in warm equatorial waters of the eastern Pacific until well into the Pliocene, with fossils such as *Denebola* present in Peru and Cedros Island. In the Atlantic, Early Pliocene (~4.5 Ma) *Delphinapterus* occurs in North Carolina (Yorktown Formation; Fig. 9C), and there are reports of geologically young (Late Pleistocene, <0.5 Ma) *Delphinapterus* and *Monodon* from midlatitude North Atlantic shores.

While most of the Late Miocene and younger fossil delphinoids are of modern aspect, two extinct families are known from the latest Miocene and earlier Pliocene of the eastern Pacific. The Albireonidae is based on the latest Miocene porpoise-like *Albireo whistleri* (Fig. 9D) from Cedros Island, whereas two species of tusked "walrus whales" (*Odobenocetops;* Odobenocetopsidae) are from the Pisco Formation, Peru, The latter are uncannily like the living walrus, *Odobenus rosmarus*, in skull form.

Several groups of river dolphin lie close to the Delphinoidea. Among members of these groups, pontoporiid fossils occur in freshwater strata in South America and Mio-Pliocene marine rocks bordering the eastern North Pacific and western North Atlantic. The small short-beaked *Brachydelphis mazeasi* (Pisco Formation, ~12–15 Ma) from Peru represents a distinct subfamily (Pontoporiidae: Brachydelphininae) related to the long-beaked Peruvian fossil *Pliopontos littoralis* (~4–5 Ma) and the living franciscana (*Pontoporia blainvillei*). Marine long-beaked species of *Parapontoporia* from Isla Cedros (Almejas Formation, ~5 Ma) and southern California (San Diego Formation, ~2–3 Ma) may be related to *Pontoporia*, although ear bone anatomy points to relationships with living baiji (*Lipotes vexillifer*). The problematic *Prolipotes*, based on a fragment of possibly Miocene lower jaw from freshwater deposits in China, is too incomplete to confirm a relationship with *Lipotes*. Many fossils have been placed in the family Iniidae, with the living *Inia geoffrensis*, but most of these belong elsewhere. Fossil iniids include the South American Late Miocene ("Mesopotamiense" horizon, >5 Ma) *Ischyrorhynchus* and probably *Saurodelphis* and may include the marine *Goniodelphis hudsoni* (Early Pliocene, 4–5 Ma) from Florida.

IV. Marine Carnivora

The record of marine CARNIVORA starts about the Oligocene/Miocene boundary (~25 Ma). Pinnipeds are most speciose and geographically widespread aquatic carnivores,

well represented in northern temperate regions. Related closely is the fossil marine amphicyonid, *Kolponomos*. The only marine ursid, the polar bear, *Ursus maritimus*, has no significant fossils and probably originated only a few tens of thousands of years ago. Otters have a meager but notable fossil record.

A. Pinnipeds: Seals, Walruses, Fur Seals, and Sea Lions

As with Cetacea, the fossil record of seals, sea lions, walruses, and relatives has expanded greatly in recent decades, particularly through finds around the North Pacific. Fossil pinnipeds are less diverse than the Cetacea in terms of species, genera, and families, and the geological record is shorter, extending back to the late Oligocene (~25 Ma) (Fig. 10). Furthermore, the lack of consensus about family level taxonomy and indeed about pinniped monophyly versus diphyly complicates a review of these animals; a genus, or different species on one genus, may be placed in one of several different taxa, some of which are acknowledged grades, and others of which are clades of varying family level rank (e.g., family or subfamily).

Pinniped diphyly was favored strongly from the 1960s to 1980s (Fig. 10A). Of the two living groups and their fossil relatives, the eared seals—fur seals and sea lions—supposedly originated from a bear-like stock in the North Pacific. The walrus was placed tentatively with the eared seals to form the group Otarioidea (or Otariidae). In contrast, the earless or true seals (Phocidae, or Phocoidea) were thought to be a distinct and different group related to mustelids and originating in the North Atlantic. By the 1990s, some anatomically based cladistic analyses of pinnipeds concluded that seals and relatives are monophyletic, with the walrus and Phocidae being the most crown-ward taxa, and Otariidae more basal in the group Pinnipedimorpha (Fig. 10B). Classification is still volatile, and communication is hampered because taxonomic names have quite different meanings to different workers. The cladistic methods seem clear and repeatable, supporting the notion of monophyly. Conversely, a good case has been made on morphological grounds that some key characters used in cladistics are ambiguous, arguably including significant reversals and convergences, undermining claims of monophyly. Further, the monophyletic pattern plotted against time (Fig. 10C, lower) produces long "ghost lineages," whereas the diphyletic pattern reveals long-ranging paraphyletic groups (Fig. 10C, upper). Some recent molecular taxonomies have corroborated anatomical cladistics and recognized the living pinnipeds as monophyletic, but have supported "traditional" views in placing the walrus closer to otariids than to phocoids. There is not yet a consensus.

The small marine carnivore *Enaliarctos mealsi* is an archaic species based on skulls and a skeleton from the Jewett Sand of California (about Oligocene/Miocene boundary; ~23 Ma) (Fig. 11A). The species typifies the Enaliarctinae (or, alternatively, Enaliarctidae), is widely regarded as a basal otariid, and may lie at the stem of all pinnipeds. Other enaliarctines of comparable age have been named from fossils from California and Oregon (e.g., *Pteronarctos goedertae*, Astoria Formation, Middle Miocene, ~16 Ma) (Fig. 11B), and an undetermined *Enaliarctos*-like species occurs in Japan (late Early Miocene, ~17 Ma). Also from California, and roughly contemporaneous with *Enaliarctos*, is *Pinnarctidion bishopi*, an archaic pinniped also initially placed in the Enaliarctinae. A second species, *P. rayi*, from coastal Oregon (Early Miocene, >19 Ma) includes skulls and postcranial bones, which, alternatively, have been allied with Phocidae.

Fur seals and sea lions, [Otariidae (or Otariinae)] appeared by the Late Miocene (>9 Ma) in the North Pacific, as shown by *Thalassoleon* and *Pithanotaria* (Fig. 11C). The two living otariid groups, the fur seals and sea lions, have a short fossil record around the Pacific and Southern Ocean. Fossil northern fur seals (arctocephalines) include the small Late Pliocene (2–3 Ma) *Callorhinus gilmorei* (Japan, California, Baja, California), which is close to the living North Pacific *C. ursinus*. A larger, southern fur seal is the Late Pliocene (~2 Ma) *Hydrarctos lomasiensis* from Peru, which is possibly allied to living fur seals in the genus *Arctocephalus*. Among sea lions (otariines), North Pacific fossil *Eumetopias* is known from teeth and some postcranial bones of latest Pliocene age (~2.5 Ma, Japan), and there are reports of Pleistocene *Zalophus*. In the south, the extinct *Neophoca palatina* is based on a single skull of middle Pleistocene age (~0.5+ Ma, New Zealand).

The diverse cluster of medium to large extinct pinnipeds known as allodesmines is typified by the rare *Allodesmus kernensis* and *A. kelloggi* (Fig. 11D) and more common *A. gracilis* (Fig. 11E) from Sharktooth Hill, California (Middle Miocene, 13–14 Ma). Allodesmines range temporally from the early Middle to Late Miocene, and widely across the North Pacific (Japan, and Washington to Baja California, Mexico). At least eight species have been described in four genera (*Allodesmus*, *Brachyallodesmus*, *Atopotarus*, and *Megagomphos*). They were large-eyed, deep-diving animals that swam by forelimb propulsion. *Allodesmus* and its relatives have been placed variously (as a family or a subfamily) in the Otariidae or alternatively close to the true seals, Phocidae.

The single species of living walrus is the sole survivor of a once diverse group. Walrus origins may lie with the Early Miocene (16–22 Ma) genus *Desmatophoca*, which contains two large rare species from the Northeast Pacific (Fig. 11F). Alternatively, *Desmatophoca* has been allied with the phocid radiation. Another group implicated in walrus origins is the North Pacific Miocene Imagotariinae. Of these, the basal *Neotherium* was small, but most imagotariines were medium to large archaic sea lion-like forms. Middle Miocene (~13–16 Ma) fossils include species of *Prototaria* (Japan) and *Proneotherium* (Oregon); *Imagotaria* (California) is a representative Late Miocene form. Though on the walrus lineage, these were not particularly mollusk eaters but probably had a generalized piscivorous diet.

The North Pacific group Dusignathinae includes extinct forms regarded variously as walrus-like sea lions ("pseudowalruses") or, alternatively, true walrus relatives (with sister group status in Fig. 11C, upper and lower). These animals, including *Dusignathus* and the very large *Gomphotaria* (known from a nearly complete skeleton), range from Late Miocene (5–8 Ma) to Late Pliocene (2–3 Ma). Dusignathines differ from odobenines in that both the upper and the lower canines are enlarged as tusks.

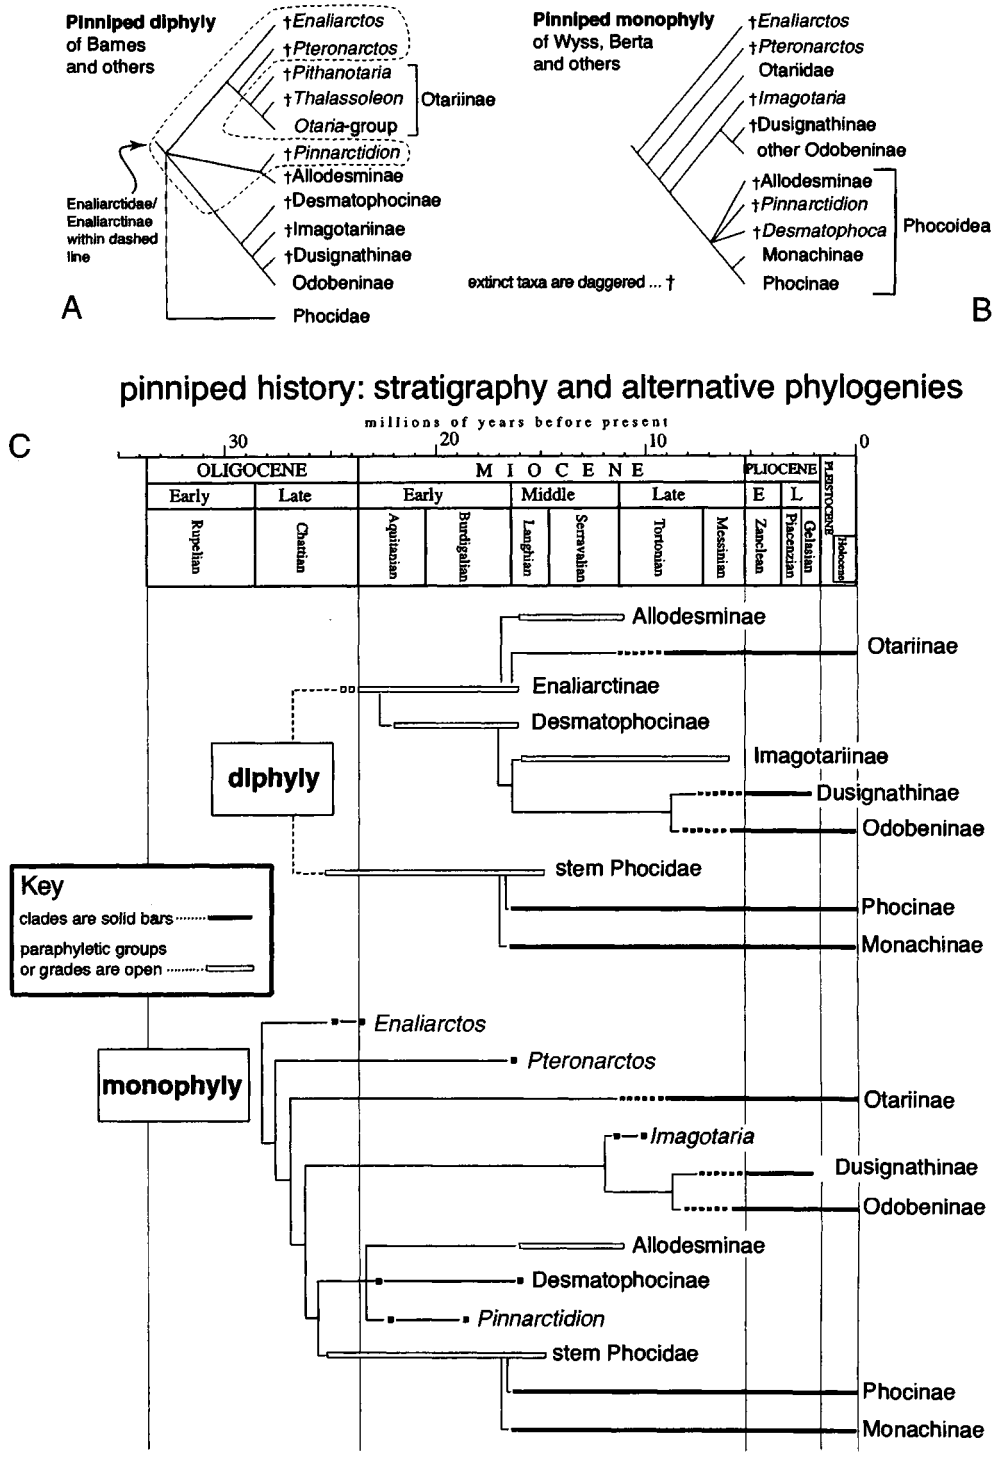

Figure 10 *Different hypotheses of relationships among pinnipeds, and geological age ranges of major groups of pinnipeds. (A) One concept of pinniped diphyly, based on Barnes and others. (B) One concept of pinniped monophyly, based on Berta and others. (C) Geological age ranges of major groups of pinnipeds, plotted against a standard time scale (for time scale details, see Fig. 2). Hypotheses of diphyly (upper) or monophyly (lower) are used to show inferred relationships. Bars show age ranges for taxa, which are mostly families and subfamilies but sometimes genera. Clades are in-filled bars, grades or paraphyletic or stem groups are open bars, and genera or key species within genera are dots.*

(F) Skull of* Desmatophoca brachycephala *(Early Miocene, California), lateral view, after Barnes. (G) Skull and mandibles of* Protodobenus japonicus *(Early Pliocene, Japan), lateral view, after Horikawa (1995,* The Island Arc *3[4]).*

Many extinct genera have been placed with the large, tusked living walrus, *Odobenus rosmarus*, in the Odobenidae. Late Quaternary fossils (<1 Ma) of walrus are known around the margins of the North Atlantic and North Pacific, with *Odobenus* sp. also reported from the Late Pliocene (2–2.7 Ma) of the North Pacific. Other extinct species of odobenine (large-tusked) walruses lived in northern waters outside polar regions, in situations known to be warmer than today. For example, the Late Pliocene *Valenictus chulavistensis*, which is related closely to *Odobenus*, is known from skulls and associated skeletons from southern California (San Diego Formation, 2–3 Ma), whereas teeth referred to the extinct *Trichecodon huxleyi* have been reported from the earlier Pliocene (Bone Valley Formation, 4–5 Ma) of Florida and Pleistocene (Red Crag, <2 Ma) of Britain,

south of the inferred range of the living walrus. *Protodobenus japonicus* (Fig. 11G), from Japan, may be as old as 5 Ma and thus is the oldest reported odobenine walrus.

In contrast to the various classifications of otariids and odobenids, true seals (Phocidae) are well unified by specialized swimming features. This unity might mislead one into thinking that phocid paleontology and phylogeny are straightforward. The fossil record of phocids is patchy, and few basal or archaic taxa are known. The oldest reported specimens, from South Carolina, are, surprisingly, from the Late Oligocene (>23 Ma). If the concept of pinniped monophyly is correct, with the Pacific Oligo/Miocene *Enaliarctos* at the stem of pinnipeds and phocids much further crown-ward, this early Atlantic record for phocids has major implications for the geography and timing of pinniped evolution. Phocids are a negligible component of North Pacific fossil faunas (with sporadic *Phoca*-like fossils from the Pleistocene and, rarely, Pliocene), but are significant in the Atlantic and, lesserly, the Southern Ocean.

The typical phocid genus *Phoca* has been used widely, and often wrongly, for diverse fossil seals and even some fossil cetaceans, but *Phoca* in the strict sense is not certainly older than Pleistocene. *Phoca* and its living relatives comprise a group Phocini (or Phocinae), which also includes fossils as old as Middle Miocene (14–16+ Ma). For example, the Middle Miocene presumed phocine *Leptophoca lenis,* which was based on an isolated humerus, is known from many skeletal elements from the Calvert Formation (~15 Ma; USA). *Leptophoca, Prophoca, Cryptophoca,* and related genera are all from the Atlantic shores of North America and Europe or from the Paratethys, which was an ancient shallow and even brackish northeastern extension of the Mediterranean Sea.

Fossils from a second group of phocid seals, the Monachinae, include a scatter of *Monachus*-like genera based on fragmentary North Atlantic fossils, such as *"Monotherium"* from the Calvert Formation (~15 Ma) related to living Monk seals (Monachini of some authors). Other excellent Late Miocene to Early Pliocene specimens are allied to living *Lobodon carcinophaga* (Fig. 12A) in the Lobodontini. Lobodontines include *Piscophoca pacifica* and the elongate, slender-bodied *Acrophoca longirostris* (both Pisco Formation, Peru, eastern Pacific) and, in the Atlantic, the Late Miocene *Properiptychus argentinus* (Argentina). From the margins of the Southern Ocean come the well-known *Homiphoca capensis* (earliest Pliocene, ~5 Ma) (Figs. 12A and 12B) from South Africa and more fragmentary *Homiphoca*-like fossils from southern Australia. The only notable fossil of a living Antarctic lobodontine seal is a jaw identified as *Ommatophoca rossi* from New Zealand (latest Pliocene, >2 Ma; southwest Pacific) (Fig. 12D).

B. Amphicyonidae

The extinct Early Miocene carnivore *Kolponomos* (Amphicyonidae) is known from two North Pacific species from the Clallam and Nye Formations of Oregon and Washington. The skull is massive, with forward-directed eyes, a narrow snout,

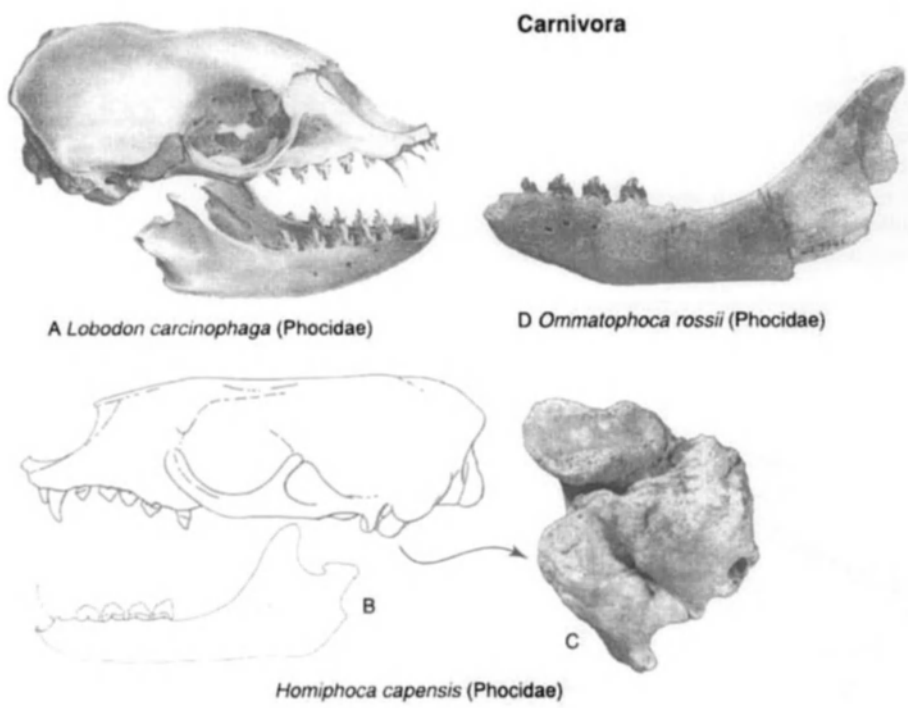

Figure 12 *Pinniped carnivores. (A) Skull and mandibles of* Lobodon carcinophaga *(extant, Antarctica), lateral view, from Gray (1846).* Homiphoca capensis *(earliest Pliocene, South Africa): (B) skull and mandibles of lateral view, after de Muizon and Hendey (1980,* Annals of the South African Museum *82[3]) and (C) right temporal bone (ear region), ventral view. (D) Mandible of* Ommatophoca rossii *(latest Pliocene, New Zealand), lateral view.*

and broad low-crowned teeth, which indicate a crushing feeding habit, probably on shelled invertebrates (Fig. 13A). Other than the skull, the skeleton is known poorly, but was presumably bear like. *Kolponomos* is interpreted as amphibious, not a strong swimmer, and living nearshore. It has been placed close to the base of the pinnipeds.

C. Sea Otters (Mustelidae: Lutrinae)

Sea otters are known as fossils from around the North Pacific and North Atlantic. Despite their presence in marine strata, none of the species was clearly an obligate marine mammal. A key diagnostic feature is blunt molar teeth, which indicate a durophagous (shell-crushing) diet. The giant Late Miocene (~7 Ma) otter, *Enhydritherium terraenovae,* is known from fragmentary specimens from marine strata in California and Florida and from an informative articulated skeleton from freshwater strata in Florida (Fig. 13B). The latter represents an animal with powerful neck muscles, forelimbs that probably helped in swimming, and hindlegs suitable for terrestrial locomotion. In younger fossils, such as *Enhydra macrodonta* (Late Pleistocene, California), limb structure indicates hindlimb swimming, with forelimbs used to manipulate food.

V. Tethytheres: Sirenians and Desmostylians

Tethytheres are herbivorous, mostly large mammals that include elephants, sirenians, and the extinct Desmostylia. Sirenians and desmostylians have a significant marine fossil record.

A. Sirenia

Living sirenians are obligate aquatic mammals that dwell in shallow subtropical and tropical waters, both marine and freshwater. The fossil record, which is mostly from the Northern Hemisphere (Fig. 14), shows that the two living families (Trichechidae and Dugongidae) have a long and diverse history. Two extinct families of sirenians are based on fossils. The fossil record of sirenians, as documented extensively by Domning, is judged reasonably complete and probably gives a reliable guide to the evolution of the group.

The oldest and most archaic sirenian is *Prorastomus sirenoides* (sole member of the Prorastomidae), named by the famous anatomist Richard Owen for a skull, mandible, and vertebra from the Early and Middle Eocene (~50 Ma) of Jamaica. A few other specimens are known. This occurrence in the western tropical Atlantic is surprising, as tethytheres are thought to have evolved in the eastern Tethys. *Prorastomus* is generally intermediate in structure between other tethytheres and later Sirenia, although perhaps it is not directly ancestral to any known later sirenian. Its notable sirenian features include the inflated rostrum, pachyostotic skull (with dense bone), retracted enlarged nares, and five premolars.

Before the end of the Eocene, sirenians occupied warm waters from the western tropical Atlantic through the Tethys to the western Pacific. Many of the fossils represent species of *Protosiren* (extinct family Protosirenidae; Middle–Late Eocene), distinguished from *Prorastomus* by details of the ear and a more down-turned rostrum. *Protosiren* occurs in Egypt and India and presumably ranged through the middle Tethys. Some specimens retained short hindlimbs and were probably amphibious rather than completely aquatic. Protosirenids are plausible structural ancestors for the two extant families: Dugongidae and Trichechidae. Despite the abundance of protosirenid fossils and the presence of effectively a circumglobal equatorial seaway (Tethys–Caribbean–Pacific), there are no reports of Eocene or Early Oligocene sirenians from outside Indonesian west Pacific.

The earliest dugongids—the halitheriines (paraphyletic subfamily Halitheriinae; Eocene–Pliocene)—were contemporaneous with protosirenids, and overlap in range, being known from Middle Eocene to Oligocene rocks in Egypt (e.g., *Eosiren,* Fig. 15A). Dugongids are characterized by a loss of hindlimbs and by changes in the ear region of the skull, but relationships among archaic forms are not fully resolved. Fossils indicate that, apart from the hydrodamalines (see later), the family is subtropical–tropical.

In the Oligocene, halitheriine dugongids occurred beyond the shrinking Tethys sea, with significant fossils of *Halitherium* in Eu-

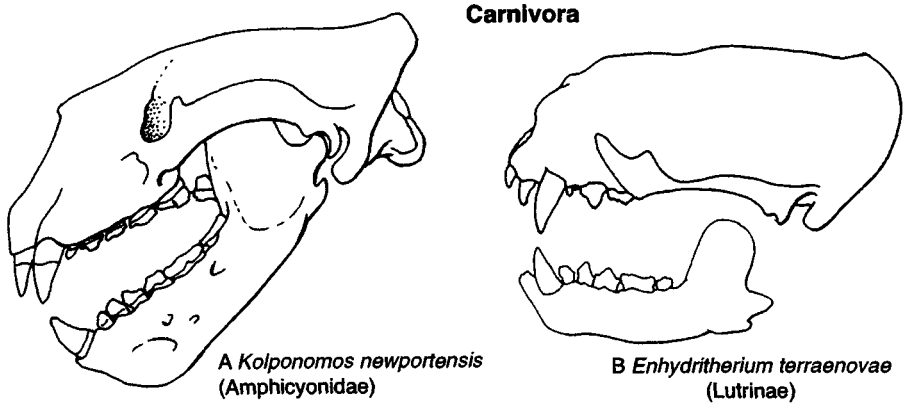

Figure 13 *Other marine carnivores. (A) Skull and mandibles of* Kolponomos newportensis *(Early Miocene, Oregon), lateral view, after Tedford* et al. *(1994,* Proc. San Diego Mus. Nat. Hist. *29). Figure 14 *Geological age ranges of families and subfamilies within the Sirenia plotted against a standard time scale (for time scale details, see Fig. 2). Clades are in-filled bars, and grades or paraphyletic or stem groups are open bars. Inferred relationships follow the work of Domning (1996).*

rope and the western North Atlantic. *Halitherium* (Germany; Fig. 15B) includes some of the very few Early Oligocene marine mammals known. Geologically, younger halitheriines include species in the widespread Early–Middle Miocene *Metaxytherium* (Fig. 15C), characterized by strongly down-turned snouts and small upper incisor tusks, and interpreted as generalized bottom feeders. *Metaxytherium* is reported from Europe (eastern Atlantic/Mediterranean), the western Atlantic, and the North to equatorial Pacific. Presumably, Pacific halitheriines, with their significant Miocene record, originated from animals that spread westward through the Central American seaway. One halitheriine, *Metaxytherium crataegense*, is reported both from the western Atlantic and the eastern tropical Pacific. Older Pacific records of dugongids are fragmentary and enigmatic; they include an indeterminate Late Oligocene dugongid from Japan and an unnamed Early Miocene (18–25 Ma) halitheriine from Oregon.

In the Early to Middle Miocene, a significant new lineage of dugongids, the hydrodamalines, radiated in the North Pacific. This group, characterized primarily by a large body size, probably arose within *Metaxytherium*. Early fossils include two species of *Dusisiren*, while the cold-tolerant *Hydrodamalis* is known from the circum-North Pacific Late Miocene to Pliocene *H. cuestae* and its descendant, *Hydrodamalis gigas*. The latter, Steller's sea cow, was exterminated by humans; it was a huge animal that, unlike other sirenians, lived in exposed cold high-latitude waters where it fed on kelp. Steller's sea cow has significant Quaternary records.

The dugong lineage arose by the Late Oligocene, when the Dugonginae branched away from the halitheriines. The oldest and most archaic dugongines (*Crenatosiren*) and greatest known diversity are in the western North Atlantic–Caribbean region, and perhaps the group originated there. Dugongines are, however, known as fossils from the eastern North Atlantic–Mediterranean (*Rytiodus;* Early Miocene) and the eastern North Pacific (*Dioplotherium;* Early–Middle Miocene). Beyond a few fragments of Pleistocene age, there are no notable fossils for the living western tropical Pacific *Dugong dugon;* however, phylogenetic analyses indicate a significant long but unrecorded history for the lineage leading to this species.

Manatees (Trichechidae), characterized by a secondarily reduced rostrum, probably evolved from *Prototherium*-like dugongs in the later Eocene or Early Oligocene. The oldest trichechids are the European Miosireninae–the Late Oligocene *Anomotherium* and Early Miocene *Miosiren*. By the Middle Miocene (~14 Ma), archaic manatees, species of *Potamosiren* (Trichechinae), occupied fresh waters in South America and since then have been restricted mainly to inshore waters. The Late Miocene to Pliocene (~4–6 Ma) *Ribodon*, from the lower La Plata basin, shows the distinctive manatee-like character of supernumerary molar teeth, interpreted as an adaptation for feeding on abrasive freshwater grasses. In turn, aquatic plants perhaps evolved in response to changing South American drainages caused by the uplift of the Andes. An Early Pliocene (~5 Ma) *Ribodon* is known from North Carolina at about the time that dugongs disappeared from the Caribbean–western North Atlantic, and fossils close to *Trichechus* appear in the Late Pliocene (2–3 Ma). Such fossils indicate that manatees ecologically replaced dugongs in the Caribbean–western North Atlantic, although whether by competition is uncertain. There is no fossil record to reveal the dispersal of *Trichechus* eastward to Africa.

B. Desmostylia

Desmostylians are large extinct North Pacific marine mammals that were first described, in the 1880s, on the basis of isolated molar teeth with distinctive bundles of high columnar

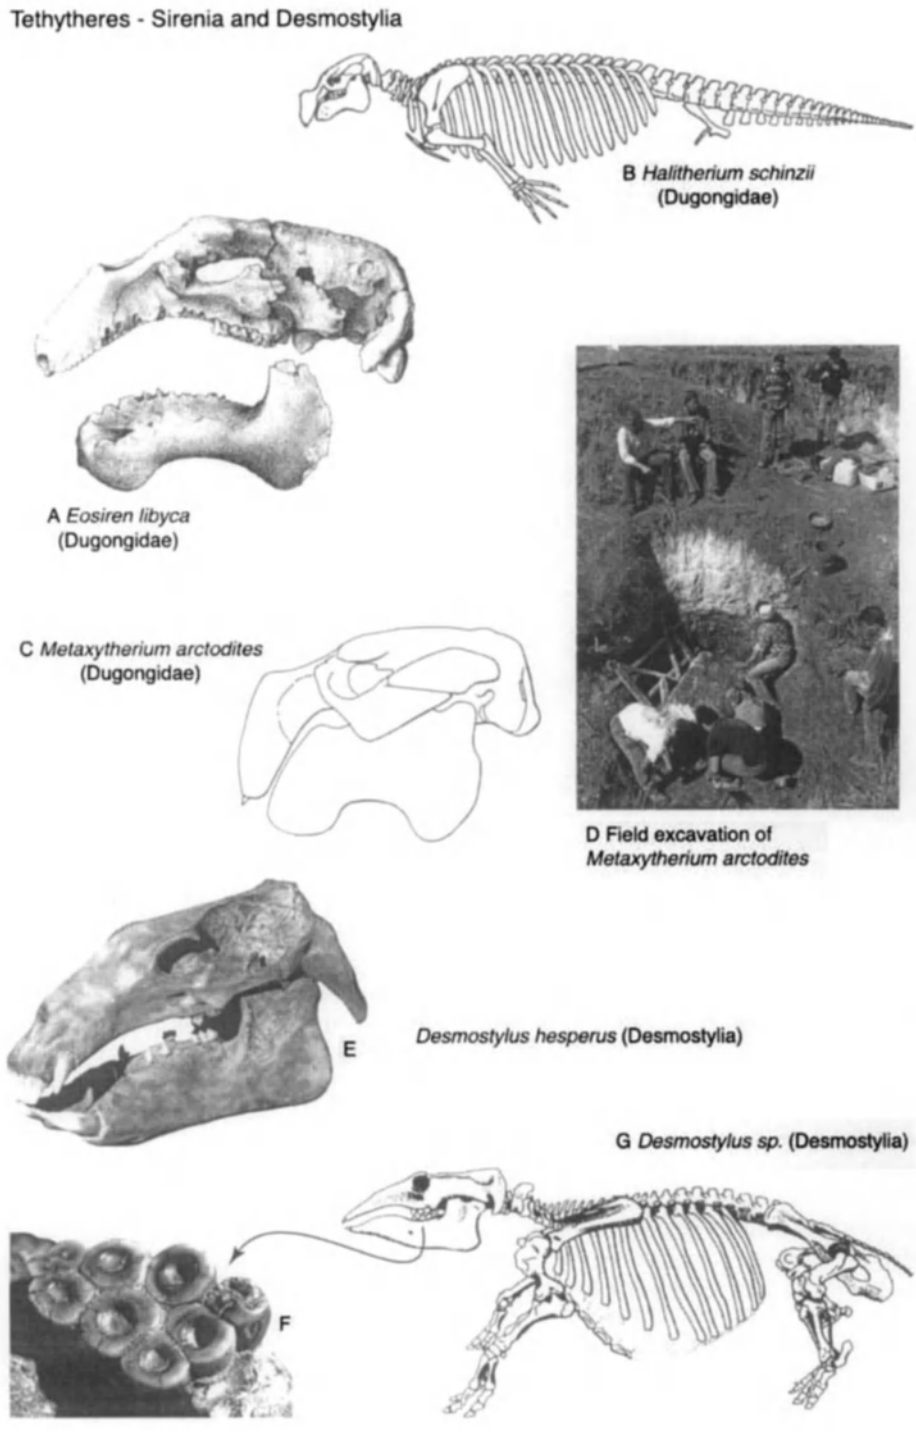

Figure 15 *Sirenians and desmostylians. (A) Skull of* Eosiren libyca *(Eocene, Egypt), lateral view, from Andrews (1906). cusps (*Desmostylus;* Fig. 15F). In 1953, they were placed in their own group, which is the only extinct order of marine mammals. Currently they are regarded as tethytheres allied with, but distinct from, Sirenia. Desmostylians have been interpreted as amphibious, HIPPOPOTAMUS-like, shallow-water mammals that fed on algae and seagrasses. They are known from subtropical to temperate coasts of North America and Japan, but did not range into the South Pacific.

The most archaic desmostylian is *Behemotops*, with a single species (*B. proteus*) based on mandibles and teeth of Late Oligocene age (~25–29 Ma) from Washington. *Behemotops* also occurs in Hokkaido, Japan. Tooth form in *Behemotops* is reminiscent of a group of terrestrial Asian tethytheres, the archaic proboscidians called Anthracobunidae.

Among the four other recognized genera, *Cornwallius* (Late Oligocene) and *Vanderhoofius* (Middle Miocene) are known only from western North America. Both species of *Desmostylus* (Early to Middle Miocene) (Figs. 15E–15G), which are distinguished on the basis of teeth and skulls, occur on both the eastern and the western coasts of the Pacific. Similarly, *Paleoparadoxia* (Early to Middle Miocene), with three to four species, also occurs on both Pacific coasts. Desmostylians have not, however, been reported from the Southern Hemisphere.

Unifying features for desmostylians include a skull with a long broad muzzle and prominent tusk, dorsally protruding eyes, a shortened neck, a broad sternum, and many details of the postcranial skeleton. The matter of body stance is contentious; it has been reconstructed, using skeletal form and fossilized posture, as reptilelike, with the limbs extended laterally. Alternatively, stance has been interpreted as the familiar quadrupedal form of mammals, with the body well off the ground and limbs more or less under the body. Irrespective of stance, desmostylians were probably large and slow moving on land and swam much like polar bears.

C. Edentata

One of the most unusual fossil occurrences is that of abundant ground sloths from marine Pliocene strata (~4 Ma) of Peru. The extinct marine sloth, *Thalassocnus natans*, is from a rich assemblage of marine vertebrates. Although the sloth shows no clearly obligate aquatic features, its structure would allow swimming comparable to that of otters. Because the adjacent Peruvian coast was a desert, the sloth probably ate seaweeds or seagrasses.

Fossil Sites

R. EWAN FORDYCE
University of Otago, Dunedin, New Zealand

Fossil marine mammals—Cetacea, Sirenia, Desmostylia, Pinnipedia, and other aquatic carnivores—are known from hundreds of sites worldwide (Fig. 1). In the 1800s most localities were in temperate northern latitudes, but since 1900 finds have spanned from modern tropics to poles, in both north and south and on all major continents. Usually, sites preserve marine sedimentary rocks, which have been exposed on land through sea-level fall and/or uplift, followed by erosion. There are negligible records (dredgings) from the deep ocean, but there are some important freshwater sites for secondarily nonmarine species. Clearly, fossils give only a rough and indirect guide to former distributions in ancient oceans. Sites vary from rich localized concentrations at sites a few tens of meters across, to scattered occurrences across many kilometers, which become significant at the regional level, and they range in age from Eocene to Pleistocene (Fig. 2). The case studies in this article, given in sequence from oldest to youngest, span all the major time intervals and oceans.

I. Role of Geological Processes

Marine mammal history has been affected by geological changes in oceans and climates during the last 50+ million (M) years. These changes ultimately reflect global tectonic processes. Continents are now relatively more emergent than for much of the past 50 M years, with less continental shelf and less extensive shallow continental sea than in the past. Most continents preserve coast-parallel strips of ancient marine rock now exposed on land. These may be extensive and a notable source of cetacean fossils (e.g., the Atlantic Coastal Plain of the eastern United States) or limited (e.g., most of Africa). Sometimes extensive shallow epicontinental seas onlapped the continents, as

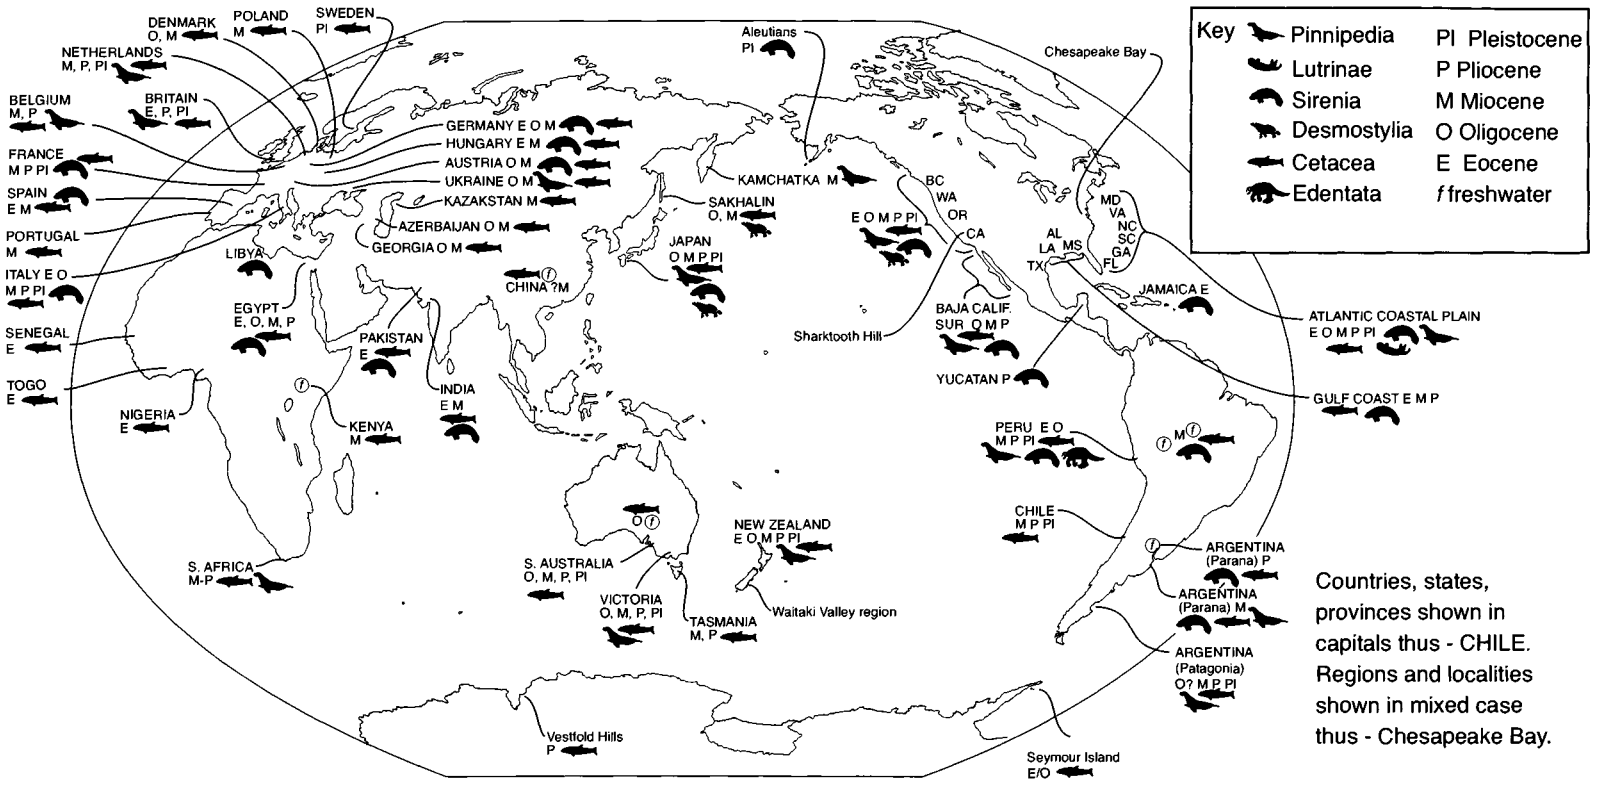

Figure 1 *Selected localities for fossil marine mammals.*

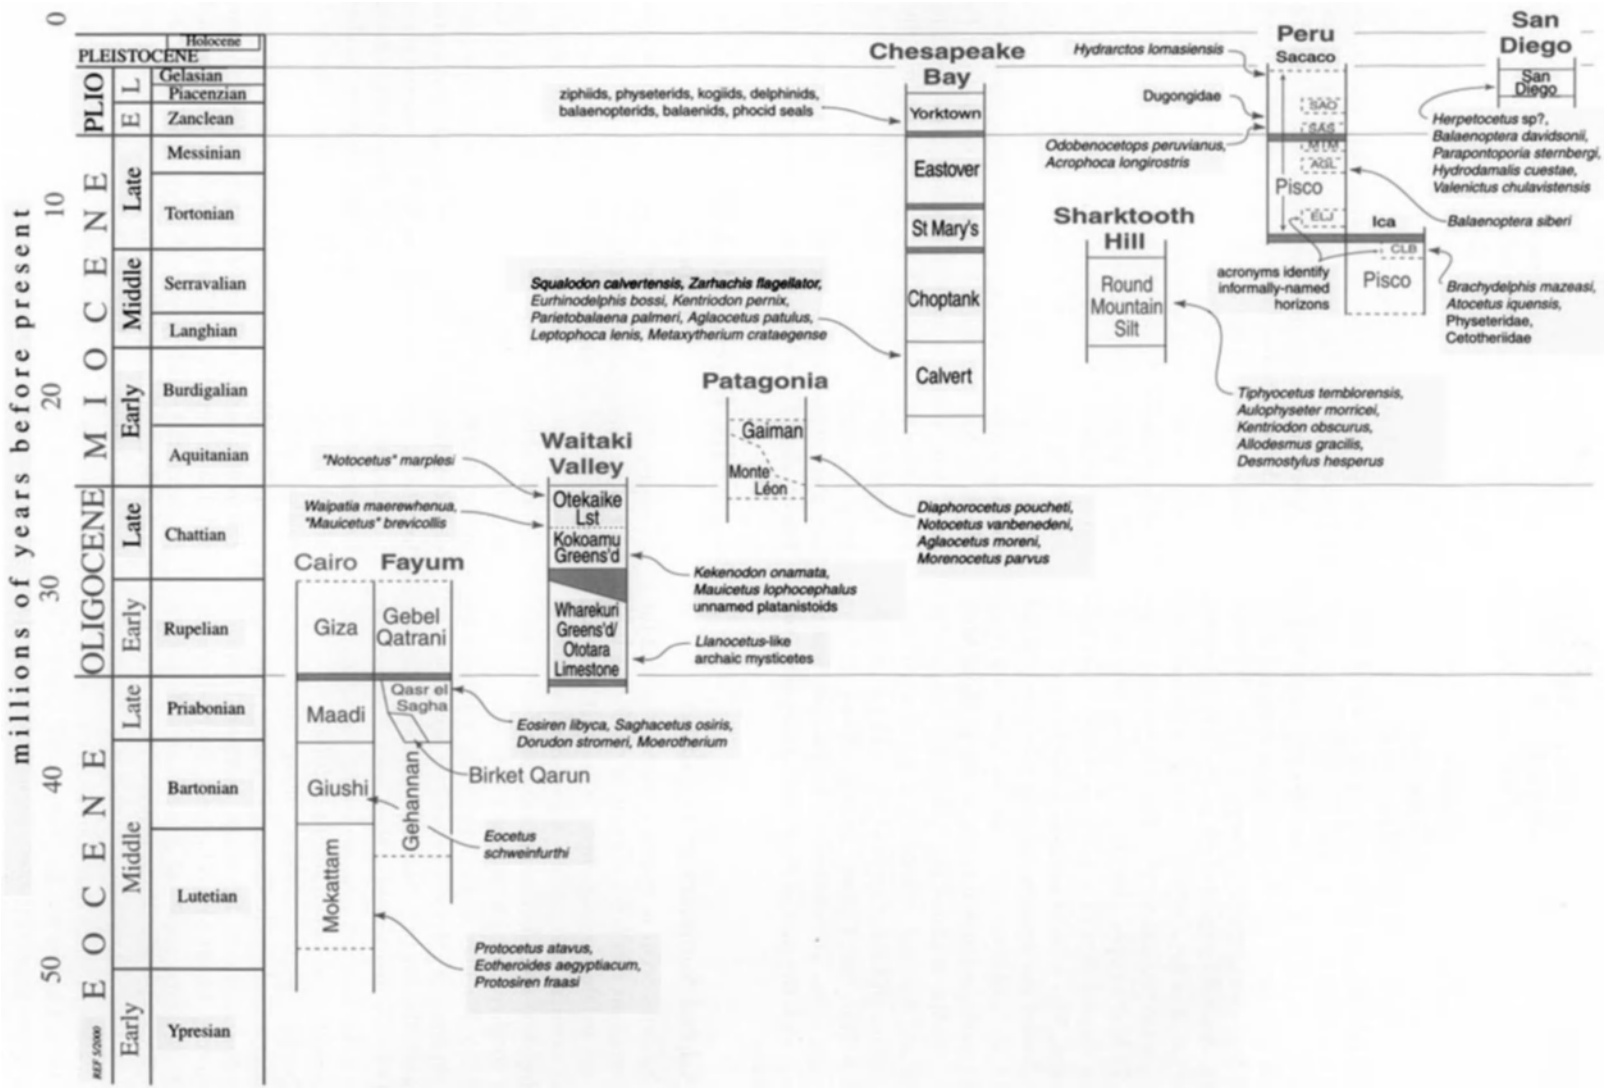

Figure 2 *Geological age ranges for key localities for fossil marine mammals, as discussed under case studies.*

in northern Europe and the Paratethys (see later). Major drops in sea level occurred about 30 million years before the present (Ma) and, associated with widespread glaciation and global cooling, since 2 Ma (major fluctuations).

When the first marine mammals appeared, the extensive shallow Tethys Sea stretched from the Pacific to about the modern Mediterranean. By the end of the Eocene, India had moved northward to collide with Asia, closing much of the Tethys. More western remnants of the Tethys, through what is now southern Eurasia, were eliminated in the Miocene, when Africa collided with Eurasia. Later, the Mediterranean dried out completely about 6 Ma, with dramatic consequences for the biota.

In the south, Australia moved north away from Antarctica opening part of the Southern Ocean by the end of Eocene time (34 Ma). Later, Antarctica and South America separated in the Oligocene (>23 Ma) to open the Drake Passage, which allowed the west to east flow of a newly developed Circum-Antarctic Current. This current isolated Antarctica thermally and probably allowed the Antarctic ice cap to expand, global climates to cool, and global oceans to become more heterogeneous. Australia continued to drift north, so that in about Middle Miocene (~15 Ma) it closed the Indopacific seaway between Australia and Asia and restricted equatorial circulation between the Indian and the Pacific Oceans. In the middle Pliocene (~3–4 Ma), the Panama Seaway closed, cutting Caribbean–Pacific links. The closure of the Panama Seaway correlates closely with the start of Northern Hemisphere continental glaciation.

II. Global Summary of Localities

Important localities occur in marine sequences around the modern Mediterranean, which is a remnant of the formerly extensive Tethys sea and the now-vanished Paratethys. Cetaceans, pinnipeds, and sirenians are notable. Italy has many sites of Pliocene to Oligocene age, whereas the most significant localities along the southern Mediterranean are in the Egyptian Eocene (see later). Paratethyan localities to the northeast include some in Austria (e.g., Miocene cetaceans), Hungary, (e.g., Eocene sirenians), Slovakia (e.g., Miocene pinnipeds), Croatia, Romania, and Ukraine and several in the Caucasus mountains and borders of the Caspian Sea, including Georgia (e.g., Oligocene cetaceans), Azerbaijan, and Kazakhstan.

Eastern North Atlantic faunas have come from Miocene–Pleistocene and, rarely, Eocene–Oligocene sequences bordering the North Sea, in Denmark, northern Germany, Poland, Sweden (e.g., Pleistocene cetaceans), the Netherlands, Belgium, North Sea dredgings, and Britain (e.g., Pleistocene cetaceans and pinnipeds). Eocene to Pliocene fossils from the western North Atlantic include many for Cetacea, Sirenia, pinnipeds, and sea otters in strata from the Atlantic Coastal Plain (from Delaware to Florida; see later) and Gulf Coast. The Caribbean has a few important sites (sirenians; Yucatan, Jamaica). Southwest Atlantic fossils from Argentina include cetaceans, sirenians, and pinnipeds from Oligocene–Miocene marine and Miocene–Pliocene nonmarine strata (see later). A few sites in the eastern tropical Atlantic have produced Eocene cetaceans (Nigeria, Senegal, Togo); the tip of South Africa has rich Pliocene bone beds, including cetaceans and pinnipeds; and cetacean bones have been dredged from near Cape Agulhas.

Bordering the Indian Ocean, Eocene Tethyan species from Pakistan and India represent ancient cetaceans, and less common sirenians. There are scattered reports of younger Cetacea. From Kenya comes a Miocene apparent freshwater beaked whale (Ziphiidae), and ziphiid rostra have been dredged from off Western Australia but, otherwise, there are no other significant described faunas from around the Indian Ocean.

A few regions around the Pacific, which was the largest ocean during cetacean history, have received concentrated attention. Japanese Neogene cetaceans, sirenians, desmostylians, and pinnipeds are well documented, and studies of Oligocene species are underway. There are only sporadic records of fossil marine mammals from further north in the Pacific (Sakhalin and the Aleutian chain). From the eastern North Pacific (Mexico to British Columbia; see later), Miocene–Pleistocene assemblages, including cetaceans, desmostylians, and pinnipeds, are well documented, but of hundreds of known Oligocene marine mammals, only a few species are described. Rich assemblages of Neogene marine mammals come from Peru (see later), with a few records from Chile. New Zealand assemblages, from the Southern Ocean margin, span from the Eocene to Quaternary, including important Oligocene material (see later). A scattered Oligocene to Neogene record from Australia also hints at the composition of Southern Ocean faunas. One Paleogene and one Pliocene site are known from Antarctica.

III. Eocene: Mediterranean/Tethys (Northern Egypt)

Eocene strata in northern Egypt, near Cairo, and southward at Fayum have produced fundamentally important archaeocete cetaceans and sirenians. Although assemblages are modest in terms of diversity, fossils are generally well preserved and may be quite abundant. The Cairo sequence, at Gebel Mokattam, is slightly older than that of Fayum. Recent work by Gingerich interpreted the fossiliferous strata in terms of changing sea levels interacting with shallow marine deposition at a passive continental margin. The sequences include marked unconformities caused by a lowered sea level. Paleoenvironments range from nonmarine (riverine; which has, however, produced sirenians) through estuarine, active shoreface, barrier bar, and shallow shelf.

At Gebel Mokattam, Cairo, the oldest unit comprises about 120 m of limestones of the Mokattam Formation, deposited in a shallowing marine shelf setting from 48 to ~41 Ma; this unit produced the widely cited archaic cetacean *Protocetus atavus* and early sirenians, including *Eotheroides aegyptiacum* (named by famous anatomist Richard Owen) and *Protosiren fraasi,* all about 46 Ma. From the overlying shallow marine Giushi Formation (30 m of limestone with shale, ~41 to 37 Ma) comes the archaeocete *Eocetus*. Significant marine mammals have not been described from younger units of Gebel Mokattam, but there are important assemblages in the Fayum.

In the south, Fayum marine strata span the Middle and Late Eocene (~43–43 Ma). Gehannan Formation limestone has yielded fossils of the sirenians *Eotherioides* and *Protosiren*,

and more or less articulated skeletons of the archaeocetes *Dorudon* (formerly *Prozeuglodon*) *atrox* and *Basilosaurus isis*, the latter known to have hindlimbs. Archaeocete skeletons are abundant at horizons interpreted as representing low stands of sea level and *Moeritherium*, an estuarine proboscidean, is present. The top of the Gehannan Formation varies in age according to locality. It is succeeded in places by barrier beach sands of the Birket Qarun Formation, a unit that has many archaeocete skeletons in the base. The youngest marine rocks at Fayum are lagoonal strata of the Qasr el Sagha Formation (~35–37 Ma). It has produced the sirenian *Eosiren libyca*, two dorudontine archaeocetes—the small *Saghacetus osiris* and larger *Dorudon stromeri*—and *Moeritherium*. Above this marine sequence, a sirenian has been found in Oligocene riverine strata of the Gebel Qatrani Formation.

The two Egyptian localities are important because they produced some of the earliest recognized archaic cetaceans and sirenians. The specimens—many of which are types (basic standards of reference)—include some of the youngest archaeocetes known, being close in age to the oldest crown-group Cetacea from about the Eocene/Oligocene boundary.

IV. Oligocene: Southwest Pacific (Waitaki Valley, New Zealand)

Thin marine Oligocene strata (23–33 Ma) (Fig. 3) in North Otago and South Canterbury, around the Waitaki Valley area, are a source of early "modern" Cetacea. Important localities include those near Oamaru, Duntroon, Wharekuri, and Hakataramea Valley, spanning some tens of kilometers. Notable earlier work is that of B. J. Marples on archaic mysticetes referred to *Mauicetus*. Most of the abundant modern finds are undescribed.

The Wharekuri Greensand (~12 m) and equivalents such as the Ototara Limestone have produced some of the few Early Oligocene (~33 to ~30 Ma) cetaceans known worldwide. These units are truncated by a major unconformity caused by sea level fall at ~30 Ma and are succeeded by the Kokoamu Greensand, a thin (usually <5 m), burrowed, shelly, sediment-starved unit. In turn, Greensand grades up over several meters into the massive bioclastic Otekaike Limestone (~50 m thick), which spans the later Late Oligocene (~26 Ma) to earliest Miocene (~23 Ma). Sediments accumulated mainly in a quiet setting below storm wave base in mid to outer shelf depths. Associated vertebrates include penguins, sharks, and bony fish, but no other marine mammals. Macroinvertebrates are locally abundant and probably caused the bioerosion seen on many bones. Cetaceans occur both as isolated bones and as skeletons (Fig. 4). The source units are often cemented, producing resistant outcrops so that excavations need pneumatic tools, are limited in scope, and mostly recover partial rather than whole skeletons.

Cetaceans from the Wharekuri Greensand include two presumed mysticetes, a large species showing severe vertebral pathology ("spina bifida" and periostitis), and a juvenile or neonate. Elsewhere, fragments from the Ototara Limestone include a small *Llanocetus*-like toothed archaic mysticete. Mysticetes from the overlying Kokoamu Greensand include enigmatic and rare archaic toothed forms such as *Kekenodon*

Figure 3 *Outcrop of Earthquakes Marl, Kokoamu Greensand, and Otekaike Limestone, Waitaki Valley region, New Zealand. Otekaike Limestone here is about 10 m thick. Photo by R. E. Fordyce.*

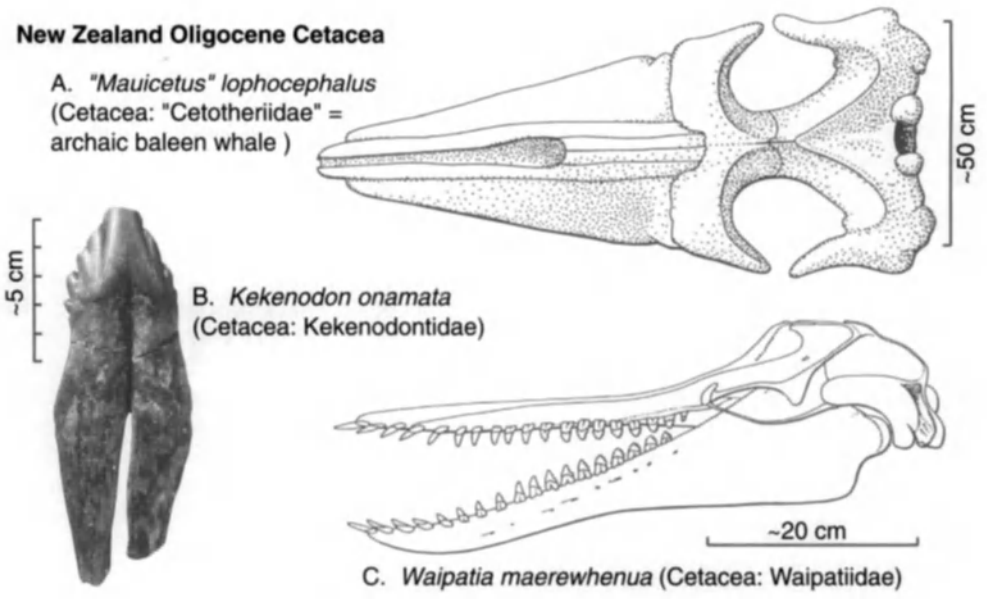

Figure 4 *Oligocene Cetacea from New Zealand. (A) Skull of cetacean* "Mauicetus" lophocephalus, *dorsal view, after Marples. (B) Tooth of cetacean* Kekenodon onamata; *photo by R. E. Fordyce. (C) Skull and mandible of cetacean* Waipatia maerewhenua, *lateral view, after Fordyce and Barnes (1994).*

onamata (formerly misidentified as an archaeocete), *Mammalodon*-like species, and an unnamed species with teeth reminiscent of the odontocete *Squalodon*. More common baleen-bearing whales include the enigmatic *Mauicetus lophocephalus*, which is one of the older global records of a toothless mysticete, and other fossils more closely matching cetotheres in the traditional sense. Odontocetes from the lower to middle Kokoamu Greensand mostly belong in the Platanistoidea. They include species of Squalodontidae and provisionally identified Waipatiidae, Squalodelphinidae, and Dalpiazinidae; all are unnamed new species. There are no true dolphins (e.g., Kentriodontidae) from lower in the Greensand.

Cetaceans appear less common but are better preserved in the uppermost Kokoamu Greensand and overlying Otekaike Limestone. No species identified from the underlying Greensand is known to occur in the Limestone. Mysticetes include unnamed species of "*Mauicetus*" and other cetotheres in the broad sense. Odontocetes are mainly rare but well-preserved platanistoids, including new species of Squalodontidae, the small *Waipatia* (Waipatiidae), "*Microcetus*" and *Notocetus* (both Squalodelphinidae), and undescribed Dalpiazinidae. Tantalizing fragments of an archaic delphinoid (not a kentriodontid) and a sperm whale are known. There are notable absences, including the mysticete group Aetiocetidae, archaic odontocetes comparable to *Agorophius* and *Xenorophus*, Eurhinodelphinidae, and beaked whales (Ziphiidae).

Overall, small to medium-sized mysticetes dominate assemblages, with small odontocetes also conspicuous. The shallow broad seaway could have been a breeding ground for mysticetes from the recently developed Southern Ocean ecosystem south of New Zealand. Why platanistoids are common but delphinoids and sperm whales are rare is not clear. Perhaps the shallow seaway was only rarely inhabited by more oceanic or deep-diving species of delphinoids and sperm whales.

The assemblages reinforce the idea that the Oligocene was a time of structural/ecological experiment. Species were scattered more evenly among diverse family level taxa. In contrast, for extant cetaceans, a few families account for most of the species diversity. Some of the better-preserved fossils will help resolve cladistic relationships of extant Cetacea, thus providing an independent standard against which to compare molecular classifications. Revised classifications should also help quantitative zoogeography. Meanwhile, qualitative comparisons suggest a faunal composition more similar to that of the Caucasus than of the Atlantic Coastal Plain or northeast Pacific. Only archaic-toothed mysticetes hint at trans-Pacific links.

V. Miocene: Southwest Atlantic (Patagonia)

Strata of the "Patagonian" marine stage in Santa Cruz, Chubut, and Rio Negro Provinces of southern Argentina have produced Early Miocene Cetacea, which include some of the oldest described representatives of modern families (Fig. 5). These fossils are from the Gaiman and Monte Leon Formations and represent the Leonian local stage, Early Miocene, and possibly latest Oligocene. The strata represent shallow-water settings, in which age-diagnostic microfossils are uncommon, and exact international correlations are uncertain. The Chubut River region has provided the main described material. Other marine mammals, e.g., Sirenia, pinnipeds, are unknown. More than a century of basic taxonomy includes work by Moreno, Lydekker, True, Cabrera, and Kellogg, with significant modern contributions from Cozzuol and de Muizon. Conse-

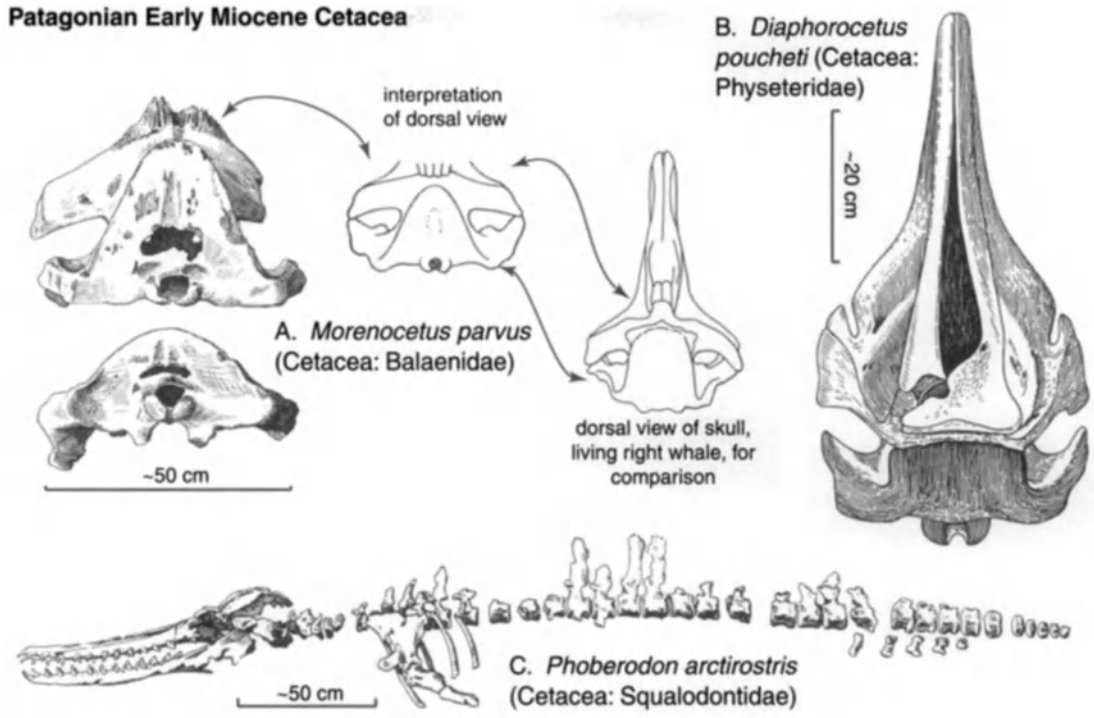

Figure 5 *Miocene Cetacea from Patagonia. (A) Skull of cetacean* Morenocetus parvus, *dorsal and posterior views and interpretive dorsal view (all from Cabrera, 1926), and interpretive view of skull of a living right whale (after Van Beneden and Gervais, 1868–1880). (B) Skull of cetacean* Diaphorocetus poucheti, *dorsal view, from Raven and Gregory (1937). (C) Skeleton of cetacean* Phoberodon arctirostris, *lateral view, from Cabrera.*

quently, the fossils have been cited widely and are entrenched in the literature.

Among the Early Miocene Cetacea, the small *Morenocetus* is the world's oldest described right whale. The rostrum is not known, but other skull features indicate that *Morenocetus* is a balaenid. Of less certain relationships are the "cetotheres" *Aglaocetus* and "*Plesiocetus*," also known from skulls. Skull form is quite different between these mysticetes, indicating quite different habits.

Odontocetes are notably more diverse and include some of the best-known early sperm whales: the small *Diaphorocetus* and the much larger *Idiorophus*. Both are archaic in appearance, retaining upper teeth with obvious enamel and a narrow anterior on the rostrum. Archaic platanistoid odontocetes are significant, including rather complete material for the large and long-beaked shark-toothed dolphin *Phoberodon* (Squalodontidae) and the short-beaked *Prosqualodon*. *Prosqualodon* is also present in New Zealand and Australia; it has been variably placed in the Squalodontidae or its own group Prosqualodontidae, in turn dubiously allied with the true dolphins (Delphinida). A third group of platanistoids, the Squalodelphinidae, is represented by *Notocetus*, in turn important in refining the higher classification of the Platanistoidea. *Notocetus*-like odontocetes also occur in New Zealand pointing, as for *Prosqualodon*, to a Southern Ocean distribution. The distribution pattern for *Notocetus* and squalodelphinids also includes the North Atlantic and Mediterranean. The eurhinodelphinid *Argyrocetus* shows extreme lengthening of the rostrum; this genus occurs in contemporaneous strata in California. True dolphins (Delphinida) are rare, represented by the kentriodontid *Kentriodon*.

Patagonian cetaceans indicate the start of "modern" ecological structuring (e.g., deep-diving sperm whales, skim-feeding balaenids). They also reveal distribution patterns (e.g., circum-Southern Ocean) seen among living cetaceans.

VI. Miocene: Northwest Atlantic (Chesapeake Bay)

Flat-lying strata of the Chesapeake Group exposed around the western shores of Chesapeake Bay, in Maryland (Fig. 6) and Virginia, have been an important source of Miocene and Pliocene marine mammals for over 150 years. Fossil cetaceans, sirenians, and phocid seals are present (Fig. 7). Early studies on these fossils were made in the 1800s by the pioneering vertebrate paleontologists Harlan, Leidy, and Cope. Later, F. W. True (early 1900s) and A. R. Kellogg (1920s to 1960s) produced such detailed descriptions of taxa such as *Delphinodon*, *Squalodon* and *Parietobalaena* that the Chesapeake fossils have become international standards of comparison. Significant collections are held in the Smithsonian Institution.

Marine mammals occur in five formations of the Chesapeake Group: Calvert (Early to Middle Miocene) (Fig. 6), Choptank (Middle Miocene), St. Mary's (later Middle Miocene), Eastover (Late Miocene), and Yorktown (Pliocene). These are mainly fine-grained and shallow-water deposits

Figure 6 *Outcrop of Calvert Formation, north of Scientists Cliffs, Maryland. Photo by R. E. Fordyce.*

deposited in climate regimes that ranged from subtropical early in the Miocene (~17 Ma) to near-modern in the Pliocene (~4.5 Ma). Strata are soft so that fossils can be collected easily. The fossils are often preserved well, with fine sutural detail present and only limited crushing. Material ranges from single worn bones to nearly complete skeletons.

Fossils from the Calvert Formation are important in revealing faunal composition around the Early to Middle Miocene boundary. Among the diverse cetaceans, odontocetes include species in three families of Platanistoidea: the shark-toothed dolphins, Squalodontidae (*Squalodon*), Squalodelphinidae (*Phocageneus, Notocetus*), and Platanistidae (*Zarhachis, ?Pomatodelphis*). At least 2 and possibly more than 10 species of the long-snouted enigmatic Eurhinodelphinidae occur (*Eurhinodelphis, "Rhabdosteus"*). True dolphins—Delphinoidea—are placed in the archaic grade family Kentriodontidae (*Kentriodon, Macrokentriodon, Delphinodon, Liolithax,* and *Hadrodelphis*). There is a small sperm whale, Physeteridae (*Orycterocetus*), and various extinct dolphins of uncertain affinities (*Tretosphys, Araeodelphis,* and *Pelodelphis*). Five genera of mysticetes represent the paraphyletic and possibly polyphyletic family Cetotheriidae (*Parietobalaena, Mesocetus, Diorocetus, Aglaocetus,* and *Pelocetus*). Other marine mammals are markedly rare in the Calvert Formation. Phocid seals, known mostly from isolated elements but also from rare partial skeletons, form the basis for the phocine *Leptophoca* and a species of the monachine *Monotherium*. Sea cows include the extinct dugongid sirenian *Metaxytherium crataegense*, which also occurs in the Pacific (Montera Formation, Peru), indicating movement presumably through the Central American Seaway.

Marine mammal assemblages from the Chesapeake Group reveal marked faunal change over time. Archaic cetaceans from the Calvert Formation, such as eurhinodelphinids, squalodontids, and squalodelphinids, are rare or absent in overlying (younger) units, whereas extant families such as the Delphinidae and Balaenopteridae become significant by the Pliocene. Concurrently, species level diversity drops, and ecological shifts are indicated particularly by the absence of squalodontids and long-snouted eurhinodelphinid dolphins.

South of Chesapeake Bay, strata of the lower Yorktown Formation (Early Pliocene, ~4.5 Ma) at Lee Creek Mine, North Carolina, have produced thousands of isolated marine mammal bones, expanding the fauna beyond the Yorktown at Chesapeake Bay. Fossils include ziphiids, physeterids, kogiids, delphinids, balaenopterids, balaenids, and phocid seals. Unusual elements include monodontids (now found only at high latitudes) and pontoporiids (now restricted to the South Atlantic). Similar assemblages occur in the San Diego and Pisco Formations (see later).

Strata of Chesapeake Group, especially the Calvert Formation, are one of the world's richest sources of fossil marine mammals. The abundance of young animals could reflect favorable conditions for calving or, equally, a high mortality for young individuals.

VII. Miocene: Northeast Pacific (Sharktooth Hill, California)

The Sharktooth Hill bone bed (Fig. 8) of Kern County, in the foothills of the Sierra Nevada, California, is one of the most important horizons for marine mammal fossils in the Pacific Basin. The assemblage includes more than 100 marine vertebrates documented thoroughly by Kellogg, Mitchell, Barnes, and others. Cetaceans, pinnipeds, rare desmostylians, and terrestrial vertebrates occur abundantly in, and less commonly above, a thin (10–30 cm) dense, and geographically widespread layer near the top of the Round Mountain Silt (Temblor Formation, Middle Miocene). This bone bed formed over thousands of years, about 13–14 Ma; it represents a mix of taxa from different environments. Most fossils are isolated bones, but sometimes there are natural associations of bones from one individual. Preservation varies; bones may be finely preserved or eroded, and sometimes with marks caused by scavengers or predators.

Cetaceans dominate the assemblage. Mysticetes comprise four cetotheres (*Aglaocetus, Parietobalaena, Peripolocetus,* and *Tiphyocetus*) known from partial skulls and a possible right whale (undetermined Balaenidae). Among odontocetes, sperm whales (Physeteridae) include the moderate-sized *Aulophyseter.* The taxonomy of the smaller odontocetes is less certain, for Kellogg based several new species and genera on isolated periotics, which, in some cases, have been linked to later-discovered SKULLS. The latter represent a long-beaked platanistid-like dolphin (*"Squalodon" errabundus*) and species in the archaic delphinoid group Kentriodontidae (*Kentriodon, Kamptholophos*). Several named species of odontocete are still enigmatic (e.g., species of *Oedolithax* and *Lamprolithax*). In terms of ecological composition, cetaceans are comparable to faunas in Californian waters today.

Otariid (or otarioid) pinnipeds are significant and include the types for some species or genera. They are the small ar-

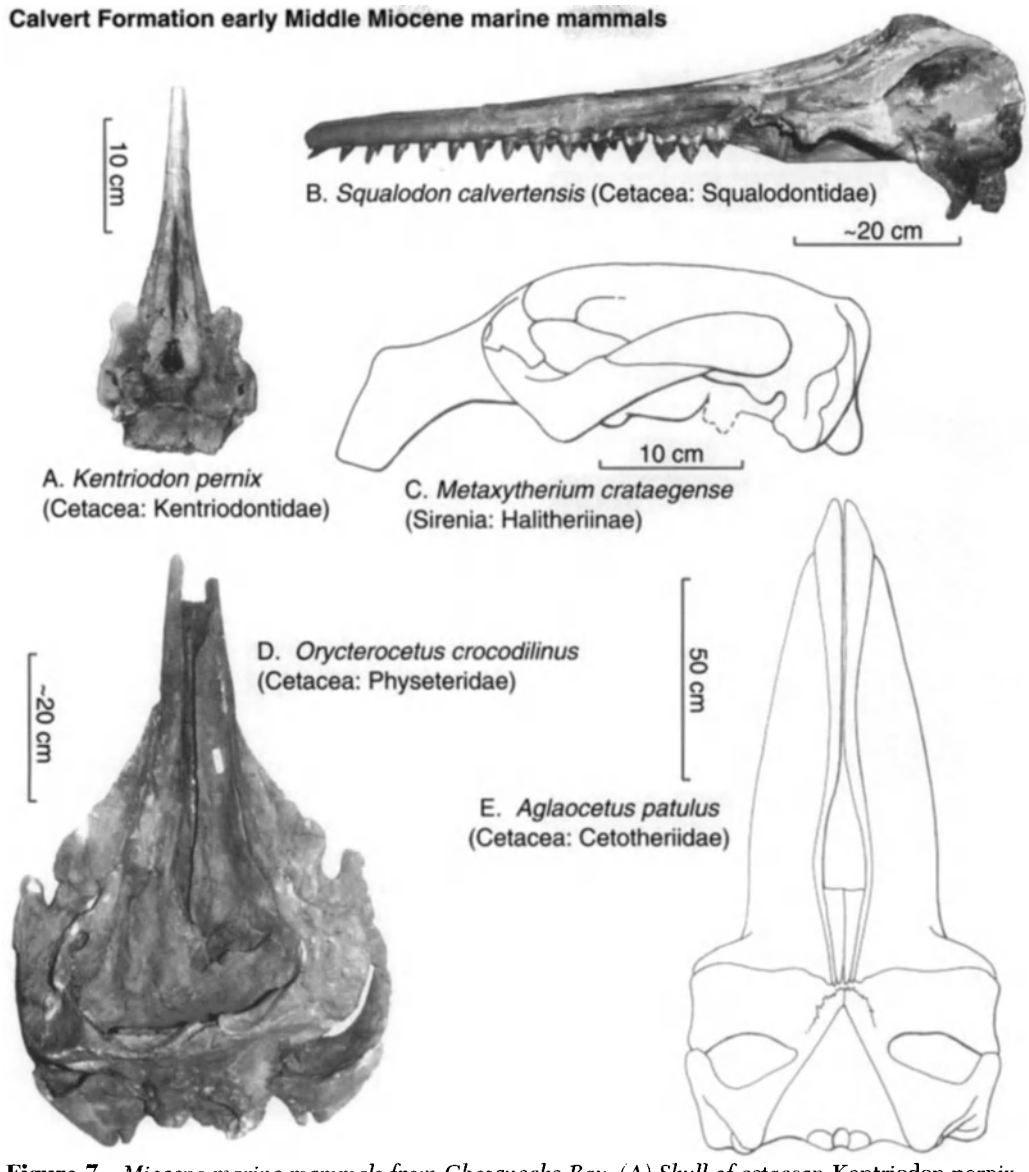

Figure 7 *Miocene marine mammals from Chesapeake Bay. (A) Skull of cetacean* Kentriodon pernix, *dorsal view (paratype), photo by R. E. Fordyce. (B) Skull of cetacean* Squalodon calvertensis, *lateral view, photo by R. E. Fordyce. (C) Skull of sirenian* Metaxytherium crataegense, *lateral view, after Kellogg. (D) Skull of cetacean* Orycterocetus crocodilinus, *dorsal view, photo by R. E. Fordyce. (E) Skull of cetacean* Aglaocetus patulus, *dorsal view, after Kellogg (1968,* U.S. Nat. Mus. Bull. *247).*

chaic imagotariine *Neotherium*, three species of the large *Allodesmus* (including the rare type-species *A. kernensis* and more common *A. gracilis*), the large rare *Pelagiarctos*, and two unnamed "desmatophocines." No phocids have been identified. Of other marine mammals, sirenians have not been reported, but fragmentary desmostylians occur.

There are conspicuous faunal similarities with the slightly older assemblage from the Calvert Formation of Maryland and Virginia, western North Atlantic; for example, *Parietobalaena* and *Kentriodon* are reported for both places. Differences are also marked; phocid seals and squalodontid and eurhinodelphinid odontocetes are absent from the Sharktooth Hill bone bed.

VIII. Mio-Pliocene: Southeast Pacific (Peru)

Since the early 1980s, de Muizon has documented diverse later Miocene and Pliocene marine mammals (Fig. 9), including some quite surprising ecotypes, from the Pisco Formation of the southern coast of Peru. Rich localities are around Sacaco,

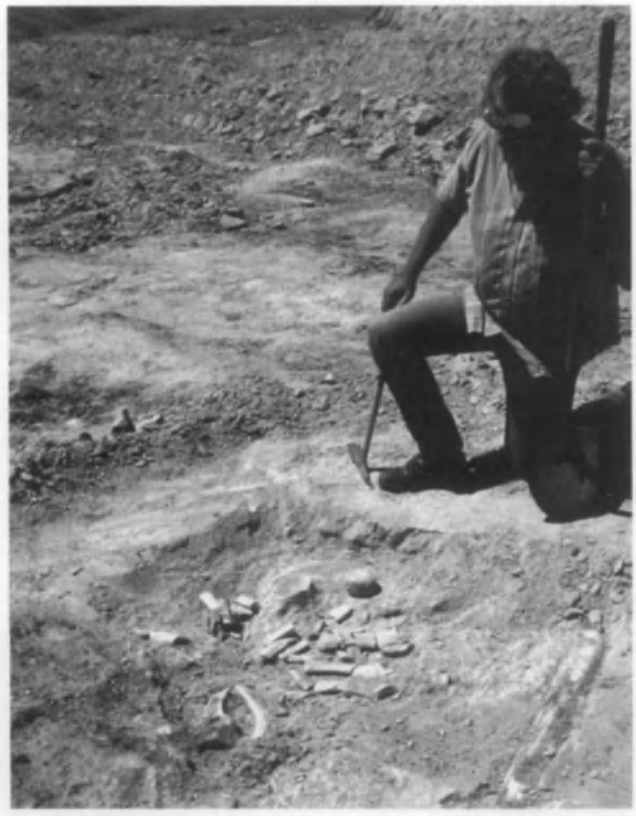

Figure 8 *Outcrop of Round Mountain Silt, Sharktooth Hill, California. L. G. Barnes is looking at cetacean remains, including part of a cetothere. Photo by R. E. Fordyce.*

near Lomas, where well-preserved skeletons of cetaceans and pinnipeds occur, and Ica, to the north. Pisco strata include sandstone, siltstone, and occasional conglomerate, sometimes volcanic rich, with marine invertebrates and bone-rich horizons. Settings are intertidal, barrier bar, and lagoonal; these environments were mostly protected from the open Pacific, perhaps by rocky promontories. The sequence of vertebrate faunas is not in doubt (Cerro la Bruja at the base, Sacacao at the top), but age determination is difficult because the Pisco Formation mostly lacks fossils useful in international correlation.

Odontocete cetaceans are the most diverse marine mammals. The oldest productive Pisco horizon, Cerro la Bruja, may be of late Middle Miocene age (>11 Ma); if so, its odontocetes include an early record for the Pontoporiidae or franciscanas (the peculiarly short-beaked *Brachydelphis*). Other younger Miocene horizons provide early records of porpoises (Phocoenidae: *Australithax*, *Lomacetus*, and *Piscolithax*) and pygmy sperm whales (Kogiidae, narrow-skulled *Scaphokogia*), accompanied by archaic dolphins (Kentriodontidae: *Atocetus*, *Belonodelphis*, and *Incacetus*), beaked whale (Ziphiidae), and sperm whales (Physeteridae). Younger assemblages, from Pliocene horizons within the Pisco Formation, are similar in taxonomic structure, containing pontoporiids (*Pliopontos*), porpoises (*Piscolithax*), ziphiids (*Ninoziphius*), sperm whales (Physeteridae), and kentriodontids, but also more modern dolphins (Delphinidae) and an unnamed beluga-like species (Delphinapterinae). The most peculiar Pliocene odontocetes are two species of the extinct tusked *Odobenocetops*. These animals, reported only from the Pisco Formation, have secondarily lost many of the distinctive facial features of odontocetes.

Mysticeti from the Pisco Formation include two cetotheres and up to six balaenopterids for which few details are published. Species briefly described and named by Pilleri include the small cetothere, *Piscobalaena*, the larger *Piscocetus* (Cetotheriidae?), and an extinct *Balaenoptera* (Balaenopteridae). Several specimens of balaenopterids preserve baleen plates *in situ* on the skull.

Up to nine species of phocid seals (Phocidae) are present. Two lobodontines, the *Monachus*-like *Piscophoca pacifica* and long-skulled *Acrophoca longirostris*, are known from well-preserved fossils, including articulated skeletons. From the relatively barren upper Pisco Formation comes the unique specimen of an extinct fur seal, *Hydrarctos* (Otariidae: Arctocephalinae), which is probably Late Pliocene. There is a single record of a sirenian, probably close to *Dugong*, from Early Pliocene lagoonal deposits. Despite the unexpected occurrence, it seems certain that the extinct Pisco sloth *Thalassocnus* really was a marine mammal. Fossil sloths occur in the five main levels at Sacaco, they are abundant, there are no other putative land mammals in the vertebrate assemblage, and the adjacent coast was a desert.

Pliocene assemblages from the Pisco Formation include cetaceans and pinnipeds similar to those from the Yorktown Formation of the Chesapeake Group, North Atlantic, indicating contact through the Central American Seaway before the uplift of Panama. Several genera also occur at Isla Cedros, Baja California Sur. When considered with roughly contemporaneous assemblages from elsewhere in the eastern Pacific (Isla Cedros; also San Diego) and contrasted with modern communities, it seems that there must have been considerable faunal turnover late in the Pliocene or in the Pleistocene.

IX. Plio-Pleistocene: Northeast Pacific (San Diego, California)

Well-preserved geologically young marine mammals—from the later Pliocene and earlier Pleistocene—are rare, but important in revealing marine mammal ecology before the dramatic climate shifts and sea level change of the Pleistocene glaciations. One notable sequence is the ~84 m of San Diego Formation at and near San Diego, southern California. This sandy to gravelly unit was deposited late in the Pliocene (2–3 Ma) and possibly Pleistocene (>1.5 Ma) in settings mostly from shoreface to mid- and outer shelf. The lower finer strata with abundant fossils are marine, whereas the coarser and sparsely fossiliferous upper strata are partly nonmarine. The formation contains many marine mammals that are now extinct, including some whose descendants live in quite different settings today.

Pinnipeds, Cetacea, and Sirenia are present, including many complete enough to identify to species level. The pinnipeds include Otariidae (an extinct species of *Callorhinus* and an unnamed genus) and Odobenidae—the extinct long-tusked walrus *Valenictus*. *Dusignathus*, also present, has been allied variously with walruses or identified as a "pseudo-walrus"; there are no phocids.

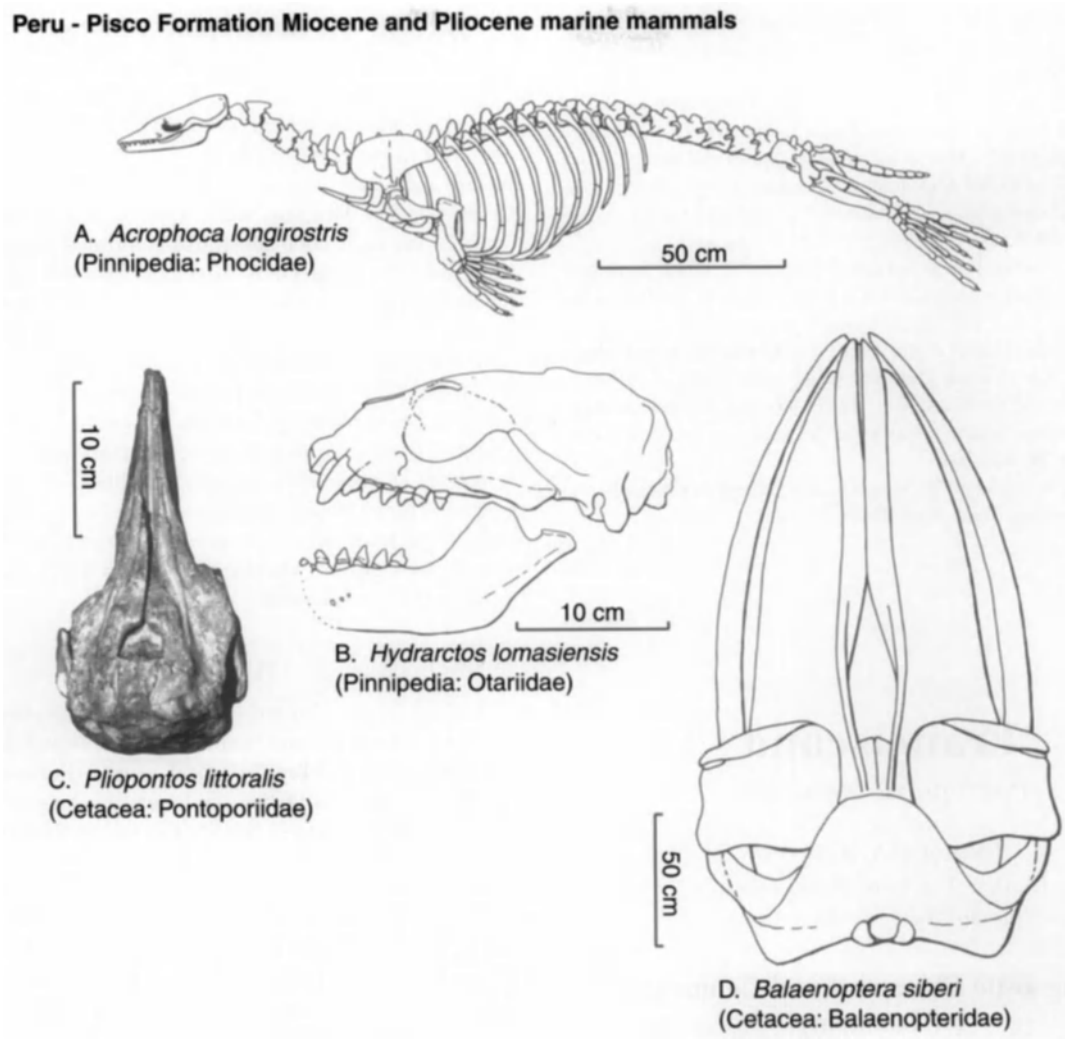

Figure 9 *Miocene and Pliocene marine mammals from Peru. (A) Skeleton of pinniped Acrophoca longirostris, lateral view, after de Muizon (1985). (B) Skull of pinniped Hydrarctos lomasiensis, lateral view, after de Muizon (1978,* Bull. d'Inst. Fr. d'Etud. Andines *7). (C) Skull of cetacean Pliopontos littoralis, dorsal view, photo by R. E. Fordyce. (D) Skull and mandibles of cetacean Balaenoptera siberi, dorsal view, after Pilleri (1989).*

Three families of mysticetes include two species of the cetothere *Herpetocetus,* providing one of the last records of Cetotheriidae *sensu stricto.* The extinct minke whale *Balaenoptera davidsonii* is one of five rorquals (Balaenopteridae), and there are two right whales (Balaenidae). Among odontocetes, the long-beaked *Parapontoporia* has been regarded as one of the last marine Pontoporiidae or, alternatively, a marine relative of the endangered Yangtsze dolphin *Lipotes.* Other odontocetes are two porpoises (Phocoenidae), a beluga-like animal (Delphinapterinae), and two dolphins (Delphinidae, including *Stenella* or *Delphinus*). The huge sirenian *Hydrodamalis cuestae* appears to be a direct ancestor to the recently exterminated *Hydrodamalis gigas,* Steller's sea cow, of the cold North Pacific.

These fossils imply a major shift in geographic range and/or ecology in geologically recent times: walruses (now only one species, of *Odobenus*) and belugas currently live in cold northern waters, as *Hydrodamalis,* also did until a few hundred years ago. Descendants of *Parapontoporia* have left the eastern Pacific, and cetotheres are extinct.

Franciscana

Pontoporia blainvillei

ENRIQUE A. CRESPO
Centro Nacional Patagónico, Puerto Madryn, Argentina

I. Diagnostic Characters and Comments on Taxonomy

The franciscana (*Pontoporia blainvillei*) is also known as the La Plata River dolphin. In Uruguay and Argentina it is called *franciscana* whereas in Brazil it is called *toninha* or *cachimbo*. While both this species and the Yangtze river dolphin, *Lipotes vexillifer*, were until recently regarded as of the family Pontoporiidae, the franciscana is now the sole member of this family. The franciscana is the only one of the four river dolphin species living in the marine environment. It is one of the smallest dolphins and has an extremely long and narrow beak and a bulky head. The franciscana is brownish to dark gray above turning lighter on the flanks and belly (Fig. 1). The number of teeth in the upper and lower jaws ranges from 53 to 58 and from 51 to 56, respectively.

II. Distribution/Range Map

The species is endemic in southwestern Atlantic waters. Based on the distribution of sightings and catches, the franciscana lives in a narrow strip of coastal waters beyond the surf to the 30 m isobath (Fig. 2). The complete range known for the franciscana extends from Itaúnas (18°25′S, 39°42′W) in Espirito Santo, Brazil, to the northern coast of Golfo San Matías (41°10′S) in northern Patagonia, Argentina.

III. Geographic Variation

Skull morphology, genetic markers, and parasites have been used to identify stocks. The existence of two potential populations was tested by means of the differences in skull morphology. A northern (smaller) form was proposed between Rio de Janeiro and Santa Catarina, and a southern (larger) form for Rio Grande do Sul, Uruguay, and Argentina. The existence of differences between populations was confirmed some years later using mitochondrial DNA from samples collected at Rio de Janeiro and Rio Grande do Sul. It was found that six exclusive haplotypes were present in the northern population and 5 in the southern one, indicating some degree of segregation between the stocks. Gastrointestinal parasites were also used as bioindicators in order to study the existence of stocks in franciscana. The PARASITES seem to indicate segregation into two functional or ecological stocks between southern Brazil–Uruguay and Argentina. Three species of parasites were recommended as biological tags [*Hadwenius pontoporiae*, *Polymorphus* (*P*) *cetaceum* and *Anisakis typica*]. On the basis of this information, at least three stocks or populations could exist.

IV. Ecology

Little is known about the northern stock or population, between Espirito Santo and Santa Catarina, a region that is under the influence of the Brazil tropical current. Between southern Brazil and Golfo San Matías, the franciscana lives in a transition zone in which the surface circulation of the southwestern Atlantic is dominated by the opposing flows of subtropical and sub-Antarctic water masses. The coastal marine ecosystem is characterized by continental runoffs with a high discharge of high-nutrient river flows (e.g., Lagoa dos Patos, Río de la Plata). Juvenile sciaenids, the most important prey of the franciscana, are typically associated with those continental runoffs and the influence of subtropical shelf waters. The franciscana feeds mostly near the bottom on fishes of several families, such as sciaenids, engraulids, batrachoidid, gadids, carangids, and atherinids. However, sciaenids account for most of the fish species. The DIET also includes squids, octopus, and shrimps. The franciscana feeds on the most abundant species in the region and seems to change its diet according to seasonal prey fluctuations. A comparison of results between two studies carried out 15 years apart in Rio Grande do Sul showed shifts in prey composition in which important prey of the former period were depleted in artisanal fisheries. Among predators, remains of franciscanas were found in stomach contents of killer whales and several species of sharks.

V. Behavior

Very little is known about the behavior of free-ranging franciscanas, in part because they are difficult to observe in the wild and in part as a consequence of low sighting effort. The franciscana is thought to be solitary or not gregarious. Herd size may range from 2 to 15 individuals. In aerial surveys carried out in southern Brazil with the objective of estimating abundance, 37 sightings gave a mean herd size of 1.19 (SD: 0.47, range: 1–3). A study of wild behavior at Bahía Anegada in southern Buenos Aires Province showed a seasonal pattern with cooperative FEED-

Figure 1 *Lateral view of a 137.5-cm adult female franciscana.*

ING, with traveling activities increasing during winter and high tide. The mean swimming speed was estimated in 1.3 m/sec (±0.09) with a maximum of 1.8 m/sec, and mean dive duration was estimated in 21.7 sec (±19.2) (range from 3 to 82 sec).

VI. Notable Anatomy, Physiology, Life History

Females are larger than males. Adult females range between 137 and 177 cm in total length whereas males range between 121 and 158 cm. The weight of mature females ranges between 34 and 53 kg and that of males ranges between 29 and 43 kg. Neonates in Uruguay range in size between 75 and 80 cm, whereas in southern Brazil they range between 59 and 77 cm (some of the smaller neonates could be near-term fetuses). Neonates weigh around 7.3 to 8.5 kg. Age at sexual maturity was estimated to be 2.7 years, and the gestation period is between 10.5 and 11.1 months. Females gave birth around November and lactation lasts for 9 months. However, calves take solid food around the third month, weighing between 77 and 83 cm. Mating seems to occur in January and February. The calving interval is around 2 years; nevertheless, few females

Figure 2 *Distribution range of the franciscana dolphin in the southwestern Atlantic Ocean. The shaded area represents the area inside the approximate 30-m isobath.*

were found lactating and pregnant at the same time. Reproductive capacities and life span are low for the species, which is a problem for the population to sustain the mortality rates caused by fisheries. Longevity has been estimated close to 15 years for males and 21 for females, fairly low when compared to most of the small cetaceans. Few individuals attain ages over 10 years. Three types of acoustic signals have been recorded, including low, high, and ultra high frequency clicks.

VII. Fossil Record

Three records have been related to the franciscana and assigned to the family Pontoporiidae: *Brachidelphis mazeasi*, a middle miocene fossil from the Pisco Formation (Perú); *Pontistes rectifrons*, a late miocene fossil found in the Paraná Formation (Argentina); and *Pliopontos littoralis*, a pliocene fossil closely related to the living species described for the Pisco Formation (Perú).

VIII. Interactions with Humans

Incidental catches in gill nets, mostly of juvenile individuals, became a serious problem for the species throughout its distribution range probably since the end of World War II. At that time, many artisanal fisheries for sharks developed in the region for vitamin A production, which was exported to Europe. During the 1970s, gill net mortality in Uruguay was estimated at above 400 individuals/year and fell to around 100 individuals/year in the last few years for economic reasons. Nevertheless, minimum mortality rates were always estimated at several thousands of individuals throughout the distribution range. At present, higher mortality rates are shown by the fisheries at Rio Grande do Sul and Buenos Aires Province, where no less than 700 and 500 are, respectively, incidentally taken. The estimated mortality for the whole distribution range could be no less than 1500 individual per year. It is not known if these mortality rates are sustainable. There has been only one attempt to estimate abundance, carried out at Rio Grande do Sul, where around 42,000 individuals were estimated to be in 64,000 km^2 between the coast and the 30-m isobath. The upper limit of the ABUNDANCE ESTIMATION cannot sustain the lowest estimates of mortality. Therefore, more precise estimates are needed along with conservation measures in order to preserve the species. Other threats to the franciscana include habitat degradation. A large proportion of the distribution range is subject to pollution from several sources, especially the agricultural use of land and heavy industries between São Paulo in Brazil and Bahía Blanca in Argentina. The coastal zone is also intensely used for boat traffic, tourism, and artisanal and industrial fishing operations.

Fraser's Dolphin

Lagenodelphis hosei

M. Louella L. Dolar
Tropical Marine Research, San Diego, California

Fraser's dolphin was described in 1956 based on a skeleton collected by E. Hose from a beach in Sarawak, Borneo in 1895. F. C. Fraser gave it the genus name *Lagenodelphis*, due to what appeared to him as similarity of the skull to those of *Lagenorhynchus* spp. and *Delphinus delphis*. The external appearance of this species was not known until 1971 when specimens were found in widely separated areas: near Cocos island in the eastern tropical Pacific, South Africa, and southeastern Australia.

I. Characters and Taxonomic Relationships

Fraser's dolphin is easily identified by its stocky body, short but distinct beak, and small, triangular or slightly falcate dorsal fin—the flippers and flukes are also small (Fig. 1). The color pattern is striking and varies with age and sex. For example, a distinct black stripe that extends from eye to anus is absent or faint in juveniles, wider and thicker in adult males, and variable in adult females. The same is true with the facial stripe or "bridle": it is absent in calves, variable in females, and extensive in adult males, where it merges with the eye-to-anus stripe to form a "bandit mask." Color pattern in the genital region may also be sexually dimorphic. The back is brownish gray, the lower side of the body is cream colored, and the belly is white or pink. Other features that appear to vary with age and sex are dorsal fin shape and the postanal hump. With some variability, the dorsal fin is slightly falcate in calves and females and more erect or canted in adult males. Similarly, the postnatal hump is either absent or slight in females and young of both sexes and well developed in adult males. From a distance, the eye-to-anus stripe makes Fraser's dolphin look similar to the striped dolphin, *Stenella coeruleoalba*. However, the distinctive body shape of Fraser's dolphin rules out confusion with other species. The largest male recorded was 2.7 m long and the largest female 2.6 m with males over 10 years old significantly larger than females. Large males could weigh up to 210 kg. Based on a limited number examined, it is tentatively proposed that Fraser's dolphins in the Atlantic are larger than those in the Pacific. Fraser's dolphin belongs to the subfamily Delphininae. Based on cytochrome b mtDNA sequences, it is more closely related to *Stenella, Tursiops, Delphinus*, and *Sousa* than it is to *Lagenorhychus*. Morphologically, the skull structure shows close similarity with that of the common dolphin, *D. delphis*, in terms of the presence of deep palatal grooves and with those of *S. longirostris, S. coeruleoalba*, and the clymene dolphin *Stenella clymene* in several other characteristics.

II. Distribution and Ecology

Fraser's dolphin is a tropical species, distributed between 30°N and 30°S. Strandings outside this limit, such as in southeastern Australia, Brittany, and Uruguay, are considered unusual and are probably influenced by temporary oceanographic events. It is typically an oceanic species, except in places where deep water approaches the coast such as in the Philippines, Indonesia, and Lesser Antilles, where Fraser's dolphins can be observed within 100 m from shore. In the eastern tropical Pacific, they were observed to occur at least 15 km offshore and, mostly, on high seas approximately 45–110 km from the coast where water depth was between 1500 and 2500 m. In the Sulu Sea, Philippines, highest sighting rates were in waters >500 m and up to 5000 m, although some animals were observed in shallower waters adjacent to the continental shelf. In the Gulf of Mexico, sightings have been around 1000 m depth, and the animals appear to be more common in the Gulf than anywhere else in the North Atlantic. Affinity to deep waters can be explained by the type of prey eaten by Fraser's dolphins, which is composed of mesopelagic fish, crustaceans, and cephalopods. It is also suggested that Fraser's dolphins feed selectively on larger prey that inhabit deeper waters. In the eastern tropical Pacific and the Sulu Sea, the most common fishes in the diet are the Myctophidae and Chauliodontidae, and the most common crustaceans are the Oplophoridae. Cephalopods were not reported eaten by Fraser's dolphins in the eastern tropical Pacific, but this group comprised a significant amount of the DIET in the Sulu Sea animals, i.e., about 30% by volume. Based on prey composition, it was hypothesized that Fraser's dolphins in the eastern tropical Pacific feed at two depth horizons: the shallowest level of no less than 250 m and the deepest no less than 500 m. In the Sulu Sea, Fraser's dolphins appear to feed from near surface to at least 600 m. Examination of myoglobin (Mb) concentrations in the skeletal muscles of Fraser's dolphin support the distribution and feeding habits of this species. The value averages at 7.1 g Mb 100^{-g} muscle and is comparable to those of the very best divers such as the Weddell seal (*Leptonychotes weddellii*), bottlenose whale (*Hyperoodon ampullatus*), and sperm whale (*Physeter macrocephalus*). However, in South Africa and in the Caribbean, Fraser's dolphins were observed FEEDING near the surface.

Although no PREDATION has been reported, Fraser's dolphins may be preyed upon by killer whales (*Orcinus orca*), false killer whales (*Pseudorca crassidens*), and large sharks. Cookie cutter sharks (*Isistius brasiliensis*) are thought to inflict circular wounds.

An external PARASITE, *Xenobalanus* sp., and internal parasites (*Phyllobothrium delphini, Monorhygma grimaldi, Anisakis*

Figure 1 *Fraser's dolphins in the eastern tropical Pacific. Courtesy of R. L. Pitman.*

simplex, *Tetrabothrius* sp., *Bolbosoma* sp., *Strobicephalus triangularis*, *Campula* sp., and *Stenurus ovatus*) have been observed in Fraser's dolphins.

III. Behavior and Life History

Fraser's dolphins often swim in tight fast-moving schools of 100 to 1000 individuals with the members of the school "porpoising in low-angle, splashy leaps" and have been reported to swim away from vessels in the eastern tropical Pacific. In the Philippines they were observed to ride the bow if the boat ran at less than 3 knots but were often displaced by melon-headed whales (*Peponocephala electra*).

In the eastern tropical Pacific and the Gulf of Mexico, Fraser's dolphins are often found together with melon-headed whales. Although also sometimes seen with melon-headed whales (when in relatively shallow waters), Fraser's dolphins in the Sulu Sea are often seen with short-finned pilot whales, *Globicephala macrorhynchus*. Other species Fraser's dolphins are seen with are the false killer whale, Risso's dolphin (*Grampus griseus*), spinner dolphin, pantropical spotted dolphin (*S. attenuata*), bottlenose dolphin (*Tursiops truncatus*), and sperm whale. In the western tropical Indian Ocean, Fraser's dolphins were not seen with any other species.

A sample of 108 dolphins from a school captured in Japan showed a mixed-age group and a ratio of 1:1 between males and females; the oldest was estimated to be 17.5 years old. Males reach sexual maturity at about 7–10 years at 220–230 cm and the females at 5–8 years at 210–220 cm. Mating may be promiscuous. The annual ovulation rate is about 0.49, and the gestation period is about 12.5 months. The calving interval is approximately 2 years; in Japanese waters, calving appears to peak in spring and fall. Limited samples from South Africa suggest that calving occurs in summer. Length at birth is estimated to be about 100–110 cm.

IV. Interaction with Humans

Fraser's dolphins are caught in drive nets in Japan and by harpoon in Lower Antilles, Indonesia, and (before they became protected) in the Philippines. They are also caught incidentally in purse seines in the eastern tropical Pacific and the Philippines, in traps nets in Japan, in gill nets in South Africa and Sri Lanka, in antishark nets in South Africa, and in drift nets in the Philippines.

Gastrointestinal Tract

JAMES G. MEAD
National Museum of Natural History, Smithsonian Institution, Washington, DC

The gastrointestinal tract consists of all structures derived from the primitive gut tube and distal to the esophagus, including the stomach, small intestine, large intestine, and those accessory structures that have formed from that part of the gut (liver, gallbladder, pancreas, hepatopancreatic duct, anal tonsils). The posterior boundary is the lower part of the anal canal where the mucous membrane of the gut ends and the epidermis begins. This article follows the terminology of Chivers and Langer (1994).

The anatomy of the gastrointestinal tract has long fascinated workers. Grew (1681) is the earliest worker who dealt with that topic exclusively. Tyson (1680), in his marvelous treatment of the anatomy of the harbor porpoise (*Phocoena phocoena*), went extensively into the gastrointestinal tract. Owen dissected the dugong (*Dugong dugon*) (1838) and then summarized all the information on the digestive system of mammals in his magnum opus on comparative anatomy (1868). William Turner did extensive studies of the stomach of cetaceans, which are summarized in his catalog of the specimens of marine mammals in the Anatomical Museum of the University of Edinburgh (1912). Langer (1988) and Reynolds and Rommel (1996) did a very good treatment of the gastrointestinal tract of the sirenians.

Measurements of the gastrointestinal tract, both in terms of length and volume, are extremely difficult due to the elasticity of the organs. At death the muscles lose their tonus and the length and volume can double or triple (Slijper, 1962).

The parts of the gastrointestinal tract are described starting with the stomach and progressing distally. The anatomy of each part is treated in sequence according to the following classification: Pinnipedia (Phocidae, Otariidae, Odobenidae); Sirenia (Dugongidae, Trichechidae); Cetacea-Odontoceti [Delphinoidea (including Phocoenidae and Monodontidae), Platanistoidea (including Platanistidae, Iniidae, Pontoporiidae, and Lipotidae), Physeteroidea, Ziphiidae]; and Mysticeti (Balaenopteridae, Balaenidae, Eschrichtiidae, Neobalaenidae). The major features of the gastrointestinal tract are summarized in Table I.

I. Major Organs

A. Stomach

The stomach is a series of compartments starting with the cardiac, fundic, and ending with the pyloric. The boundary of the stomach with the esophagus is determined by the epithelial type: stratified squamous for the esophagus and columnar for the stomach. The distal boundary is marked by the pyloric sphincter.

The stomach is suspended by the mesogastrium, which, in development, becomes complexly folded and differentiated into the greater and lesser omenta.

1. Pinnipedia The stomach in pinnipeds is relatively uncomplicated when compared to the rest of marine mammals. The stomach in the California sea lion (*Zalophus californianus*) consists of a simple cardiac chamber into which the esophagus enters, followed by a narrowing into the pyloric chamber. There is a prominent pyloric sphincter. The pyloric end of the stomach is strongly recurved onto the cardiac portion. The stomach in the southern sea lion (*Otaria flavescens*) and Weddell seal (*Leptonychotes weddellii*) does not differ from the California sea lion. The stomach of the walrus (*Odobenus rosmarus*), although it is not described in any detail, does not appear to differ markedly from that of the other pinnipeds.

Pinnipeds seem to follow the carnivore plan of a relatively simple single-chambered (monolocular), nonspecialized stomach.

2. Sirenia The stomach in the dugong is moderately complex. Externally it is a simple oval organ with the esophageal opening in the center. Internally, there is a ridge (gastric ridge) that divides the stomach into two compartments: the cardiac and pyloric portions. There is development of a powerful sphincter up to 4 cm thick at the esophageal/gastric junction (Owen, 1868). The stomach walls are highly muscular. The cardiac gland is roughly spherical and about 15 cm in diameter in adults. The cardiac gland opens into the first compartment, where the esophagus also opens. The mucosa in the cardiac

[a]hypertrophied.
[b]undifferentiated.

gland is packed with gastric glands that are distinguishable from the glands in the main stomach compartment. The glands consist of chief and parietal cells at a ratio of 10:1. The mucosa in the cardiac glands is arranged in a complex plicate structure. The pyloric aperture is in the second compartment. The cardiac region of the stomach extends for several centimeters from the esophageal junction. The stomach is lined by gastric glandular epithelium with a particular abundance of goblet cells and mucus-secreting gastric glands.

The stomach of the dugong appears to be modified to secrete mucus to aid in lubricating the ingested material and prevent mechanical abrasion to the mucosa. It is interesting that the salt content of the dugong diet is high; sodium is about 30 times and the chloride about 15 times that of terrestrial pasture plants.

The stomach in the recently extinct *Hydrodamalis gigas* (Steller sea cow) was apparently very large. According to Steller, it was 6 feet long and 5 feet wide when distended with masticated seaweed.

The stomach in the manatees (*Trichechus* spp.) is very similar to that in the dugong. The stomach is divided by a muscular ridge into cardiac and pyloric regions. A single cardiac gland opens into the cardiac region of the stomach.

3. Cetacea The cetacean stomach is a diverticulated composite stomach (pleurolocular), consisting of regions of stratified squamous epithelium, fundic mucosa, and pyloric mucosa.

The stomach, as typified by a delphinid, consists of four chambers (Fig. 1). These have been referred to by a variety of anatomical terms: forestomach (first, esophageal compartment, paunch), main stomach (second, cardiac, fundus glandular, proximal), connecting chamber (third, fourth, "narrow tunneled passage," "conduit ètroit," intermediate, connecting channel, connecting division), and pyloric stomach (third, fourth, fifth, pyloric glandular, distal).

A. FORESTOMACH

There has been discussion about the homologies of the forestomach in Cetacea. It is lined with stratified squamous epithelium, like the esophagus, and there was reason to believe that it was just an esophageal sacculation. Embryological work in the common minke whale (*Balaenoptera acutorostrata*) demonstrated that the forestomach was formed from the stomach not the esophagus and that it was homologous to the forestomach of ruminants.

Odontocetes

Delphinoid: The forestomach is lined with stratified squamous nonkeratinized epithelium. The epithelial lining is white in freshly dead animals and is thrown into a series of longitudinal folds when empty. The forestomach was often referred to as the "paunch" in older literature. Like the other chambers in the stomach, it is variable in size. It is pyriform and on the order of 30 cm long in an adult *Tursiops truncatus* (280 cm total length). The forestomach is highly muscular but has no glandular functions. The forestomach/main stomach is a wide opening (3 to 5 cm in adult *Tursiops*) in the wall of the forestomach near the esophageal end. The forestomach functions as a holding cavity analogous to the crop of birds or the forestomach of ungulates. Because the communication with the main stomach is so wide, there is a reflux of digestive fluids from the main stomach and some digestion takes place in the forestomach.

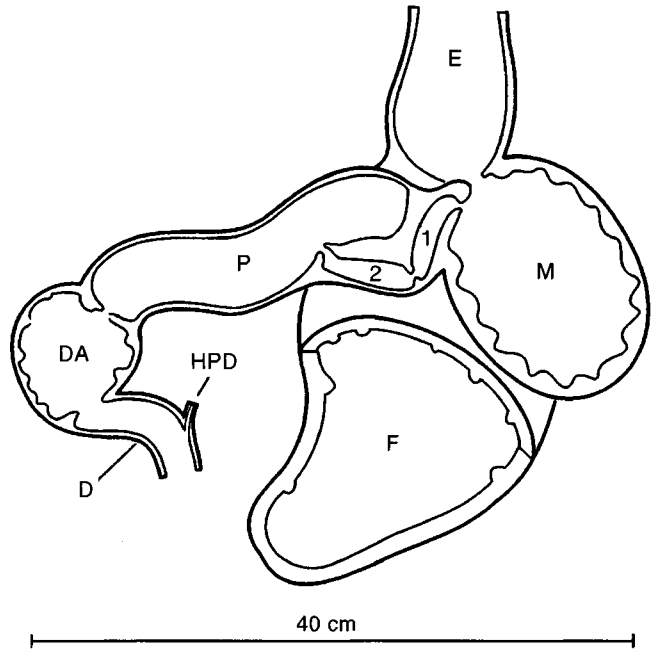

Figure 1 *Stomach of a spinner dolphin,* Stenella longirostris, *ventral view. D, duodenum; DA, duodenal ampula; E, esophagus; F, forestomach; HPD, hepatopancreatic duct; M, main stomach; P, pyloric stomach; 1, 2, compartments of connecting chambers. After Harrison et al. (1970).*

The same general relationships hold in *Phocoena, Delphinapterus leucas,* and *Monodon monoceros.*

Platanistoid: The forestomach is unusual in *Inia geoffrensis* and *Platanista gangetica* in that the esophagus runs directly into the main stomach and the forestomach branches off the esophagus. In the two other families of platanistoids, the forestomach is lacking entirely.

Physeteroid: The forestomach is present in *Physeter macrocephalus.* It was a compartment about 140 and 140 cm, lined with yellowish-white epithelium in a 15.6-m male.

Ziphiidae: The forestomach is absent in all ziphiids.

Mysticetes

The forestomach is present in all species of mysticetes.

B. MAIN STOMACH The main stomach has a highly vascular, glandular epithelium that is grossly trabeculate. The epithelium of the main stomach is dark pink to purple. The main stomach secretes most of the digestive enzymes and acids and where digestion commences. It has also been known as the fundic stomach. It is present in all cetaceans.

Odontocetes

Delphinoid: The main stomach is approximately spherical and on the order of 10–15 cm in adult *Tursiops.* The same general relationships hold in *Phocoena, Delphinapterus,* and *Monodon.*

Platanistoid: In *Platanista* there is a constricting septum of the main stomach that forms a small distal chamber, through which the digesta must pass.

Lipotes vexillifer presents an unusual situation in having three serially arranged main stomach compartments. The second and third compartments are very much smaller than the first and are topographically homologous with the connecting chambers. However, they are lined by epithelium that has fundic glands, typical of the main stomach.

Physeteroid: There is nothing remarkable about the main stomach of physeteroids.

Ziphiid: Some ziphiids develop a subdivision in their main stomach. There is an incipient constriction in the main stomach of *Berardius bairdii* and *Mesoplodon bidens* that divides the stomach into two compartments. The connecting chambers exit off the second compartment. Another type of stomach modification has occurred in *Mesoplodon europaeus* and *M. mirus*, where a large septum has developed, forming a blind diverticulum in the main stomach. An additional septum has developed in the diverticulum in *Mesoplodon europaeus* subdividing it.

Mysticetes

There is nothing remarkable about the main stomach in mysticetes.

C. CONNECTING CHAMBERS The connecting chambers, also called the connecting channel, the intermediate stomach, and the third stomach are present in all Cetacea. They are lined with pyloric epithelium and are easily overlooked in dissections. They are small in most cetaceans but have been developed greatly in ziphiids. Because of their proliferation in ziphiids, where they seem to function as something more than channels between the main and pyloric stomachs, their name was changed from connecting channels to connecting chambers.

Odontocetes

Delphinoid: The connecting chambers in a typical delphinoid consist of two narrow compartments lying between the main stomach and the pyloric stomach. The diameter of the connecting chambers is 0.8 cm in adult *Tursiops* and the combined length is 7–9 cm. The epithelial lining is very similar to pyloric stomachs. In some species the compartments are simple serially arranged; in others they may have diverticulae.

The same general relationships hold in *Phocoena, Delphinapterus,* and *Monodon.*

Platanistoid: They occur in all the species of platanistoids, with the exception of *Lipotes.* In that species the compartments lying between the main stomach and the pyloric stomach (second and third compartments of the main stomach) are lined with epithelium containing fundic and mucous glands in the first compartment and fundic glands in the second compartment. This would make them subdivisions of the main stomach. The connecting chambers appear to be absent in *Lipotes.*

Physeteroid: Although none of the works that describe the sperm whale stomach mention the connecting chambers, there is no reason to assume that they are absent.

Ziphiid: The connecting chambers in ziphiids are globular compartments, ranging in number from 2 to 11 (Fig. 2). They are separated by septa and communicate by openings in the septa. The openings are either central or peripheral in the septa. The connecting chambers are lined with pyloric epithelium. The connecting chambers in specimens of adult *Mesoplodon* (ca. 5 m long) are about 10 cm in diameter.

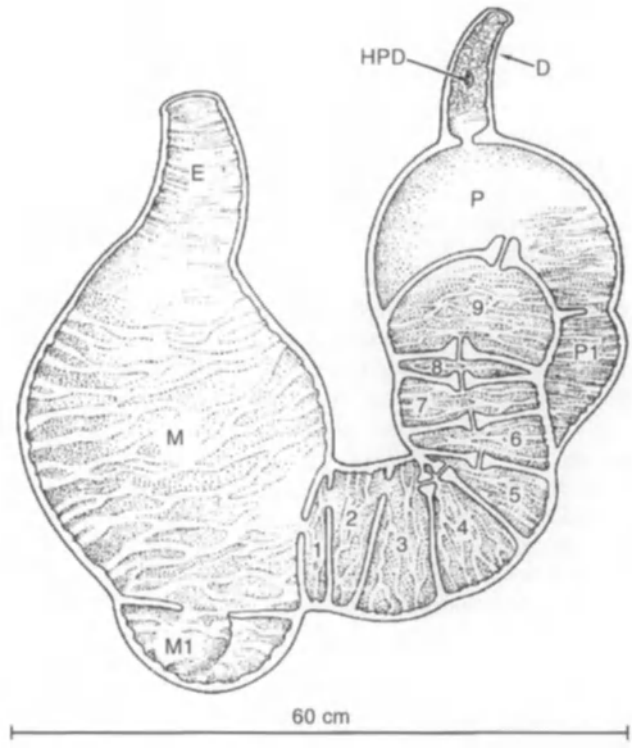

Figure 2 *Stomach of a Gulf Stream beaked whale,* Mesoplodon europaeus, *dorsal view. D, duodenum; DA, duodenal ampulla; E, esophagus; HPD, hepatopancreatic duct; M, main stomach; M1, accessory main stomach; P, pyloric stomach; P1, accessory pyloric stomach; 1, 2, etc., compartments of connecting chambers. Drawing by Trudy Nicholson.*

Mysticetes

Balaenopterid: Many workers have described the connecting chambers in a number of species of *Balaenoptera* (blue, *B. musculus*; fin, *B. physalus*; sei, *B. borealis*; minke, *B. acutorostrata* and *B. bonaerensis*). The connecting chambers in common minke whales are 10 to 30 cm in length.

Balaenid: The inflated connecting chambers in an 8.5-m female *Balaena mysticetus* were 5 cm in diameter and 17 cm combined length. The presence of connecting chambers was not mentioned in dissections of right whales.

Eschrichtiid: The connecting chambers are relatively large in a newborn *Eschrichtius robustus.*

Neobalaenid: There are no data on the connecting chambers in *Caperea marginata.*

D. PYLORIC STOMACH

Odontocetes

Delphinoid: The pyloric stomach in delphinoids is a simple tubular cavity lined by typical mucous-producing pyloric glands. The epithelium is in many ways similar to the epithelium of the small intestine. The pyloric stomach is about 20 cm long and 4 cm in flat diameter in an adult *Tursiops.*

The same general relationships hold in *Phocoena, Delphinapterus,* and *Monodon.*

Platanistoid: The pyloric stomach in *Platanista gangetica* is a single chamber about 12 cm long and contains abundant

large tubular pyloric glands. The pyloric stomach is comparable in *Inia* and *Pontoporia*, but differs markedly in *Lipotes*. In that species it is differentiated into a proximal bulbous compartment and a smaller distal compartment. The epithelial lining in *Lipotes* is similar to all other Cetacea.

Physeteroid: Available data on the pyloric stomach of physeterids are scanty. The pyloric compartment is present and there is no reason to assume that it is different from the rest of the cetaceans.

Ziphiid: The pyloric stomach in a newborn *Ziphius* is a simple spherical compartment that measures about 10 cm in diameter. It is lined with smooth pyloric epithelium and communicates with the duodenum through a strong pyloric sphincter. This is also the case in *Hyperoodon* spp., *Tasmacetus*, and some species of *Mesoplodon* (*M. densirostris*, *M. hectori*, and *M. stejnegeri*).

In *Berardius bairdii* the main pyloric compartment has expended in volume to where it is nearly the size of the main stomach and has developed a small distal accessory chamber. The pyloric compartments are in series, with the accessory chamber communicating with the duodenum.

In all other species of *Mesoplodon* examined to date (*M. bidens*, *M. europaeus*, and *M. mirus*), a blind diverticulum has developed. The diverticulum comes off the proximal side of the pyloric stomach and lies along the distal connecting chambers. The accessory pyloric stomach communicates with the pyloric stomach through a wide opening.

Mysticetes

Balaenopterid: In all of the balaenopterid species examined (*B. acutorostrata*, *B. borealis*, *B. musculus*, and *B. physalus*), the pyloric stomach is smaller than the stomach. The pyloric stomach contains 8.5 to 12.1% of the total inflated stomach volume (18–391).

Balaenid: The balaenids appear to be similar to the balaenopterids.

Eschrichtiid: In a dissection of a newborn *Eschrichtius*, the pyloric compartment seemed to be comparable to that in balaenopterids.

Neobalaenid: There are no data available on the pyloric stomach in *Caperea*.

B. Small Intestine

The small intestine starts at the pyloric sphincter. Digestion continues in the small intestine where absorption of the nutrients takes place. The duodenum derives its names from its length of about 12 inches (30 cm) in humans. It has no mesentery and its wall has longitudinal folds. The hepatic and pancreatic ducts open into the duodenum.

The longitudinal folds of the duodenum become circular (plicae circulares) in the jejunum. The jejunum starts when the small intestine becomes suspended by a mesentery.

Differentiation between the jejunum and the ileum is not sharp. The distal portions of the ileum contain longitudinal folds, which differentiates it from the proximal portion of the jejunum, which contains circular folds. The distal boundary of the ileum is sharp. The diameter of the intestine increases at the ileocolic orifice. This orifice is usually provided with a sphincter permitting partial closure.

The small intestine is characterized by the presence of absorptive villi in the mucosa.

1. Pinnipedia

Phocid: The demarcation between pylorus and duodenum is not sharply marked by position of the duodenal (Brunner's) glands in *Leptonychotes weddelli*. The duodenum is 1 or 2 feet in length. Small plicae circulares and short irregular villi were present in the duodenum. Jejunum and ileum are hard to differentiate.

Phoca vitulina has a small intestine of "great length": 40 feet (~12 m) in a seal 3 feet (91 cm) long (snout → end of flippers). An adult male *Mirounga leonina* (4.80 m sl) had a small intestine length of 202 m.

Otariid: *Otaria flavescens* lacks plicae circulares, with villi being arranged on delicate transverse linear folds. *Eumetopias jubatus* has a small intestine length of 264 feet (~80 m).

Odobenid: Owen (1853) described the intestine in passing in his description of a young walrus. The small intestine was 75 feet (~23 m) long, the cecum was 1.5 inches (3.8 cm), and the large intestine was 1 foot (~30 cm) in length.

2. Sirenia The duodenum of the dugong and manatees has two duodenal diverticula that are crescentic in shape and about 10–15 cm long, measured in the curve. They communicate via a common connecting channel with the duodenum. The lining of the diverticulae is similar to the pyloric region of the stomach and contains mucous glands. The duodenum is about 30 cm in length, similar to other medium-sized mammals. Both the duodenum and the diverticulae contain prominent plicae circulares. There is a weak sphincter at the distal end of the duodenal ampulla. The length of the small intestine is from 5.4 to 15.5 m, four to seven times the body length of the animal. The small intestines were about 1 inch (2.5 cm) in diameter in the juvenile that Owen dissected. Brunner's glands are present in the duodenum and diverticulae. Paneth cells are absent in contrast to most domestic terrestrial herbivores. The diverticulae appear to enlarge the surface of the proximal duodenum, which would allow a larger volume of digesta to pass from the stomach at one time.

3. Cetacea

Odontocetes

Delphinoid: In delphinoids there is no cecum and no marked differentiation between large and small intestines. Intestine length ranged between 8.85 and 16.80 m in specimens of *Tursiops*, *Delphinus delphis*, and *Stenella* spp. (total lengths from 160 to 230 cm). There is a duodenum about 30 cm long, but differentiation between a jejunum and ileum is lacking. Examination of the small intestines by light microscopy revealed a lack of well-developed villi in delphinids.

Platanistoid: The length of the small intestine in a 204-cm *Inia geoffrensis* was 4.15 m. The duodenum was approximately 20 cm long. The jejunum was not differentiated from the ileum. A prominent longitudinal fold began at the opening of the hepatopancreatic duct in the duodenum and continued throughout the small intestine. The small intestine varied in diameter from 0.7 to 0.8 cm. The small intestine graded into a "smooth-walled portion" that was 1 cm in diameter. The authors were unable to tell where the small intestine ended and the large in-

testine began. The "smooth-walled portion" was 80 cm in length and graded into the colon distally.

There are no plicae circulares or typical villi in the intestine of *Pontoporia*. A distinct uninterrupted longitudinal fold occurs in the small intestine.

There were abundant plicae circulares in the proximal part of the intestine in *Platanista gangetica*, changing to longitudinal folds in the last meter or two. There was a prominent cecum and an ileocolic sphincter.

The small intestine in most platanistids is extremely long. The ratio of small to large intestine length is between 50 and 60% in *Pontoporia*, 50% in *Inia*, but only around 9% in *Platanista*.

Physeteroid: The total intestinal length in adult sperm whales can range up to 250 m. The plicae circulares were unusual in that they appeared to be spiral, giving the impression of a spiral valve in sharks. There is no cecum and the transition between the small and the large intestine is gradual.

Ziphiid: It is said that the combined intestinal length of *Hyperoodon* is six times the body length. There is a unique vascular rete (mirabile) intestinale associated with the large and small intestine in at least *Ziphius cavirostris* and *Berardius* spp. There is no cecum.

Mysticetes

Balaenopterid: The mean ratio of the length of the small intestine to body length in minke whales (*Balaenoptera acutorostrata*) was rather small (3.92) and averaged 36 m in length. The minke whale possessed a duodenal ampulla, but there was no indication of differentiation of the jejunum and ileum.

Balaenid, Eschrichtiid, and Neobalaenid: Nothing is available on the anatomy of the small intestine for balaenids, eschrichtiids, and neobalaenids.

C. Large Intestine

The large intestine consists of the colon (ascending, transverse and descending), cecum, vermiform appendix, rectum, anal canal, and anus. The cecum is a diverticulum off the proximal end of the colon, near the ileocolic juncture. The vermiform appendix is the narrowed apex of the cecum. The sigmoid colon of humans is that portion of the distal end of the colon that has its mesocolon extended so that it is free in the brim of the pelvis.

The colon is suspended by a mesentery (mesocolon). The colon functions to absorb water and consolidate fecal material. Most mammalian colons have their longitudinal muscle fibers arranged into bands called taenia coli. The colon is formed into sacculations, which are called haustra. The rectum is the straight portion of the large intestine that transverses the pelvis. The anal canal is the specialized terminal portion of the large intestine. The anal canal has many lymph nodes and glands that reflect the difficulties of fecal excretion. The anus represents the end of the gastrointestinal tract. The anal sphincter controls excretion of fecal wastes.

1. Pinnipedia In pinnipeds the cecum is short and blunt or round and an appendix is not present. The large intestine is relatively short and not much larger in diameter than the small intestine. No taenia coli, plicae semilunares, haustra, and appendices epiploicae are present.

Phocid: The colon is about 6 feet (183 cm) long in an adult *Leptonychotes*. The colon grades into the rectum, which begins at the pelvic inlet and ends at the anal canal. Throughout the length of the rectum the lining is thrown into large irregular transverse rectal plicae. Toward the distal portion of the rectum, the plicae become organized into five longitudinal anal columns that continue into the anal canal. The anal canal is much smaller in diameter than the rectum. Small coiled tubular rectal glands were present. The anal canal ends where the mucosa changes into a pigmented cornified stratified squamous epithelium (epidermis). Circumanal glands, coiled tubular structures, representing modified sweat glands, were confined exclusively to this region. In *Leptonychotes* there was no evidence of other anal glands, sacs, or scent glands.

2. Sirenia The cecum in the dugong is conical and was about 6 inches (~15 cm) long and 4 inches (~10 cm)wide at the base in the half-grown specimen. A sphincter is present in the ileocecal juncture. There is no constriction between the cecum and the colon. The epithelial lining of the cecum is smooth and its walls are muscular.

The colon in the dugong is thinner walled than the small intestine and is between 4 and 11 times the total body length. There are no taeniae coli. The lining of the colon is smooth, with the exception of irregular folds that are present at the wider terminal portion. The lining of the rectum is provided with longitudinal folds, which become finer and more numerous in the anal canal. The lining of the anus is grayer and harder than the lining in the rectum. The anal canal is about 5 cm long. At the distal end of the canal the longitudinal folds become higher and terminate in globular swelling, which occlude the lumen and which have been termed "anal valves."

The cecum in manatees is very pronounced and unusual in shape. It is an oval body about 20 cm in diameter and has two horn-shaped appendages that can reach up to 15–20 cm in length.

3. Cetacea

Odontocetes

Delphinoid: As was stated earlier, there is no cecum and no marked differentiation between large and small intestines in delphinoids.

Platanistoid: The colon in a 204-cm *Inia geoffrensis* was 40 cm long, followed by a 5-cm rectum and a 3-cm anal canal. The proximal and distal portions of the colon were 1 and 1.5 cm in diameter, respectively.

There is a pronounced cecum that is 5 to 9 cm long in *Platanista gangetica*. The large intestine is short, 60 cm in adults. Lengths of the large intestine (cecum, colon, rectum, and anus) in four specimens that ranged between 76 and 127 cm total length ranged from 25.5 to over 58 cm (the 127-cm specimen was lacking the cecum). There was no trace of taenia coli.

There is no cecum in *Pontoporia*. The longitudinal fold in the small intestine of *Pontoporia* becomes two distinct longitudinal folds. Taenia and haustra coli were not found.

Physeteroid: In large adult *Physeter* the large intestine can be up to 26 m long. The mucosa of the large intestine in *Physeter* is not folded. There is no cecum. The diameter of the descending colon is increased markedly in *Kogia* spp.

Ziphiid: There is no cecum and the transition between large and small intestines is gradual.

Mysticetes

Mysticetes have a very short cecum except in the case of right whales where the cecum is absent. There is a marked difference between the diameter of the large and small intestines in right whales (*Eubalaena* spp.). There is one mention of taeniae and haustrae coli in the blue whale where the taeniae consisted of three longitudinal muscular bands.

Balaenopterid: The mean ratio of the large intestine to body length in common minke whales was 40%. The mean ratio of cecum length to body length was 4%; the cecum varied between 30 and 50 cm.

Balaenid, Eschrichtiid, and Neobalaenid: There appears to be no specific data for the large intestine of balaenids, eschrichtiids, and neobalaenids.

II. Accessory Organs

A. Liver

The liver is derived from a diverticulum of the embryonic duodenum. That diverticulum also gives rise to the gallbladder, which serves as a reservoir for hepatic secretions. The liver expands to become the largest internal organ. The liver functions in the storage and filtration of blood, in the secretion of bile, which aids in the digestion of fats, and is concerned with the majority of the metabolic systems of the body.

1. Pinnipedia The liver is multilobed in pinnipeds; up to seven or eight lobes have been reported in *Otaria*.

2. Sirenia The diaphragm has become oriented in the dorsal plane instead of the transverse plane, as it is in other mammals. The liver in the dugong and manatees is flattened against the dorsally oriented diaphragm. The liver is composed of four lobes: the normal central, left and right and the fourth, Spigelian lobe that lies on the dorsal border of the liver and is closely associated with the vena cava.

3. Cetacea The liver in cetaceans is divided into two lobes by a shallow indentation. Occasionally a third intermediate lobe develops. Because relative liver weights are more than would be expected, the tentative conclusion is that cetaceans, particularly odontocetes, may have increased metabolic rates.

B. Gallbladder

The gallbladder is located on the posterior side of the liver where the hepatic duct issues. The developmental origins of the pancreas, liver, and gallbladder are related. The gallbladder stores and concentrates the bile that is secreted by the liver.

1. Pinnipedia The gallbladder is present universally in pinnipeds and tends to be pyriform and located in a fossa of one of the subdivisions of the right lobe of the liver.

2. Sirenia The gallbladder is small in the dugong and is strongly sigmoid in shape. It lies on the ventral surface of the central lobe where the falciform and round ligaments attach. It does not appear to be described in manatees.

3. Cetacea The gallbladder is absent in all members of the order Cetacea. Part of this lack is compensated for by an increased capacity for storage in the hepatic and bile duct system.

C. Pancreas

The pancreas develops out of outgrowths of the embryonic duodenum. It consists of two developmental bodies, the dorsal and ventral pancreas, which may empty into either the hepatic duct or directly into the duodenum. The pancreas secretes enzymes that are discharged into the duodenum and insulin that is discharged directly into the blood.

The pancreas in marine mammals appears to have no remarkable differences from that in other mammals.

D. Hepatopancreatic Duct

The hepatopancreatic duct represents the developmental fusion of the hepatic, ventral, and dorsal pancreatic ducts. The hepatopancreatic duct opens into the duodenum through the major duodenal papilla.

1. Pinnipedia

Phocids: In *Phoca vitulina* and *Leptonychotes* the pancreatic duct joined the common bile duct before either of them come into contact with the duodenum. In this case they coalesce to form a hepatopancreatic duct, which empties into the duodenum.

Otariids and Odobenids: In *Otaria* and *Odobenus* the pancreatic duct and common bile duct empty separately into the duodenum. In the case of *Odobenus* the two ducts coalesce within the walls of the duodenum and enter via a common opening.

2. Sirenia A hepatopancreatic duct does not form in the Sirenia; the common bile and pancreatic ducts open separately into the duodenum.

3. Cetacea The bile duct and pancreatic ducts coalesce into a hepatopancreatic duct in all known cetaceans.

E. Anal Tonsils

Tonsils are bodies of organized lymphatic tissues around crypts used to communicate to the lumen of whatever system they are in. They are most common in the digestive system where everyone is familiar with the tonsils at the back of the throat. In some marine mammals, clusters of lymphatic tissue that fall into the definition of tonsils occur at the other end of the digestive system, in the anal canal.

1. Pinnipedia and Sirenia There is no mention of anal tonsils in pinnipeds or sirenians. There is enough description of the anal canal to be relatively certain that they do not occur.

2. Cetaceans

Odontocetes

Delphinoid: Anal tonsils have not been reported in delphinoids.

Platanistoid: Anal tonsils were found in the anal canal of *Platanista gangetica* and *Stenella coeruleoalba*. Lymphoid tissue was found in the anal canal of *Inia geoffrensis* that was not organized into structures that could be called tonsils. There

was no trace of lymphatic tissue in the anal canal of *Pontoporia blainvillei*.

Physeteroid: Similar structures were also found in some sperm whales in South Africa. These were noticed upon external examination of the whales, so they were at the distal end of the anal canal. There were no comparable data on other whales so their findings may have represented abnormal swelling in normal lymphatic tissue.

Ziphiid: No anal tonsils have been reported in ziphiids.

Mysticetes

Eschrichtiid: Anal tonsils were found in the gray whale. These tonsils consisted of masses of lymphatic tissue that communicated with the anal canal via crypts. They lie near the boundary of the anal canal with the rectum, 30 to 40 cm from the anal orifice.

Balaenopterid, Balaenid, and Neobalaenid: No anal tonsils have been reported.

Genetics, Overview

Per J. Palsbøll
University of California, Berkeley

Genetics constitute the study of heredity and variation of inherited characteristics. In the case of genetic analyses of natural animal populations at the level of organisms or above (e.g., populations or phyla), most studies draw their inferences from relative differences in consanguinity (i.e., kinship or relatedness). However, in the case of natural populations, we usually possess little or no prior knowledge as to the exact degree of relatedness among the individuals that we are comparing (whether from the same or different species). Hence, the primary task becomes to obtain an accurate estimate of the degree of relatedness among individuals sufficient for the purposes of the specific study.

In principle, the relative degree of relatedness among organisms is estimated from, and positively correlated with, the proportion of shared inherited characters. It is possible to use any trait of an organism toward this end; however, the further removed from the locus encoding the trait (i.e., the DNA itself), the higher the chance that external factors may have altered the phenotypic expression of a trait. Hence, while relatedness can be estimated from morphological characters and a single morphological character might represent many loci, the phenotypic expression might be influenced by extrinsic factors, such as environmental or physiological variables, to an unknown extent. In contrast, the composition of most cellular components is not susceptible to such extrinsic variables and thus the interpretation of the observed variation can be directly linked to the state of the encoding locus, the genotype. This explains why biochemical/molecular methods were so readily adopted and applied to estimate genetic and phylogenetic relationships when these first emerged in the mid-1960s. Until the 1980s the biochemical/molecular methods applied to natural populations were mainly indirect, e.g., the most widely employed method, isozyme electrophoresis, detects differences in the overall electric charge of enzymes due to amino acid substitutions. An important limitation of isozyme analysis is that the proportion of the genome, which encodes for detectable proteins, is very small, and only a subset of amino acid substitutions will yield a change in the overall electric charge of the enzyme. In addition, homoiotherm organisms (birds and mammals) have a reduced level of isozyme variation compared to poikilotherm animals and plants.

Despite these limitations, a large number of studies have been conducted based on isozyme electrophoresis, providing novel and valuable insights. Interested readers should consult the works of Wada and Danielsdóttir, both of whom have undertaken extensive isozyme-based studies of various species of cetaceans.

The most basic source of genetic data, the nucleotide sequence of the genome itself, became accessible in a practical manner due to a series of technical advances during the 1980s culminating with the development of the polymerase chain re-

action (PCR) by Mullis and co-workers in 1987. The PCR technique permits simple *in vitro* amplification of any specific nucleotide sequence if the nucleotide sequence of the flanking regions is known. Once amplified, the exact nucleotide sequence of the locus is readily determined. Today, PCR-based analyses of DNA sequences are the predominant methods used in genetic studies of marine mammals, which is why this article relies on examples based on the analysis of DNA sequences rather than isozymes or morphological characters.

I. Obtaining Tissue Samples

A prerequisite for DNA-based methods is, naturally, DNA. The most common source is samples of soft tissue from which the DNA subsequently is extracted. Soft tissue samples are readily available from dead animals, e.g., stranded or killed specimens. However, it is often scientifically or ethically desirable to obtain samples from free-ranging, live animals. The advantage of PCR-based techniques is that only a minute amount of target DNA is required. Adequate amounts of DNA are contained in skin biopsies, sloughed skin, hair, and even feces, which can be collected from free-ranging marine mammals with relative ease.

The sensitivity of PCR-based methods also enables the use of historical samples, such as hair from old furs, baleen, or even dried blood obtained from old log books. However, the quality of DNA extracted from such historical samples is usually inferior and obtained in much lower concentrations than DNA extracted from current samples. The same is usually true for DNA extracted from fecal or similar degraded samples. The low concentration and often highly degraded DNA obtained from such samples necessitate additional precautionary measures to prevent contamination as well as repeated analyses to ensure that a correct genotype is obtained.

Tissue samples from free-ranging animals can be collected by invasive and noninvasive techniques, each with their respective advantages and disadvantages. Invasive techniques, such as the collection of skin biopsies, enable a directed sampling scheme. This implies that, conditions permitting, skin biopsies can be collected from individuals relevant to the specific objective and a biopsy can be linked to a specific individual. Multiple biopsy systems have been developed to collect skin biopsies from marine mammals, all principally consisting of a delivery unit, such as a crossbow or gun, and a projectile unit, usually an arrow. The projectile unit carries the biopsy tip and a stop to limit the depth of penetration, which may act as a float as well. The biopsy tip is typically a simple hollow tube of stainless steel with one or more barbs retaining the sample. Systems of various kinds and ranges have been developed, the most recent is the long-range system developed by Dr. Finn Larsen at the Danish Institute for Fisheries Research with which a skin biopsy was collected from a blue whale, *Balaenoptera musculus,* at a distance of approximately 70 m (~210 feet, see Fig. 1). Skin biopsies from pinnipeds or smaller odontocetes are usually collected when the animals haul out on land or bow ride using a pole onto which a biopsy tip is mounted. Invasive sampling techniques are at times viewed as intrusive and thus undesirable. In order to investigate such concerns, data have been collected during biopsy sampling in order to detect possible adverse effects. To date the only discernible effects appear to be short term and may be equally attributable to the close approach of the boat necessary to collect a sample.

The alternative, noninvasive sampling methods are usually of a more opportunistic and random nature, which may prohibit the pursuit of some research objectives. For cetaceans, the most common kind of noninvasive sample is sloughed skin. The outer epidermis in cetaceans differs from most other mammals by the lack of dead keratinized cells and consists mostly of live cells complete with nuclei and mitochondria: the organelles that host the two cellular genomes. There is considerable variation among cetacean species in terms of the amount and how often they slough skin. Sperm whales have been observed to slough massive amounts of skin, whereas other species, such as fin and minke whales, rarely slough any skin. The main disadvantage when collecting samples such as sloughed skin is the opportunistic nature of the samples and the difficulty in linking a specific sample to a particular individual during multi-individual sightings, which may influence the pursuit of some objectives. In addition, the quality and quantity of DNA extracted from such samples are more variable than those obtained from skin biopsies.

Genomic DNA has also been extracted successfully from fecal plumes collected in the water column from dugong and dolphins, which contain epithelial cells from the intestinal tract. Among pinnipeds, the most common type of noninvasive samples is fecal samples, typically collected from haul-out sites on land. In bears, sloughed hair has proven an excellent source of noninvasive samples where the DNA is extracted from the root cells. In the case of bears, a simple, yet highly effective sampling scheme has been utilized based on "hair traps" with scent lures to attract bears and barbed wire that passively collects hair samples.

Samples are usually preserved by freezing with or without conservation buffer. Commonly used conservation solutions are 70–96% ethanol or distilled water saturated with sodium chloride and 20% dimethyl sulfoxide (DMSO).

II. Commonly Analyzed Loci

As mentioned earlier, genetic analyses of different taxa, e.g., individuals, populations, or species, are basically about estimating relative degrees of consanguinity. Put simply, the higher the proportion of shared traits/characters between two taxa, the higher degree of relatedness or, in the case of nucleotide sequences, the more mutations (i.e., differences in the nucleotide sequence) at the same locus separating two different taxa, the less related.

In principle, two kinds of mutations are observed in nucleotide sequences: single nucleotide substitutions or insertions/deletions of one or more nucleotides.

The latter kind of mutation is common at microsatellite loci. The most commonly analyzed microsatellite loci are dinucleotide repeats (e.g., GT), which are more common than tri- and tetranucleotide microsatellite loci in the mammalian genome. Most sequence changes at microsatellite loci consist of additions or deletions of one or more repeats. This kind of mutation is likely due to single-strand slippage, which subsequently results in misalignment during DNA replication. This mode of mutation is termed a stepwise mutation model (Fig. 2). Mutation rates at microsatellite loci are often high and have been estimated at 10^{-4}–10^{-5}, which is severalfold higher than that observed for single nucleotide substitutions. The high mutation rate typically yields multiple alleles at each locus and consequently high levels of heterozygosity. Microsatellite loci are thus well suited as genetic markers in the estimation of close relationships, such as parent–offspring relations. In contrast, microsatellite loci are less well suited to estimate more distant relationships due to high levels of homoplasy generated by the high rate and mode of mutation (insertion/deletion of repeats). Alleles at a microsatellite locus will differ solely by the number of repeats, and two copies of the same allele (i.e., the same number of repeats) may be allozygous or autozygous (Fig. 2). This aspect has to be taken into account during data analysis, and several estimators of genetic divergence have been developed specifically for microsatellite loci. However, the stepwise mutation mode introduces additional variance in the estimation of genetic divergence, which in turn reduces the precision. While the probability of homoplasy is low among closely related individuals, such as members of the same population, it increases with genetic divergence and thus poses more of a problem at distant relationships. Other mutational constraints appear to occur at microsatellite loci as well, such as a limit on the number of repeats and rare multirepeat mutations, both which affect the feasibility of microsatellite loci to estimate distant evolutionary relationships, such as divergent populations or different species.

The rate of single nucleotide substitutions is typically severalfold lower than that of single-strand slippage at microsatellite loci. The lower mutation rate implies that single nucleotide substitutions are less prone to homoplasy and thus in many ways are better suited than microsatellite loci to estimate more distant evolutionary relationships. However, the rate of single nucleotide substitutions differs among and within loci due to varying (often unknown) selective pressures. An example is codons in exons. In most cases a single amino acid is encoded by at least four different codons. The different codon sequences encoding for the same amino acid typically differ at the third position, at times on the first, and only rarely at the second codon position. Hence, nucleotide substitutions at the third position are usually synonymous and not subject to selective constraints. In contrast, the majority of nucleotide substitutions at the first and second codon positions are nonsynonymous. The selective constraints are thus higher at the first and second codon positions, and the substitution rate is usually lower than that of the third codon position. Because of the different selective pressures relative to codon position, phylogenetic analyses usually stratify nucleotide sequence data according to codon position. There are, however, multiple exceptions to this rule of thumb.

In mammals the vast majority of the genome does not encode for proteins and is thus presumably under little or no selection pressure. However, the large variations in mutation rates among such noncoding DNA sequences indicate the existence of selective constraints acting on these DNA sequences

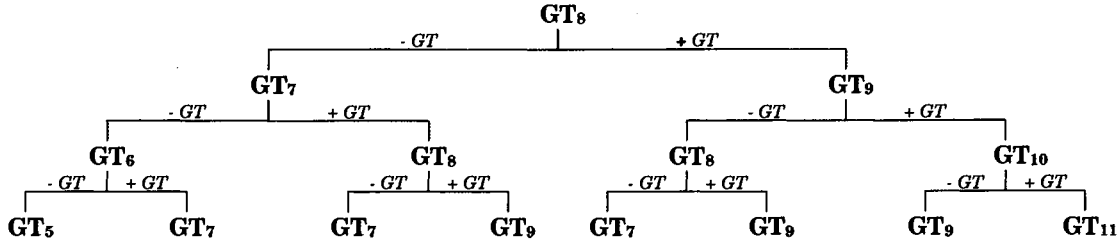

Figure 2 *The stepwise mutation mode at microsatellite loci. +/− (GT) denotes a mutation by single-strand slippage, i.e., addition or deletion of a single GT repeat unit.*

as well. Possible explanations are aspects such as chromosome pairing during meiosis, replication and transcription rates, and chromosomal stability.

A prerequisite for the estimation of the relative degree of genetic divergence among taxa is a model of the underlying evolutionary mechanisms. One important assumption in most evolutionary models is the absence of homoplasy. The commonly employed infinite-site mutation model assumes that mutations always occur at a new site in the nucleotide sequence. The infinite-allele model differs slightly in that multiple mutations at the same position can occur, but no allozygous alleles have identical nucleotide sequences. The consequence of either model is that identical nucleotide sequences all are assumed to be autozygous. While these idealized models probably are applicable to closely related taxa, multiple mutations do occur at the same position, especially at fast evolving nucleotide sequences, such as the commonly analyzed mitochondrial control region.

The earlier mentioned variance in mutation rates among loci is in fact an advantage as it enables the researcher to pick loci with mutation rates appropriate for the level of divergence under study. Usually the goal is to uncover sufficient amounts of variation to facilitate accurate estimations, while keeping the amount of homoplasy as low as possible.

Mammalian cells, like all eucaryotic cells, contain two different genomes; the cell nucleus harbors a paternal and maternal set of chromosomes, and the mitochondria, in the cell cytoplasm, possess a small genome, a circular DNA molecule of approximately 16,500 nucleotides in length in cetaceans and pinnipeds. During formation of the zygote, the sperm cells do not seem to contribute any mitochondria in mammals, although rare cases of paternal leakage of mitochondrial DNA have been reported. Thus in principle and for all practical purposes, the offspring inherits only the maternal mitochondrial genome.

III. Analyses of Individuals

In the case of marine mammals, genetic methods have been applied to identify individuals and parent–offspring relations as well as full siblings for a number of different purposes.

Identifying marine mammals by traditional tagging methods is often not feasible in most species. In many instances, marine mammals are simply too large, have too wide ranges, and live in a too dense medium to make traditional tagging practical. Tag attachments are usually relatively short-lived, in part because of the significant drag caused by the water unless attached to solid structures, such as the tusk of a male narwhal. While individual identification from natural markings has been applied successfully to a number of marine mammal species, this approach is limited to species with sufficient levels of natural variation among individuals.

In comparison, individuals from most species can be identified by "genetic fingerprinting," even species with much reduced levels of genetic variation, such as northern elephant seals, *Mirounga angustirostris*. Palsbøll and co-workers (1997) set out to verify if "genetic tagging" was feasible for a wide-ranging cetacean species. Their study included 3068 skin biopsy samples collected over a period of 8 years (from 1988 to 1995) from humpback whales, *Megaptera novaeangliae*, across the North Atlantic. Each humpback whale was identified by its composite genotype collected from six hypervariable microsatellite loci. The main issue in individual identification from a genetic profile is the probability of identity. The probability of identity is estimated readily for all degrees of consanguinity, ranging from unrelated individuals to parent–offspring pairs, from the population allele frequencies and decreases with the number of loci genotyped. The difficulty lies in determining the proportion of each kind of relationship among the collected samples, which in turn determines the expected number of individuals that have identical genetic profiles by chance. While the probability of identity is positively correlated with the degree of consanguinity, the proportion of pairs of a specific degree of relation decreases with consanguinity. In the case of the humpback whale study mentioned earlier, the probability of identity and expected numbers of different individuals with identical composite genotypes were estimated for unrelated individuals only, first for each maternally related FEEDING aggregation and subsequently for the entire population. The expected number of pairs of different individuals with identical genetic profiles by chance in the total sample of 3068 samples was estimated at less than one. Consequently, skin biopsy samples with identical genetic profiles were inferred as originating from the same individual. In total, 698 such samples with duplicate genetic profiles were detected. In a few cases, samples had been collected from the same individual humpback whale as far apart as 7500 km. The overall pattern of resightings within and among sampling areas was in agreement with data based on two decades of sighting records of individual humpback whales from their natural markings. The genetic "tags" were also used to estimate the abundance of humpback whales on the breeding grounds in the West Indies using mark-recapture techniques. Because the sex of each individual whale had been determined by genetic analysis as well, separate estimates of male and female abundance were calculated. Unexpectedly, the study yielded a significantly higher estimate of males at 4894 (95% confidence interval, 3374–7123) relative to that of females at 2804 (95% confidence interval, 1776–4463). The reason for this apparent underrepresentation of females on the breeding range (the sex ratio among calves and all whales on the feeding grounds has previously been estimated at 1:1) could not be resolved on the basis of data collected during the study. However, the authors suggested either spatial or temporal segregation among females as the source of the difference between the two abundance estimates.

An aspect of marine mammal biology where genetic methods are especially useful is the determination of parentage, e.g., to study breeding strategies and to assign individual reproductive fitness. Paternal reproductive success can be assessed in several ways, either by determination of specific parentage or by the level of paternal variation among the offspring. The former approach is relatively straightforward, as individuals that are related as parent and offspring will have at least one allele in common at each locus. However, as is the case for individual identification (see earlier discussion), two individuals that are not related as parent and offspring may also share at least

one allele at each locus by chance. The probability that two individuals not related in parent–offspring manner share one or two alleles at each locus by chance decreases with the number and variability of loci genotyped. Hence, confident assignment of parentage requires that a relatively large number of variable loci are genotyped. In addition to a sufficient number of genetic markers, an adequate set of samples is required in order to ensure that parent and offspring pairs are contained among the samples collected. To date, only a few studies have attempted assignment of paternity in marine mammals, e.g., in gray seals, *Halichoerus grypus*, or harbor seals, *Phoca vitulina*, by analysis of either microsatellite loci or "multilocus" DNA fingerprinting as in the case of the northern elephant seal where genetic diversity is exceptionally low.

Hoelzel and co-workers compared the reproductive success of northern and southern, *M. leonina*, male elephant seals estimated as the proportion of pups fathered by the alpha male in his own harem. Previous behavioral observations indicated a higher level of competition for matings among male northern elephant seals compared to male southern elephant seals, leading to the hypothesis that northern elephant seal alpha males on average are less successful than their southern conspecifics. The genetic analysis corroborated this hypothesis, finding that southern elephant seal alpha males sired a significantly higher proportion of pups in their own harem than did northern elephant seal alpha males.

Multilocus DNA fingerprinting differs from microsatellite analysis mainly by the fact that the alleles from multiple loci are detected simultaneously. The simultaneous detection of multiple loci prevents the assignment of individual alleles to loci, which is why the degree of relatedness usually is estimated from the proportion of bands shared between individuals. However, the relationship between the degree of band sharing and relatedness is not straightforward, which is why the degree of band sharing is usually calibrated with a sample of individuals of known relationship, i.e., parent–offspring pairs.

Amos and co-workers (1993) employed multilocus fingerprinting as well as microsatellite loci to study the pod structure of long-finned pilot whales, *Globicephala melas*. Long-finned pilot whales are found in groups known as pods. Pilot whale pods appear to consist of mature animals as well as immature animals, presumably calves of the mature females. However, genetic analyses revealed that adult males within a pod were also closely related to mature females in the same pod, indicating that males stay within their natal pod, even after they become mature. Genetic analyses further revealed that mature males had not sired the calves in their own pod. Curiously, calves of the same cohort in a pod shared paternal alleles, indicating that a single or few closely related males sired calves of the same age. The authors proposed that mature males leave their natal pod briefly and mate with receptive females when pods meet during the breeding season. This hypothesis would explain why no males were found to have sired calves in their own pod, as well as the observation of few paternal alleles among calves belonging to the same cohort within a pod. Mature males of different ages within a pod would then also be maternally related.

Individual-based analyses like examples just given have the potential to address new issues with genetic methods that previously were not feasible. Traditional population genetic analyses (see later) yield evolutionary estimates of genetic divergence and may thus be of limited relevance to contemporary management and CONSERVATION issues. However, identifying individuals and parent–offspring relations provides a "real time" insight into population structure and dispersal at a time scale relevant to management and conservation purposes.

IV. Analyses of Populations

A large number of genetic studies of marine mammals have been undertaken for the purpose of identifying population structure and mechanisms of intraspecific evolution. In practical terms the aim is to determine if individuals belonging to the same partition are more closely related to each other than with individuals from other partitions, which is expected if partitions represent different taxonomic units (e.g., pods, population, or species). In numerical terms, this objective translates into estimation of the degree of genetic heterogeneity among subpopulations. The degree of genetic heterogeneity among subpopulations is traditionally estimated as the relative increase in homozygosity due to population subdivision, e.g., Wright's F statistics. The increase in homozygosity due to population structure is a product of random genetic drift. Random genetic drift denotes the oscillation in allele frequencies resulting from sampling each new generation from the parental generation. If we assume that mating is random within each subpopulation with respect to the locus under study (which is likely to be the case in most instances) and the absence of any selection, the offspring generation can then be viewed as a random sample of the parental alleles. As with any random sampling process, such sampling is subject to stochastic variation, i.e., alleles are not resampled in exactly the same proportions as those found in the parental generation and the allele frequencies will thus oscillate between generations. The long-term consequence of random genetic drift in a finite-sized subpopulation is that all but one allele will be lost from the subpopulation, in the absence of introduction of new alleles by gene flow and mutation. In other words, due to random genetic drift, alleles are lost from a subpopulation (increasing the homozygosity) at a rate depending on the rate of introduction of new alleles by either mutation and/or gene flow from other subpopulations. Because the process is random, it follows that different alleles will in/decrease in frequency due to random genetic drift in different subpopulations. Overall the effect of random genetic drift is that we find more homozygotes among the sampled individuals (collected from more than one sub-population) than expected from the overall allele frequencies *if* our sample contains individuals from a single random mating subpopulation. Gene flow will homogenize the allele frequencies among subpopulations by transferring alleles from one subpopulation to others. If there are no major fluctuations in effective population size, gene flow, or mutation rates, an equilibrium state is reached where the divergence in allele frequencies caused by random genetic drift and mutation is equivalent to the rate of homogenization due to gene flow. Even very low levels of gene flow (e.g., 10 individuals per generation) among subpopulations will homogenize allele frequencies among subpopulations to an

extent that no effect of random genetic drift and mutation can be detected. Neither the mutation rate nor the effective population size is usually known in natural populations. For instance, two populations may have a similar level of genetic variation (e.g., estimated as the heterozygosity) but differ in terms of population sizes and mutation rates. For instance, the degree of heterozygosity estimated among samples collected from a small population at loci with high mutation rates may be similar to that estimated from a large population at loci with low mutation rates. As the level of genetic variation depends on the combination of effective population size and mutation rate (and these are typically unknown), it is common to simply combine both in the composite parameter $\theta = 4N_e\mu$, where N_e denotes the effective population size and μ the mutation rate. The advantage of this approach is that the composite parameter θ can be estimated from population genetic data, i.e., from the number of alleles, heterozygosity, polymorphic nucleotide positions, and the variance in allele size (for microsatellite loci). Comparisons of estimates of θ can be used to draw inferences regarding differences in mutation rates among loci within single populations or differences in effective population size among populations as well as estimates of genetic divergence.

As mentioned earlier, many population genetic studies of marine mammals have employed analysis of microsatellite loci. In addition, the nucleotide sequence of the maternally inherited mitochondrial control region is usually determined as well. The mitochondrial control region constitutes the only major noncoding region of the mitochondrial genome, with mutation rates well above the remainder of the mitochondrial genome. Usually the sequence of the first 200–500 nucleotides in the mitochondrial region is determined, which constitutes the most variable part of the mitochondrial control region. Because the mitochondrial genome is maternally inherited, any results from this locus estimate only the degree of maternal relation among samples. Most microsatellite loci, however, are of autosomal origin and thus inherited in a Mendelian manner.

The different mode of transmission of the mitochondrial and nuclear genome implies that each may reflect a different evolutionary relationship for the same set of samples. Palumbi and Baker investigated this aspect in 1994 in a study of humpback whales. In addition to mitochondrial control region sequences, the study also included data collected from the first intron in the nuclear protein-encoding locus actin. A phylogenetic analysis of actin intron I allele nucleotide sequences revealed the existence of two main evolutionary lineages with no apparent geographic affinities. The two lineages could be distinguished by digestion with the restriction endonuclease *MnlI* basically defining a system of two alleles. This two-allele system was subsequently employed in the analysis of samples collected off Hawaii and western Mexico, both winter breeding grounds for eastern North Pacific humpback whales. While the distribution of mitochondrial control region alleles was highly heterogeneous between the same two population samples (the Hawaiian sample being almost monomorphic), no significant level of heterogeneity was detected in the distribution of the two actin intron I alleles. These "contrasting" results, i.e., little/no gene flow at the mitochondrial locus but indications of high levels of gene flow at the nuclear actin intron I locus, were interpreted as the result of male-mediated gene flow, different rates of random genetic drift at each of the two genomes, or a combination of both. However, a subsequent study by Baker and co-workers also revealed significant levels of heterogeneity at nuclear loci (mainly microsatellite loci) among humpback whale samples collected off California and Alaska, which winter off Mexico and Hawaii, respectively. The simplest explanation for the seemingly discrepant outcome of the two just-mentioned studies is likely an increase in statistical power due to larger sample sizes and the inclusion of additional nuclear loci in the analysis (actin intron I as well as four microsatellite loci). However, the results do not rule out the possibility of some contribution from male-biased gene flow to the level of heterogeneity. More work is necessary before any affirmative conclusions can be reached.

The issue mentioned earlier, i.e., different degrees of male and female gene flow, is highly relevant when studying marine mammals. This has been clearly demonstrated in several population genetic analyses of species such as the North Atlantic humpback whales as well as northern right whales, *Eubalaena glacialis*, and belugas, *Delphinapterus leucas*. Specifically, North Atlantic humpback whales summer at several high-latitude feeding grounds off the eastern sea border of North America, west Greenland, Iceland, Jan Mayen and Bear Island in the Barents Sea. Humpback whales from these distinct feeding grounds all appear to congregate on common winter grounds in the West Indies. The winter constitutes the breeding and mating season. Calves are born during the winter and follow the mother during the spring MIGRATION to a high-latitude feeding ground and later on the autumn migration back to the West Indies. At the end of their first year the calves separate from their mother. The calf will, however, continue to migrate back to the same high-latitude feeding ground in subsequent summers to which it went with its mother during the first summer. The population genetic consequence of this maternally directed migration pattern is that North Atlantic humpback whale summer feeding grounds can be viewed as a single panmictic population with respect to nuclear loci, but structured in terms of mitochondrial loci. The latter is due to the maternal transmission of the mitochondrial genome in combination with the maternally directed site fidelity to the high-latitude summer feeding grounds. Nuclear alleles are exchanged when humpback whales from different summer feeding grounds mate in the West Indies. However, the calves only inherit their maternal mitochondrial genome and thus there is in principle no exchange of mitochondrial DNA among summer feeding grounds if calves keep returning to their maternal high-latitude summer feeding ground. Several population genetic studies have analyzed North Atlantic humpback whales and, in conclusion, found what was expected from the explanation just described. However, low levels of heterogeneity have also been detected at nuclear loci when comparing western and eastern North Atlantic high-latitude summer feeding grounds, indicating that some eastern North Atlantic humpback whales may winter and breed elsewhere than in the West Indies.

On a more detailed spatial scale, Hoelzel and co-workers determined the genotype at multiple microsatellite loci and the nucleotide sequence in the variable part of the mitochondrial

control region in samples collected from pods of killer whale, *Orca orcinus*, observed in Puget Sound in the northeastern Pacific. Two kinds of killer whale pods are found in Puget Sound: resident and transient. The latter pods spend only part of the year in Puget Sound. While the resident pods seem to feed almost exclusively on fish, the diet of transient pods is mainly composed of marine mammals. The two kinds of pods also differ in the average number of individuals and vocalizations. Genetic analysis revealed significant levels of heterogeneity between resident and transient killer whales not only at the mitochondrial locus but at nuclear loci as well. This result was inferred as evidence of restricted gene flow between two different kinds of foraging specialists, and in fact it might be that this feeding specialization drives the genetic divergence between the two sympatric groups of killer whales.

All the just-mentioned examples assume the absence of selection, but one could well envision natural selection affecting the degree and distribution of genetic variation among and within subpopulations.

One such possibility is the sperm whale, *Physeter macrocephalus*, among which very low levels of variation have been detected in the mitochondrial control region on a worldwide scale. This observation prompted Whitehead to propose selectively advantageous cultural transmission in matrilineal whale species as the cause of the low levels of variation at maternally inherited mitochondrial loci. The basic principle proposed by Whitehead is that long-term association between females and their offspring facilitate an efficient cultural transmission of behavioral traits, e.g., feeding behaviors. If a maternal lineage adopts more efficient behaviors that are selectively advantageous, which in turn increases that lineage's reproductive success, such maternal lineage will eventually increase in proportion within the population. The model is similar to the genetic inheritance of selectively advantageous traits, i.e., natural selection, the only difference being that transmission across generations is cultural as opposed to inheritance. Because the mitochondrial genome is transmitted maternally, it will thus "hitchhike" along with the maternal cultural transmission of advantageous behavioral traits. The study reported low levels of genetic variation at mitochondrial loci in species which were classified as matrilineal by the author, i.e., species with pods, presumably consisting of females and their offspring, such as pilot whales (*Globicephala* spp.) and sperm whales. In contrast, the nucleotide diversity was on average 10-fold higher in species classified in the study as nonmatrilineal. Using computer simulations, the author demonstrated that the maternal cultural transmission of advantageous behavioral traits could indeed reduce the nucleotide sequence variation at mitochondrial loci significantly if the cultural transmission was efficient and the selective advantage was relatively high (~0.1). While there was no objection to the hypothesis that cultural transmission of advantageous behavioral traits might occur in cetaceans, others have pointed toward other evolutionary models, such as continued selection and fluctuating population sizes, as equally compatible with the observed data collected from sperm whales.

The environment inhabited by marine mammals is relatively devoid of physical barriers in comparison to the terrestrial environment. In addition, many marine mammal species have wide ranges and thus there is a high potential for dispersal. Despite this, most genetic studies of marine mammals have detected population structure in the distribution of genetic variation within as well as between ocean basins. The lack of physical barriers to dispersal indicates that intrinsic factors may play a role in generating population structure, such as foraging specialization and maternally directed site fidelity. Even for species where no obvious behaviors limiting dispersal have been observed, population genetic structure was detected, such as in the case of polar bears, *Ursus maritimus*, and fin whales, *Balaenoptera physalus*. In these two instances, it appears that the availability of prey is, at least in part, responsible for generating population genetic structure. In the case of polar bears, Paetkau and co-workers (1999) analyzed 16 different microsatellite loci in a total of 473 polar bears collected from all areas of the Arctic. The study detected a pattern of genetic divergence among subpopulations that was consistent with the distribution of active annual sea ice, which in turn relates to the abundance of ringed seals, which is their main prey. The study of North Atlantic and Mediterranean Sea fin whales by Bérubé (1998) was based on analyses of mitochondrial control region sequences as well as six microsatellite loci in each of 309 specimens. The population structure revealed by the genetic analyses was consistent with an isolation-by-distance model, which could be explained by a distribution, described as a "patchy-continuum" previously suggested by Sergeant and based on the overall distribution of prey. Interestingly, the fin whale study also revealed the possible effect of major geological events, in this case glaciation, on the present-day levels and distribution of genetic variation. The frequency distribution of mitochondrial nucleotide sequences suggested that the fin whale population in the western North Atlantic had undergone rapid expansion in abundance most probably from a small postglacial founder population (Fig. 3).

V. Analyses of Interspecific Relationships

A well-founded phylogenetic description of marine mammals is fundamental to our understanding of the unique evolution and adaptations observed in this group of mammals. Phylogenetic studies have been conducted at several levels, e.g., among cetaceans as well as at higher levels, such as the relation of cetaceans to ungulates.

The latter question has attracted much attention as molecular data are emerging complementing earlier morphological estimates of the phylogenetic affinities of marine mammals. Results emerging from the molecular data are, at the moment, inconsistent with the morphological findings as well as among the different molecular data sets themselves with regard to the branching order in several parts of the evolutionary tree. There are multiple possible explanations for such incongruence, such as incomplete taxonomic sampling, inadequate model of change (molecular and morphological), insufficient choice and number of outgroups, as well as incomplete fossil records. As mentioned earlier, the level of homoplasy increases with genetic divergence, which complicates the interpretation of nucleotide sequence data. Instead of DNA nucleotide sequences, the more

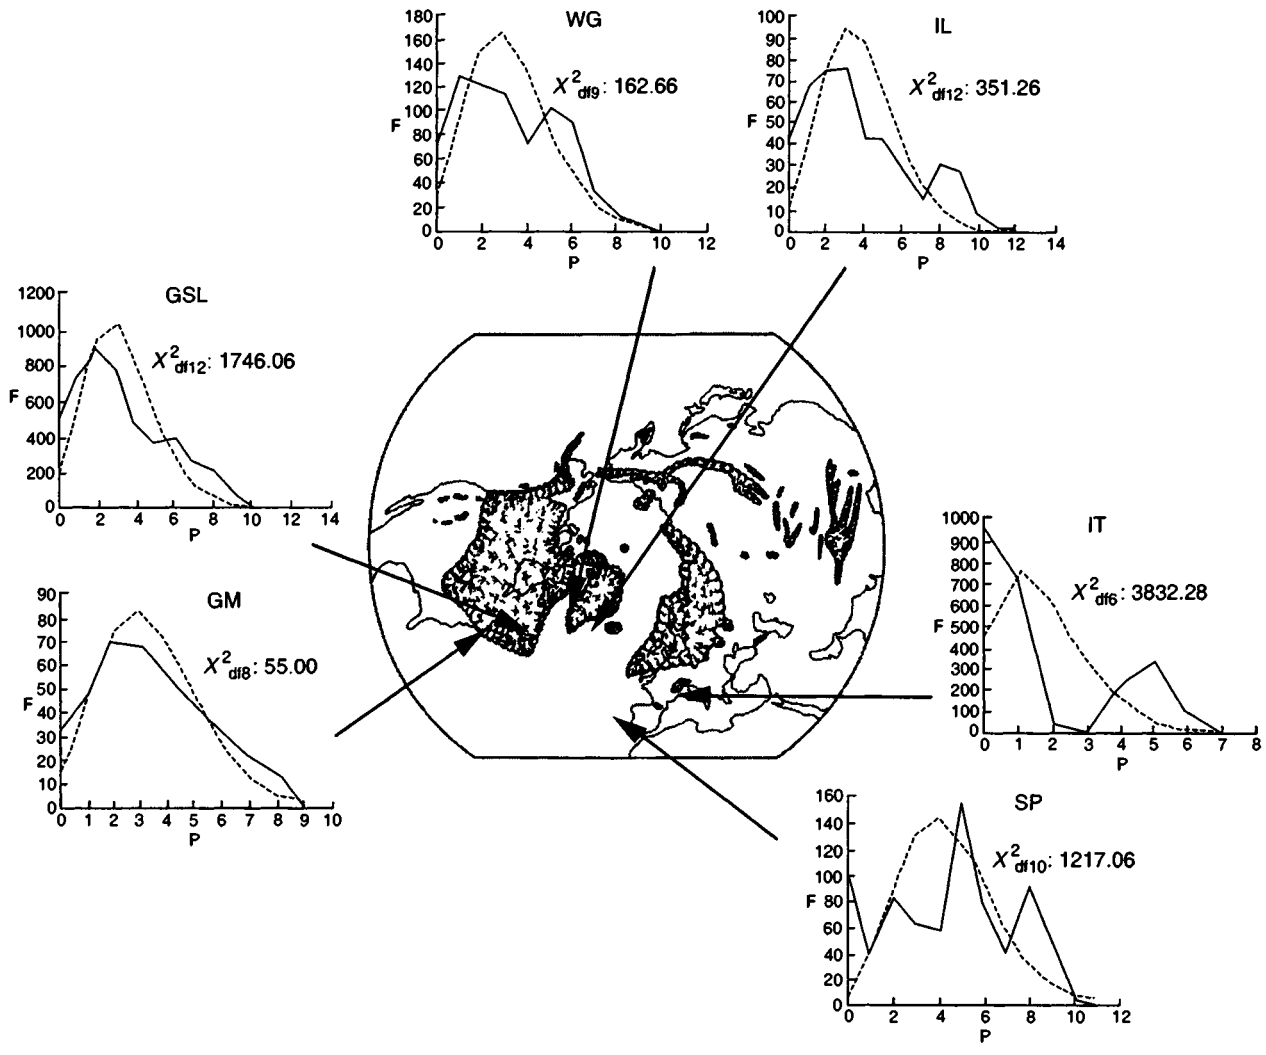

Figure 3 *Indication of postglacial expansions on western North Atlantic fin whale,* Balaenoptera physalus, *populations from genetic data. Observed (solid line) and expected (dashed line) frequency distributions of pairwise differences among mitochondrial control region nucleotide sequences in North Atlantic fin whale populations under a model of exponential expansion (see text for details). A close match between the observed and the expected distribution suggests that the samples were obtained from an exponential expanding population. The marked areas on the map of the Northern Hemisphere indicate the presence of solid ice sheets during the last Pleistocene glaciation. Map from Pielou, "Biogeography." common sort of data employed in phylogenetic analyses, Shimamura and co-workers mapped the presence or absence of retroposons, termed short interspersed elements (SINEs), at different locations in a number of ungulate and cetacean species. SINEs are in many ways thought to be ideal phylogenetic characters as they presumably are inserted into the host genome in a random and irreversible manner, i.e., a very simple mutation model devoid of many of the problems, such as homoplasy, codon position, transition/transversions ratio, and the like, which introduce variability in analyses of single nucleotide substitutions. The SINE-based study found support for the notion that Artiodactyla is a paraphyletic group in that cetaceans did not constitute a sister group but originate within Artiodactyla (Fig. 4). Earlier studies based on a sequence analysis of nuclear loci encoding milk proteins by Gatesy (1998) also arrived at the same conclusion, i.e., that artiodactyls are a paraphyletic group, also from the position of the cetacean branch. The paraphyly of Artiodactyla was subsequently supported in a comprehensive phylogenetic estimation conducted by Gatesy involving data from several nuclear and mitochondrial loci. Given the highly specialized cetacean morphology, comparisons of morphological characters with terrestrial mammals are

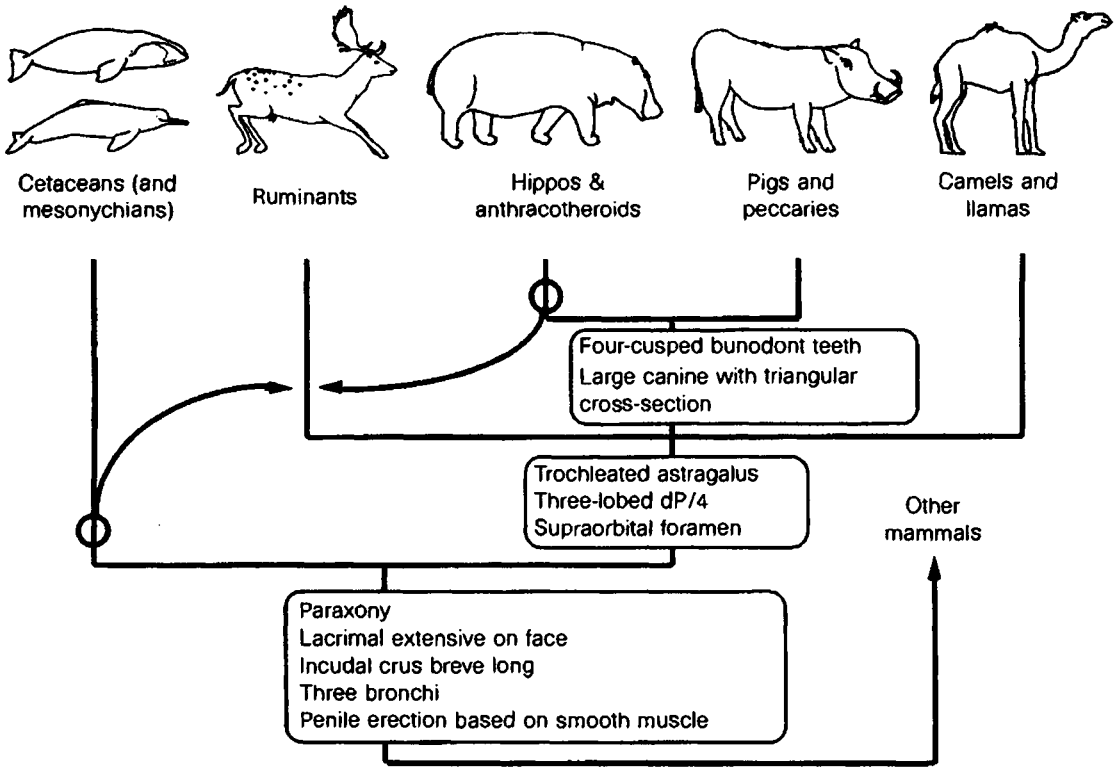

Figure 4 *Changes to the traditional artiodactyl phylogeny suggested by the findings of Shimamura* et al. *(1997). See text for details. Reprinted by permission from* Nature *388, 622–623. Copyright © 1997 Macmillan Magazines Ltd.*

not a trivial matter either and may in part account for the observed discrepancies between the morphological and molecular approaches.

A perhaps more controversial study is that of Milinkovitch and co-workers (1993) who estimated the phylogenetic position of the sperm whales within Cetacea from mitochondrial nucleotide sequences. Conventional taxonomy based on morphological characters places this distinct and old lineage of cetaceans among the odontocetes, as sperm whales share many morphological characters with other odontocetes, the presence of TEETH and ECHOLOCATION being the most obvious traits. In contrast, the study by Milinkovitch and co-workers found that sperm whales were significantly more closely related to the baleen whales than to the remainder of the odontocetes. The result of this study has since been the subject of numerous additional analyses and reanalyses and, in many ways, has become a case study of phylogenetic estimation. These additional analyses have showed that estimation of taxonomic relationships from nucleotide sequences is sensitive to aspects such as choice of outgroups, taxonomic sampling, sequence alignment, and long branches. Subsequent analyses based on nuclear and mitochondrial loci by Gatesy showed a strong support among nuclear genes for the traditional odontocete affinity of the sperm whales and less strong support for the alternate view suggested by the mitochondrial nucleotide sequences.

In both of the instances just described, the lack of congruence among the different approaches and loci demonstrates that our understanding is still far from satisfactory and that additional work is necessary before we have a more thorough and definitive understanding of the evolution of this highly specialized group of mammals and the underlying molecular mechanisms employed in our inferences.

Genetics for Management

ANDREW E. DIZON
Southwest Fisheries Science Center, La Jolla, California

Certain kinds of genetic information are particularly well suited to assist in designing strategies to protect human-impacted marine mammals. What sort of genetic information is required depends on the particular CONSERVATION goals wildlife managers seek to achieve when protecting specific species or populations within species. For example, is the goal to prevent EXTINCTION of the species as a whole or to prevent extirpation of local, but not necessarily genetically unique, populations? For most developed nations, these goals are codified in laws presumably reflecting, at least in democratic societies, the will of the public. To achieve these goals, managers often choose between controversial and conflicting strategies, such as limits on the species and numbers of marine mammals that can be incidentally killed during certain fishing operations. Relaxed limits favor the fishermen but may put a population of marine mammals at risk; stringent limits are less risky but may put an unsupportable burden on fishermen by restricting their fishing options. Obviously, the kind and quality of biological data, genetic or otherwise, informing this choice are critical. Decisions have to be based on the current scientific information available or will be challenged in the courts. While most scientific information on impacted populations is of value, certain kinds of information are much more important for the management process. If only limited data are available, inappropriate decisions can be made, eventually imperiling the population needing protection in the first place. Biological data on marine mammals, especially cetaceans, are difficult and consequently expensive to obtain. By consuming limited conservation funds, even good but irrelevant studies can impede the conservation effort. To ensure that genetic studies proposed are relevant for MANAGEMENT needs requires an understanding of the policy (the conservation goals) before doing the science (the information gathering).

Currently, management-oriented genetic studies use primarily (1) microsatellite loci within the 3×10^8 or so base pairs (bp) of the mammalian nuclear genome or (2) DNA sequence data from a portion of the 1.6×10^4 bp of the mitochondrial genome; the sub-sequence is also known as a haplotype (Fig. 1). Mitochondrial (mt)DNA is a multicopy, circular, cytoplasmic DNA that, in marine mammals, is inherited intact from the mother. In contrast, microsatellites are part of the nuclear genome and are inherited biparentally. They are short stretches of repeated DNA that are distributed abundantly in the nuclear genome and show exceptional variability in most species. In addition, gender-specific markers have been developed, and sex can be determined genetically. Finally, there is potential of measuring a variety of condition-related parameters (e.g., stress, maturity, pregnancy, spectral sensitivity, age) by examining the DNA or an expressed product of the DNA (i.e., the protein) in a small piece of skin.

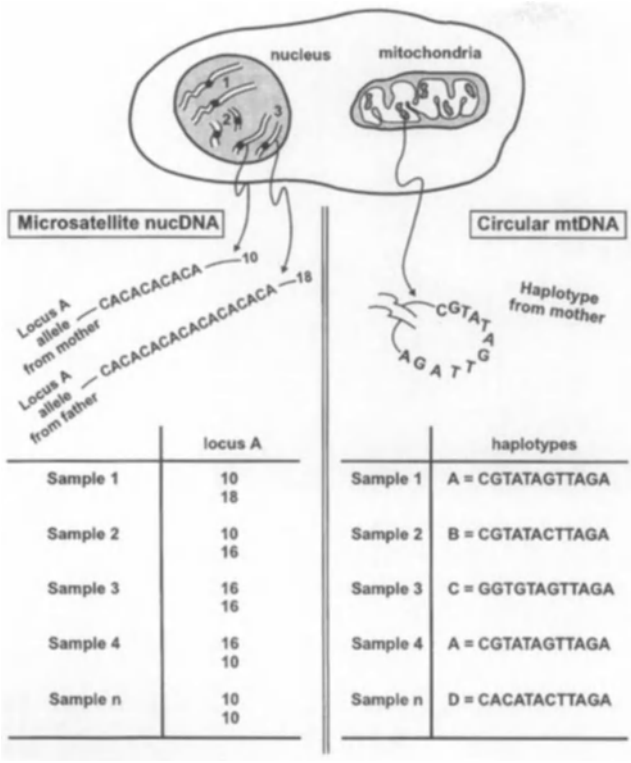

Figure 1 *Data for management genetic studies primarily consist of microsatellite DNA, mitochondrial DNA, or both. Microsatellites are short tandem repeats (two, three, or four base repeats) of base pairs, e.g., CACACACACA . . . , ATGATGATB . . . , or GATAGATAGATA . . . Microsatellite data consist of* n *pairs of alleles at* m *number of microsatellite loci within the* 3×10^8 *or so base pairs (bp) of the mammalian nuclear genome. There is estimated to be a microsatellite region every 3000 or so base pairs. Microsatellites are part of the nuclear genome and are inherited biparentally. Mitochondrial data consist of* n *subsequences of base pairs (haplotypes) at some locus within the* 1.6×10^4 *bp of the mitochondrial DNA genome. mtDNA is a multicopy cytoplasmic DNA that, in vertebrates, is inherited intact from the mother. Each mitochondria may have 5–10 DNA molecules, and there may be from 100 to 1000 mitochondria per cell. The three pairs of paired lines within the nucleus represent chromosomes; the 10 and 18 bp represent two alleles at a microsatellite locus located on the long arms of chromosome 3. For mitochondrial DNA, the arrow leading out of mitochondria shows a sequenced portion of 12 bp of the 16,000-bp molecule. For example, sample 1 is heterozygous at microsatellite locus A having a pair of alleles that have five and nine CA repeats. Sample 1 also possesses an "A"-type mitochondrial haplotype that, for example, differs by 2 bp from the "C"-type. For actual studies, the number of microsatellite loci examined might range from 4 to 10, and the size of the mitochondrial sequence examined might range from 350 to 1200 bp.*

One advantage that genetic analyses have over "whole animal" studies is that data are easier to collect and few constraints are put on the quality of a sample or its origin. DNA is a relatively tough molecule, and adequate samples can be obtained from tiny amounts of a variety of tissues such as skin, blood or blood stains, hair follicles, placenta, excrement, baleen, modern or ancient bone, or, in some circumstances, formalin-preserved tissues. For instance, adequate amounts of mtDNA from ca. 1000-year-old bowhead whale (*Balaena mysticetus*) bones from the Chukchi Peninsula have been obtained. For live animals, projectile biopsying (crossbow, firearm, or lance) has been used successfully for all but the smallest and shyest cetaceans. Harbor porpoises (*Phocoena phocoena*) have proven particularly elusive. However, Fig. 2 is a photograph of a crossbow biopsy being taken of a highly endangered North Pacific right whale (*Eubalaena japonica*) at a range of 70 m.

I. The "Conservation Unit"

Today, defining the population segment on which to focus conservation efforts is the primary use of genetic information. The U.S. Marine Mammal Protection Act of 1972 (MMPA), the Endangered Species Act of 1973 (ESA), and the Revised Management Procedure of the INTERNATIONAL WHALING COMMISSION (IWC) all direct that management efforts must be focused on populations below the species level. Although other countries have not necessarily established laws codifying the conservation unit, biologists are generally in agreement that species comprise a collection of semi-isolated populations (i.e., species-wide panmixia is the exception) and that those semi-isolated populations should be the focus of management. However, the devil is in the details, and there is much controversy on the precise definition of these units. Besides having obvious biological consequences for getting the groupings correct, there can be economic ones as well. For instance, quotas on harvest or incidental take are calculated as some allowable fraction of the overall ABUNDANCE within the chosen conservation unit. A small conservation unit is the most biologically risk averse because quotas are then necessarily small, and there is the greatest likelihood that removals will be equally distributed over the whole unit. However, a large conservation unit is the most economically risk averse because the quotas are larger, and there is the potential that excessive removals in one part of the range (the sink) will be compensated for by immigration from outside the exploited region (the source).

Policy tries to provide managers with guidance to balance conservation and economic issues by defining the management unit. For instance, the ESA seeks to prevent the extinction of distinct population segments that are evolutionarily unique. The policy addresses last-ditch efforts to rescue populations whose abundances are so low, or whose abundances will become so low in the near future, that if something is not done immediately, they will likely go extinct. These so-called evolutionarily significant units (ESU) are defined in the statues as (1) being "substantially" reproductively isolated from other population segments of the same species and (2) representing an important component in the evolutionary legacy of the species. The first criterion speaks to the rate of exchange between the population segment and other segments. The second speaks to the time the population segment has been isolated. In contrast, the MMPA seeks to maintain viable populations across their historical ranges at 50% of their historical population size. This act addresses maintenance of abundance. The

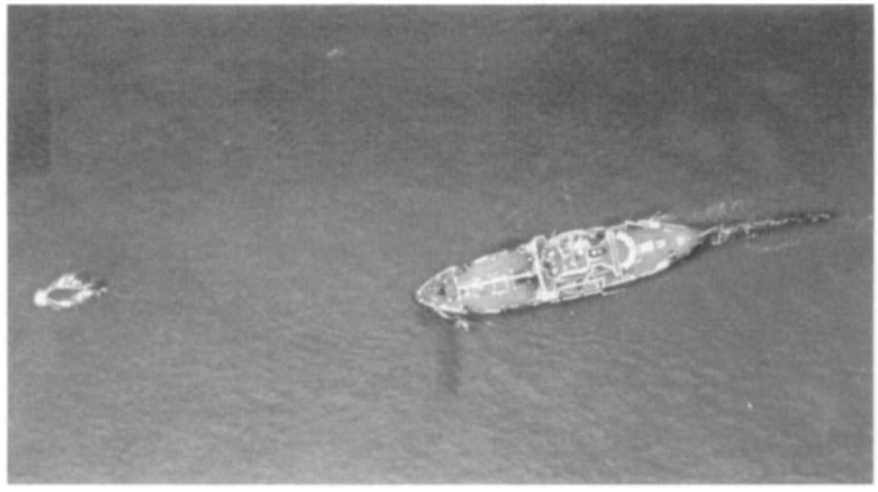

Figure 2 *Crossbow biopsy being taken of a highly endangered North Pacific right whale at a range of 70 m. Visible at about 40% of the distance from the bow of the boat and the whale is the cross-bow projectile. A genetic sample was obtained and analyzed successfully. Photo by Wayne Perryman, Southwest Fisheries Science Center, La Jolla, CA.*

MMPA conservation units could be characterized as demographically significant units (DSUs) to contrast them with ESUs. Some use the term "management unit" to refer to a DSU, but because both DSUs and ESUs are management units in the strict sense, it is important to distinguish them.

Genetic data are useful for defining both. However, the policy goals are different and, consequently, the details of genetic studies directed toward either must take slightly different approaches.

A. The Evolutionarily Significant Unit

Because the ESA is concerned with conservation units that are characterized as being "evolutionarily" different, the genetic methodology employed must be sensitive to evolutionary distances between taxa. Indeed, the traditional academic use of genetic data is employed to reconstruct common ancestry and to group taxa based on common ancestry. No restriction is based on the taxon level examined (subspecies, species, genus, family, etc.) save that the taxa are assumed to be reproductively isolated and that sufficient time has passed so that measurable genetic differences have accrued between every individual in one taxa and every individual in another. For higher level taxonomic relationships, the grouping derives *a priori* from a particular classification based on morphological distinctiveness. For groupings below the species level, the grouping derives *a priori* from geographical clustering; some have termed this phylogeography to contrast it to traditional phylogenetics.

Regardless, the key to ESU status is still reproductive isolation and time. Using DNA sequence data to test these *a priori* groupings to see if they are genetically accurate, an investigator demonstrates that all the individuals of each *a priori* stratum fall into exclusive genetic clusters. If so, ESU status can be presumed for the groupings. The evidence addresses the policy that protection should be offered to a population segment that is first of all "substantially" reproductively isolated. If they were not isolated, it would be impossible to demonstrate the presence of exclusive genetic clustering.

If animals are commonly moving between groups and interbreeding, the groups would not be reproductively isolated from one another and would share genetic material. As a result, the genetic analysis would not find unique groupings of individuals corresponding to each population, and no ESUs could be defined. However, if the individuals of *a priori* defined groups do cluster into exclusive genetic groups, that indicates they have been reproductively isolated from one another for a significant period of time and do represent at ESU. As such, they are likely following unique evolutionary pathways and each must be conserved independently. The genetic evidence is usually presented in the form of a branching diagram representing the evolutionary pathways leading to mutually exclusive genetic clusters (Fig. 3A).

B. The Demographically Significant Unit

Consider, however, if the individuals in the sample fail to fall into exclusive genetic clusters that are congruent with the *a priori* classification. For example, what is happening if some of the individuals sampled in the northern hemisphere cluster genetically with those in the south (Fig. 3B)? This situation can be the result of (1) insufficient time having elapsed from when the populations were split to purge ancestral genes from the populations, (2) a degree of gene flow exists or has existed recently (e.g., a few adventuresome individuals immigrated to the south or vice versa to breed), or (3) a combination of the two. It also means that the populations under consideration do not meet ESU criteria. Nevertheless, the populations may be genetically distinguishable if there are significant frequency differences in alleles or haplotypes between the groups. These populations would be characterized as DSUs and the definition would pertain to an intermediate situation between complete, long-term isolation of the ESU and free gene flow between geographically distinct populations (panmixia).

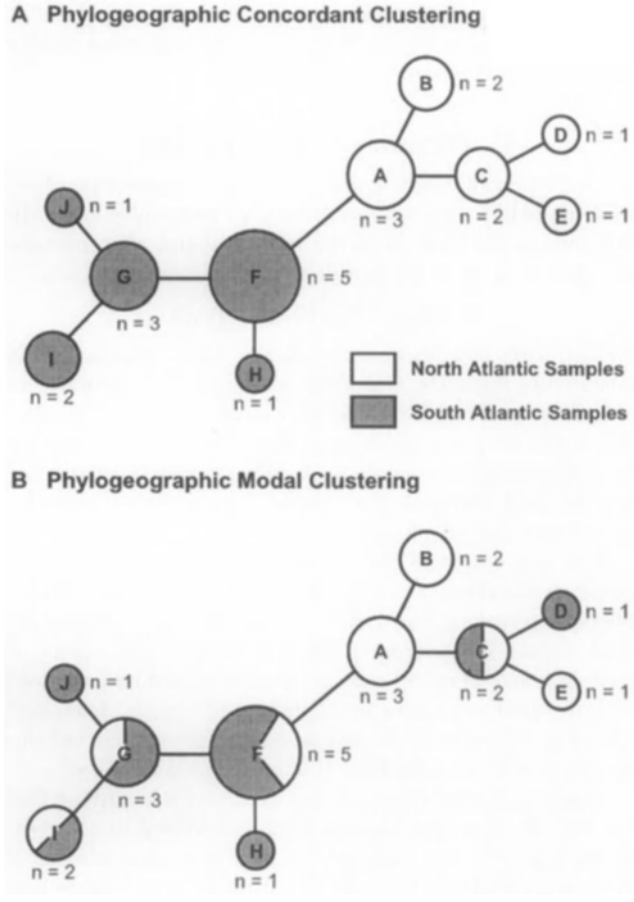

Figure 3 *Hypothetical genetic evidence representing two different evolutionary histories presented in the form of branching diagrams representing the evolutionary pathways leading to haplotypes observed in a sample of marine mammals. The size of circles is proportional to the number of individuals in the sample exhibiting the particular haplotype, and each haplotype differs from a connected neighbor by a 1-bp difference. (A) North Atlantic and South Atlantic stock has been isolated for a sufficient amount of time so that there are no haplotypes common to both. Geographic strata are concordant with genetic ones. (B) The isolation of the two stocks is (1) recent so that common haplotypes (C, F, G, and I) have not yet been purged via genetic drift from the North Atlantic, the South Atlantic, or both or (2) the isolation is incomplete, and there is a degree of continual interchange between the stocks. Even though the geography and the genetics are not strictly concordant, the distribution of haplotypes within each of the two stocks in this example is modally different.*

It is in the range of dispersal rates between the virtual isolation of the ESU and complete panmixia where the interpretation of genetic information requires an understanding of policy. The logical thread goes as follows: The MMPA establishes, albeit somewhat obliquely, that populations be maintained at 50% of their historical capacity as functioning elements of their ecosystems. This is interpreted to mean that adequate population levels shall be maintained *across their historical ranges.* It would forbid management action that resulted in extirpation in one portion of the range, although such extirpation would not reduce the overall species abundance to below 50% of historical levels.

What happens if anthropogenic mortality occurs at different levels in different parts of the range, i.e., there is heavy incidental take in the southern part of the range because it overlaps with a gill net fishery, but none at all in the central and northern part of the range? For example, consider a temperate, coastal species that inhabits waters from northern California through Canada, the Aleutian Peninsula, to Japan. Due to the large distances involved, distinct habitat differences, and the coastal behavior of this species, complete panmixia is not very likely and some population structure is, i.e., dispersal between certain population segments is reduced. Say samples are available from each of five putative population groupings (defined *a priori*) in the U.S. Pacific northwest waters. An extensive genetic analysis using both mtDNA and microsatellites is performed, and initial analyses using phylogenetic methods demonstrate no striking genetic clustering concordant with the geographic groupings. However, proximal populations were observed to share haplotypes and microsatellite, and a χ^2 analysis showed that significant frequency differences for the mtDNA haplotypes and for many of the microsatellite loci distinguish the populations. The inference here is that dispersal is sufficiently limited among the five populations so that some genetic differentiation has occurred among them. The populations are isolated but cannot be considered ESUs because the "evolutionary legacy" criterion is not met. They should be considered DSUs because dispersal between them is sufficiently reduced to warrant managing them separately (e.g., establishing individual quotas for incidental take for each population).

This recommendation can actually be made with confidence because of the shape of the curve that relates genetic differentiation and dispersal (Fig. 4). The strength of the result is reflected in the left-hand portion of the graph: genetic differentiation is detectable only when exchange rates between the putative populations are virtually nonexistent from a demographic or management point of view. This is in the range of a few dispersers per generation. However, the weakness of genetic analyses comes from how rapidly genetic differentiation falls as dispersal increases only slightly. Genetic differentiation disappears at dispersal rates that still would be considered nonsignificant from a demographic point of view, say a few percent per *year.* In other words, it is very difficult to demonstrate statistically significant genetic differentiation if dispersal between strata is more than a few dispersers per generation.

So by demonstrating genetic differentiation, the geneticist has confidently demonstrated demographically insignificant exchange rates. The management consequences are that any anthropogenic mortality within the strata must be compensated for by production from within rather than dispersal from adjacent, perhaps less impacted, units. Under this circumstance, which is actually common in coastal populations, mistakenly assuming that adjacent populations will serve as a source for the losses within the impacted population can result in destruction of the impacted population and failure to maintain it as a functioning element of its ecosystem. Disregarding the geneticist's recommendation may mean that the manager will have failed to meet a policy goal stipulated in the MMPA.

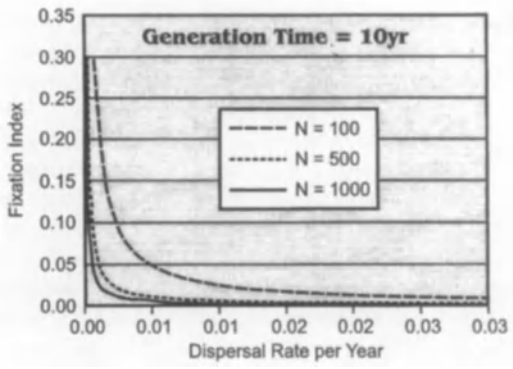

Figure 4 *The idealized relationship between the degree of genetic differentiation expressed as a fixation index, dispersal rate expressed as the average dispersal rate year, and population size expressed as the number of breeding animals or breeding females in the case of mtDNA analyses (effective population size). The fixation index ranges between 1 (no common alleles or haplotypes) to 0 (no differences in allelic or haplotypic distribution). Demographically insignificant rates of exchange (e.g., 1% per year) in anything but the smallest effective population sizes probably result in an inability to subdivide populations with any degree of statistical confidence. Perhaps more importantly, because the curve is so flat at this point and higher, genetic data have little resolution to accurately estimate dispersal rate in this range.*

However, it is not a "symmetrical" situation. What happens when genetic evidence fails to establish significant demographic isolation between units? A manager may be tempted to use this negative evidence to infer, because there was no evidence of population subdivision and hence restricted dispersal, that the putative populations could be coalesced into one larger management unit. Coalescence of two or more small populations into one larger MU would allow the manager to establish a larger incidental take quota and avoid the inevitable economic and political consequences of restricting fishing effort to reduce the incidental fishing mortality. The manager argues that high levels of take in one localized portion of the range (the sink) will be compensated for by production in and dispersal from less exploited portions of the range (the source).

This would turn out to be an appropriate decision if the failure to find evidence of population subdivision was due to demographically high levels of exchange between the exploited and the unexploited regions. However, the decision may have serious biological consequences if the failure to find genetic differences was simply because the experimental design of the genetic study lacked statistical power to discriminate subdivision (e.g., too few samples tested, too little portion of the genome tested, or an insufficiently variable portion of the genome tested). In reality, although undetected, the populations were demographically isolated, and it would be unlikely that adjacent populations could replenish losses due to incidental take in the exploited region. Because exchange between populations may be high enough to prevent detection genetically but not high enough for demographic replenishment, failure to discriminate the subdivision genetically should not at present be used as a scientific rationale for coalescing smaller populations into larger management units.

II. Focusing on the Individual

In the previous section, the focus was on a *population* of animals united by some characteristic, e.g., geographic locale. In this section, the focus is on the individual and what information genetic studies can provide to management.

A. Illegal Traffic and Trade

Two sorts of questions are usually asked: Did sample X come from the same individual as sample Y? Microsatellite analysis is used to establish an individual's genetic fingerprint; this is also known as genotyping. The second question is what is the provenance of sample X, i.e., what species or geographic population characterizes the sample? For this, sequence analyses are generally employed.

Question 1 is much like placing crime suspects at the crime scene via something the suspect has left behind (e.g., clothing fibers, fingerprints, hair, DNA), and genotyping is a highly reliable means of answering it. The genetic profile of a piece of meat in a market of unknown provenance could be compared with the genetic profiles in a database of "legally" harvested whales or, alternatively, the sample could be compared with the genetic profiles in a database of biopsied, protected ones.

Question 2 is more general and deals with establishing that the sample came from an animal that belonged to a certain group (taxa). Genetic analyses can help determine whether a given market sample came from a proscribed or a permitted taxon. For example, a particular market sample is humpback whale (*Megaptera novaeangliae*). The unknown sample is compared genetically with samples whose taxon identity is known. Because the genetic differences between taxa above the species level are so large, assignment analyses are almost infallible (e.g., Did the sample come from a whale or a cow?). In most situations, assignment is accurate at the species level (e.g., Did the sample come from a minke whale *Balaenoptera acutorostrata/ bonaerensis*, or a blue whale *B. musculus*?). However, there are exceptions, such as discriminating species among the genera *Delphinus*, *Stenella*, and *Tursiops*. Accurate assignment of an individual sample to its geographic origin is very difficult [e.g., Did the sample come from a gray whale (*Eschrichtius robustus*) harvested off the eastern Pacific Ocean or from the Okhotsk Sea?]. While there are exceptions to this rule, in general there is an increasing level of difficulty in distinguishing provenance of an individual sample, the lower the taxonomic division.

B. Other Uses of Individual-Oriented Genetic Information

Genetic mark-recapture methods based on genotyping can be substituted for traditional tagging methods, i.e., Discovery tags, for estimating population size, dispersal rate, and MIGRATION pathways. The management value of such data is obvious. However, small population sizes are necessary to ensure a high frequency of "recaptures." Large-scale mark-recapture studies based on molecular techniques are impractical because a re-

capture can only be recognized after a biopsy is taken and analyzed. As a result, a large number of expensive analyses would have to be done to ensure an adequate number of recaptures. Besides reidentification of individuals, genotyping can be used to reliably identify parent–offspring relationships, although large numbers of microsatellite loci must be examined to do this accurately. It is probably worth the effort because by doing so, dispersal can be measured over two generations rather than over the lifetime of single individuals. For conservation decisions, inter- rather than intragenerational movement is probably a more important parameter than movements of a single individual. Another important demographic parameter that emerges from a study of parent–offspring relationships is the fraction of mature animals enjoying reproductive success. In other words, what is the particular breeding structure of the population?

Finally, determining gender provides a means to examine geographical segregation by sex and whether males or females are the dispersers. It is a common situation with many marine mammal species that females tend to be strongly philopatric, returning year after year to specific feeding or BREEDING SITES. Female philopatry can be demonstrated by examining genetic population subdivision separately in males and females. If only females are strongly philopatric, mtDNA subdivision should be apparent among the females but not the males. If there are some data on age, it is sometimes possible to demonstrate that the likelihood of dispersal increases with age of the males. When males are the dispersers but not females, microsatellite subdivision should be nonexistent because the males of breeding age serve as a "conduit" to homogenize the alleles between populations. There are policy implications in demonstrating female philopatry. While this sort of population structuring would not qualify the population as an ESU, it does qualify them as a DSU worthy of management. If the animals from a particular feeding or breeding area are extirpated (males and females both), recolonization will not likely take place. The strongly philopatric females from other breeding or feeding grounds would not recolonize the depopulated region, and the dispersing males would not likely return to an area with no females. Thus, if policy deliberately excluded populations based on female philopatry, there could likely arise a situation where harvest could reduce or fragment ranges.

C. The Hidden Power of Molecular Genetics

In addition to providing answers to population subdivision, dispersal, individual identities, and breeding behavior, molecular genetic analyses present a previously unexploited opportunity for gaining understanding of marine mammals via remote, nonlethal sampling. Some of these data can have direct relevance for management. Consider that a skin sample contains the entirety of the individual's genetic blueprint. The ability to read this blueprint is progressing at an astounding rate, and although most of the progress is within the human genome, around 70% of the cetacean genes are homologous, and tools developed for medical research can be utilized for marine mammals. Two new approaches will be described briefly in which analyses of skin DNA and its expressed products can be used to gain understanding regarding the biological characteristics of populations and individuals.

DNA sequence information extracted from the genes of skin cells can provide data about expressed characteristics of other tissues or organs. Sequencing visual pigment genes from skin is a good example. With collateral data about visual performance of particular photoreceptors via behavioral or physiological testing, it is possible to extrapolate from the DNA sequence to the spectral sensitivity. Understanding the visual abilities of cetacean could aid in the design of fishing nets with increased color contrast, making them more visible to marine mammals, thereby reducing ENTANGLEMENT rates. A second approach is to directly examine expressed proteins within the skin itself, asking what proteins are up- or downregulated in skin under certain conditions. A good example is stress. Changing environmental conditions can perturb homeostasis, causing cellular stress and triggering a molecular stress response. At our laboratory, using immunohistochemical staining of thin skin sections, to date, 15 stress-responsive proteins (SRPs) have been identified whose expression is increased by 10-fold in stressed dolphins and whales in comparison to unstressed control animals (Fig. 5). The SRPs examined are widespread in the proliferating epithelial cells of the epidermis, and their induction is conserved in different species, genders, ages, and stressors. The procedure employed is simple and can be used for screening the large numbers of skin specimens necessary for correlating the presence of cellular stress with various environmental and anthropogenic factors. The management value is clear: Monitoring cellular stress in representative components of the marine ecosystem could provide an early warning system, allowing timely intervention in the case of habitat alteration. Cetaceans are top predators sensitive to many forms of environmental and anthropogenic stress, making them highly suitable as stress-reporting marine species.

III. Conclusion

While examination of genetic material offers unparalleled insights into all biological aspects of an animal's life, certain sorts of genetic information provide data that are directly relevant to the management process. The most important is the definition of the conservation unit. By common sense and by law in many countries, this unit is created out of the understanding that the vast majority of species (marine mammal or otherwise) are not panmictic. Species are subdivided geographically into isolated and semi-isolated groupings. Genetic analyses can measure this directly and provide the main avenue whereby the geneticist can provide information to facilitate decision making. Other genetic information on impacted populations is certainly of high value. This article has provided some examples. Regardless of the sort of genetic information collected, to ensure that genetic studies and information will be useful for management requires a clear understanding of the conservation policy that the studies are designed to help implement.

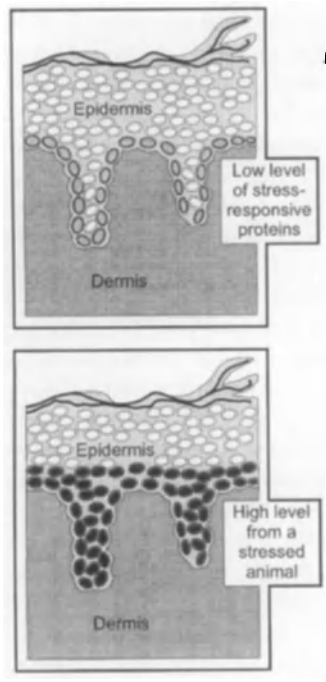

Figure 5 *Immunohistochemical staining of skin sections to examine stress in marine mammals. Rapidly proliferating epithelial cells in the basal portion of the epidermis, in dolphins and whales exposed to stressful conditions, have higher concentrations of stress-responsive proteins (shaded cells) than cells proliferating under nonstressful conditions. These higher concentrations of stress-responsive proteins are maintained as the epithelial cells are pushed to the surface of the skin and shed by new cell growth underneath. The process takes approximately 2 months. Thus the skin provides a "record" of the approximate intensity of stress that has occurred over that period. Only stress that has occurred continuously for about a half a day can be detected presently, making the test insensitive to acute stress such as short bouts of high-intensity exercise.*

Geographic Variation

WILLIAM F. PERRIN
Southwest Fisheries Science Center, La Jolla, California

I. The Nature of Geographic Variation

Mammals vary from place to place, in size, shape, coloration, osteology, and genetic features, including chromosomes, enzymes, and DNA sequences. They also vary in sounds produced, other behavior, life history, parasites, contaminant loads, biochemical features such as fatty acids, and other characters. This article focuses on geographic variation in morphology. When morphological variation and range are discontinuous, i.e., the populations or metapopulations are allopatric and can be diagnosed from one or, more commonly, a few characters, they are usually recognized as species, with the inference that they have diverged irrevocably in their evolutionary paths. When this is not true and groups differ from each other on average (modally) rather than absolutely, the variation is considered to be *geographic variation* within a species, and the form is recognized as a *subspecies, race,* or *geographic form* or *variant.*

Mammal species tend to vary geographically most in those features that vary most within a population. If, as for most mammals, body size varies broadly within a population, then geographic variants will usually differ in average body size. In another example, odontocete cetaceans are unusual among mammals in that they vary greatly in the number of TEETH and vertebrae within a species, and, as expected, these features differ sharply between geographic forms (Fig. 1).

Geographic variation may be *discordant,* i.e., the geographic pattern may differ among characters. For example, spinner dolphins (*Stenella longirostris*) in the eastern tropical Pacific vary differentially in color pattern, dorsal fin shape, and SKULL features (Perrin *et al.,* 1991), creating a complex mosaic of subspecies (see later) and varying zones of intergradation, depending on what feature is being looked at.

It is likely that most geographic variation in morphology (and the underlying genetic basis) in marine mammals is due to differential selection (ecological divergence) rather than genetic

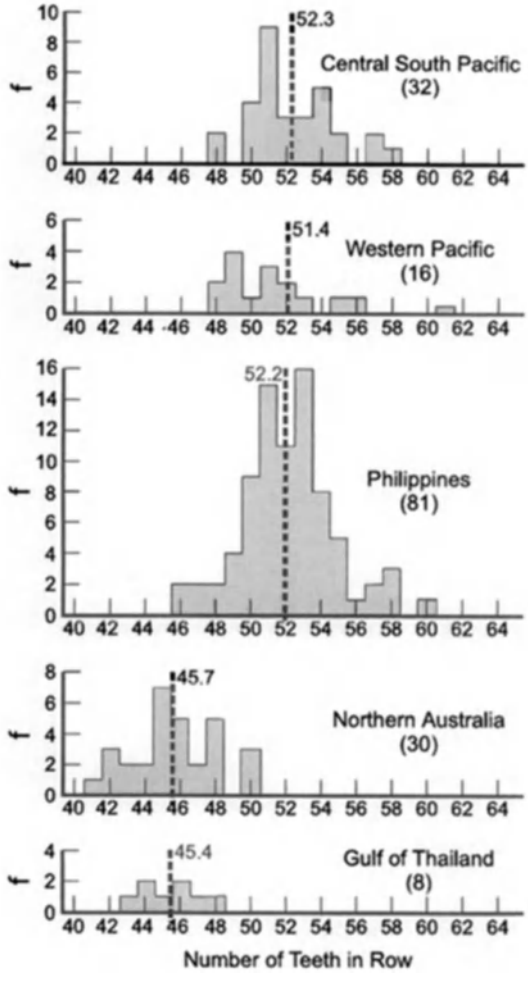

Figure 1 *Geographic variation in the number of teeth in spinner dolphins from five regions. Average and frequency distribution are shown; sample sizes are shown in parentheses. By permission from Perrin* et al. *(1999).*

drift. By saying that two populations belong to the same species, we are implying that there is, or recently has been, gene flow between them. Populations can diverge sharply morphologically in the presence of even substantial gene flow if the ecologically engendered differential selection is strong enough (Orr and Smith, 1998). However, modeling studies have indicated that social behavioral characteristics, such as female philopatry and polygynous breeding systems, both common in marine mammals, can lead to the sequestering of variation due to drift within populations; this may accelerate evolutionary divergence (Storz, 1999).

Neutral genetic differences can accumulate across populations due to drift, and markers for this geographic variation are used extensively in defining marine mammal populations for purposes of assessment and management.

II. Subspecies

Subspecies are formally named or otherwise recognized geographic variants within a species. Subspecies are currently recognized for 28 of the 127 or so marine mammal species (Table I).

The situation for subspecies is not as tidy as might be implied from Table I. Many of these subspecies were poorly described and may prove to be invalid; others may turn out to be full species. Some probably include multiple distinctive populations that deserve subspecific status but are as yet poorly understood. As indicated, some geographic forms have been recognized but not yet named. Some workers would disagree with certain of these subspecific designations and perhaps recognize others. Many additional subspecies were described in the past but have since been discounted (Rice, 1998). As for all of taxonomy, progress in classification at this level (*beta taxonomy*) is uneven and iterative.

III. Cetaceans

For the odontocetes, in every case where adequate samples of specimens from different regions have been available for examination, geographic variation has been found (Perrin and Brownell, 1994; Stacey and Leatherwood, 1997; Archer and Perrin, 1999; Amano and Miyazaki, 1992), so it can be expected to be universal.

Body size tends to be larger in open waters than in closed seas. For example, in the contiguous eastern North Atlantic, Mediterranean, and Black Sea, the short-beaked common dolphin, *Delphinus delphis,* is largest in the North Atlantic, smallest in the Black Sea, and intermediate in average size in the Mediterranean (Perrin, 1984). The bottlenose dolphin, *Tursiops truncatus,* shows the same pattern, being largest in the open Atlantic and smallest in the Black Sea, as does the beluga, *Delphinapterus leucas,* in the Canadian Arctic (Stewart and Stewart, 1989; Doidge, 1990). Body size also varies inshore/offshore and between riverine and marine populations. In the eastern tropical Pacific, the coastal subspecies of the pantropical spotted dolphin, *Stenella attenuata graffmani,* is on average larger than the offshore form, *S. a. attenuata.* It also has larger teeth; it may prey on larger tougher, benthic fish species, whereas the offshore form feeds primarily on small epipelagic fishes and squids. The pattern is repeated in the Atlantic spotted dolphin; the coastal form is larger than the offshore form in the Gulfstream (Fig. 2). However, in the bottlenose dolphin in the western North Atlantic, the pattern is reversed; the offshore form is larger than the coastal form (Hoelzel *et al.,* 1998) (in correlation with different stomach contents and parasite loads). The riverine form of the tucuxi, *Sotalia fluviatilis fluviatilis,* is smaller than the marine form, *S. f. guianensis.* Variation in size can also be latitudinal; short-beaked common dolphins in the eastern Pacific are longest in the Central Stock off Central America and shorter to the north and south (Perryman and Lynn, 1993). While it has been suggested that some of this variation in body size could be ecophenotypic (due, for example, to differential nutrition across areas of varying productivity), it is thought to most likely be determined genetically.

The dorsal fin is another feature that varies markedly with region in some odontocetes. A dramatic example of this can be seen in the tropical Pacific; whereas the fin in spinner dolphins

TABLE I
Currently Recognized Subspecies[a,b]

Species	*Subspecies*
Cetaceans	
Balaenoptera acutorostrata	*B. a. acutorostrata* (North Atlantic)
	B. a. scammoni (North Pacific)
	B. acutorostrata subsp. (Southern Hemisphere)
B. borealis	*B. b. borealis* (North Atlantic and North Pacific)
	B. b. schlegellii (South Hemisphere)
B. physalus	*B. p. physalus* (North Atlantic and North Pacific)
	B. p. quoyi (Southern Hemisphere)
B. musculus	*B. m. musculus* (North Atlantic and North Pacific)
	B. m. indica (northern Indian Ocean)
	B. m. brevicauda (Southern Hemisphere)[c]
	B. m. intermedia (Southern Hemisphere)[c]
Platanista gangetica	*P. g. gangetica* (Ganges and Brahmaputra)
	P. g. minor (Indus River system)
Inia geoffrensis	*I. g. geoffrensis* (Amazon below Bolivia)
	I. g. boliviensis (Rio Madeira, Bolivia)
	I. g. humboldtiana (Orinoco River system)
Cephalorhynchus commersonii	*C. c. commersonii* (Southern South America)
	C. commersonii subsp. (Kerguelen Islands)
Sotalia fluviatilis	*S. f. fluviatilis* (Amazon River system)
	S. f. guianensis (western Atlantic)
Stenella attenuata	*S. a. attenuata* (pelagic tropical waters)[d]
	S. a. graffmani (eastern Pacific coastal)
S. longirostris	*S. l. longirostris* (pelagic tropical waters)
	S. l. orientalis (eastern Pacific offshore)
	S. l. centroamericana (eastern Pacific coastal)
	S. l. roseiventris (inner Southeast Asia)
Lagenorhynchus obscurus	*L. o. obscurus* (southern Africa)
	L. o. fitzroyi (southern South America)
	L. obscurus subsp. (New Zealand)
Globicephala melas	*G. m. melas* (North Atlantic)
	G. m. edwardii (Southern Hemisphere)
	G. melas subsp. (Japan)
Neophocaena phocaenoides	*N. p. phocaenoides* (Indian Ocean to Southern China Sea)
	N. p. sunameri (western North Pacific)
	N. p. asiaeorientalis (Yangtze River)
Phocoena phocoena	*P. p. phocoena* (North Atlantic)
	P. p. vomerina (eastern North Pacific)
	P. phocoena subsp. (western North Pacific)
Phocoenoides dalli	*P. d. dalli* (North Pacific)
	P. d. truei (Kurile Peninsula, northern Japan)
Carnivores	
Arctocephalus pusillus	*A. p. pusillus* (southern Africa)
	B. p. doriferus (Australia)
A. australis	*A. a. gracilis* (southern South America)
	B. a. australis [Falkland Islands (Malvinas)]
Odobenus rosmarus	*O. r. rosmarus* (Atlantic Arctic)
	O. r. laptevi (Kara Sea to east Siberia)
	O. r. divergens (Pacific Arctic)
Erignathus barbatus	*E. b. barbatus* (Atlantic Arctic)
	E. b. nauticus (Laptev Sea to Pacific Arctic)
Phoca vitulina	*P. v. concolor* (western North Atlantic)
	P. v. mellonae (freshwater, eastern North America)
	P. v. vitulina (eastern North Atlantic)
	P. v. stejnegeri (western North Pacific)
	P. v. richardii (eastern North Pacific)

[d]Combines "subsp. A" and "subsp. B."

in Hawaii and the South Pacific is slightly falcate and subtriangular, typical of the species around the world, in large adult males in the far eastern Pacific (*Stenella longirostris orientalis* and *S. l. centroamericana*) the fin is canted forward, with a convex posterior margin (Perrin, 1990, 1998; Fig. 3). Animals in a broad zone of HYBRIDIZATION or intergradation are intermediate. A similar variation is present in short-beaked common dolphins; large adult males from the equatorial offshore eastern Pacific have more erect, triangular dorsal fins than in other regions. In both species the more erect (or forward-canted) dorsal fin is correlated with the development of a post-anal ventral hump (of unknown function).

The color pattern also varies within a species. In the *truei* form of Dall's porpoise (*Phocoenoides dalli truei*) in the western Pacific the ventrolateral white field is greatly enlarged from that in *P. d. dalli*. The just-described geographic variation in dorsal fin shape in the spinner dolphin is correlated with a variation in color pattern; the dorsal overlay in the eastern spinner is extensive and dark, obscuring the cape and giving the animal a monochromatic rather than a tricolor appearance. In killer whales in the Antarctic, the cape is visible; in other areas of the world it is not (Evans *et al.*, 1982). The degree of spotting in the Atlantic spotted dolphin (*Stenella frontalis*) varies from intense along the U.S. east coast to slight or none in animals in the offshore Gulf Stream to the northeast (Perrin *et al.*, 1987).

The most extensive studies of geographic variation in odontocetes have dealt with cranial features, characters that can be measured in collections of museum specimens. Within a species, variation has been found to be greatest in elements involved in feeding; size and number of teeth, length and breadth of the rostrum, and size of the temporal fossa. This implies that much geographic variation must be associated with trophic ecology: available forage, foraging techniques, and competition. Cranial variation in the offshore spotted dolphin has been shown to be correlated with environmental parameters such as water depth, solar insulation, sea-surface temperature, surface salinity, and thermocline depth (Perrin *et al.*, 1994), and the distribution of two forms of the spinner dolphin in the eastern Pacific is associated with different water masses (Fiedler and Reilly, 1994). Different geographic forms or subspecies may also exhibit different patterns in life history parameters, such as age and size at attainment of sexual maturity, fecundity, and survival, but these differences can be due to differential population status as well as genetic factors (Chivers and DeMaster, 1994).

Mysticetes have not been as well studied because of their large size and a paucity of MUSEUM series of specimens (Rice, 1998). Subspecies and populations have been recognized mainly on the basis of DISTRIBUTION and, more recently, genetic differences. No adequate comparisons of the recognized populations of bowhead whales, *Balaena mysticetus*, have been carried out; the same is true for the two extant populations of the gray whale, *Eschrichtius robustus*, and the several populations of humpback whales, *Megaptera novaeangliae*. It is only in the rorquals that progress has been made in documenting geographic variation in morphology; this has been due to the availability of large series of specimens in factory-ship whaling operations. A dwarf form of the minke whale, *Balaenoptera acutorostrata*, exists in the Southern Hemisphere. Minke whales from the Sea of Japan ("J Stock") and Pacific coast of Japan ("O Stock") may differ modally in body proportions and baleen and flipper coloration (Kato *et al.*, 1992). Small coastal and large offshore forms of Bryde's whale, *B. edeni*, have been

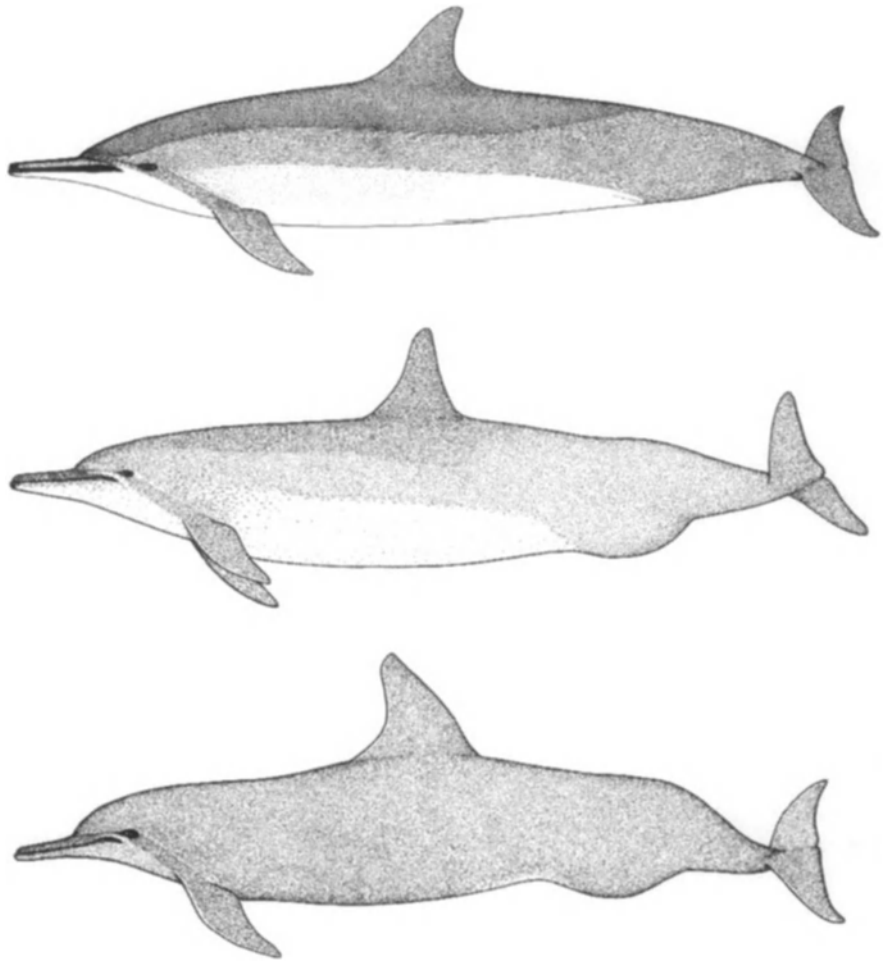

Figure 2 *Geographic variation in shape and color pattern in spinner dolphins from the eastern and central Pacific: (top) Hawaii, (bottom) far eastern Pacific, and (middle) intermediate form from region between far offshore in eastern Pacific. By permission from Perrin (1990).*

described from South Africa and Japan. A pygmy "Bryde's whale" from Southeast Asia (Perrin *et al.*, 1996) may belong to a different species (which may carry the name *B. edeni;* if it does, the name *B. brydei* would probably then apply to the "ordinary" Bryde's whale). The pygmy blue whale, *B. musculus brevicauda*, is shorter (by 2 m in the North Pacific; Gilpatrick *et al.*, 1998) and heavier than other blue whales. (Thus the heaviest animal on earth is called "pygmy.")

IV. Carnivores

While for some small cetaceans, efforts to find genetic markers concordant with geographic morphological variation have failed (e.g., Dizon *et al.*, 1991, for *Stenella longirostris*), the reverse is true for pinnipeds; genetic differences or reproductive isolation have been found between populations that cannot be distinguished morphologically in *Arctocephalus forsteri, Zalophus californianus, Eumetopias jubatus*, and *Pusa hispida* (Rice, 1998; Hoelzel, 1997; Loughlin, 1997). The reasons for this may be polygyny and strong phylopatry (promoting accumulation of neutral variation due to drift) combined with relatively uniform ecological selection (promoting morphological homogeneity) over the range of the species.

Like cetaceans, pinnipeds can vary geographically in body size (e.g., *Arctocephalus tropicalis* among Amsterdam, Gough, and Marion Islands; *Odobenus rosmarus* between the Atlantic and Pacific Arctic; *Mirounga leonina* between Macquarie Island and South Georgia; *Pusa hispida* between the Baltic and the Sea of Okhotsk; Rice, 1998), coloration (*Phoca vitulina* between different islands off California; Yochem *et al.*, 1990), and cranial features (*Phoca vitulina* among several subspecies; *Pusa hispida* between pack ice and shore-fast ice and between the freshwater populations; *Halichoerus grypus* between the two sides of the Atlantic and the Baltic; *Histriophoca fasciata* between the western and eastern parts of the Bering Sea; and *Monachus monachus* between the Mediterranean and Atlantic; Rice, 1998).

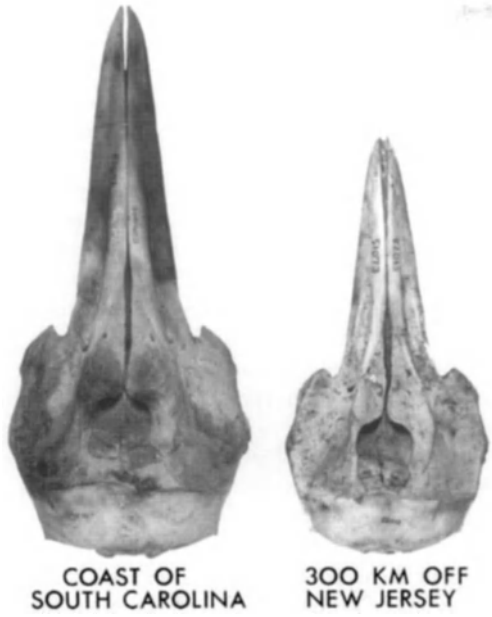

Figure 3 *Geographic variation in adult skull size in the Atlantic spotted dolphin: larger size in coastal waters than in offshore waters. (Large skull, 461 mm long; small skull, 360 mm).*

The three subspecies of sea otter are distinguished on the basis of body size and cranial characters (Wilson *et al.*, 1991) and the two subspecies of polar bears on the basis of skull size (Rice, 1998).

V. Sirenians

A molecular study of *Trichechus manatus* (García-Rodríguez *et al.*, 1998) found variation not in accordance with the presently recognized subspecies based on cranial characters; *T. m. latirostris* is closely linked to the Caribbean population of *T. m. manatus*, whereas the phylogenetic distances among the Caribbean, Gulf of Mexico, and South American populations of *T. m. manatus* are comparable to that between *T. manatus* and the Amazonian manatee, *T. inunguis*. As for many other marine mammal taxa, the taxonomy is ripe for revision based on both morphological and molecular characters.

Geographic variation in cranial morphology has been found within *Dugong d. dugon*, between Australia and Tanzania and between the Gulf of Carpentaria and Queensland in Australia (Rice, 1998).

Geological Time Scale

ELLEN M. WILLIAMS
Northeastern Ohio Universities College of Medicine, Rootstown

Much of our concept of time is measured by our daily and yearly activities, but time in terms of Earth history is infinitely longer. Rather than increments of minutes, hours, or even years, geological time ticks by at millions and billions of years. The calendar of Earth's existence is the geological time scale; a measure developed over the last four centuries by many geoscientists and paleontologists.

I. Methods for Deriving the Time Scale

A. Lithostratigraphy

The geological time scale is based on principles of lithostratigraphy that allow geologists to decipher a geologic history from a sequence of strata. These include the principle of superposition, developed in the late 17th century by Nicolaus Steno, which states that in any sequence of undisturbed strata, the oldest layers lie at the bottom and progressively become younger toward the top. In practical application, if a geologist can identify the bottommost and topmost beds in a sequence, he or she might also be able to infer the relative ages of those beds. Steno also founded the principle of original horizontality (under the influence of gravity, sediment will settle horizontal or parallel to the earth's surface) and lateral continuity (as originally deposited, strata will extend laterally thinning at the basin margin), which further aid in the identification of beds and their relationship to one another.

In traveling through the world's mountain belts, it is apparent that not all beds lie in a horizontal position, nor do they lie in undisturbed sequences. Therefore, the concepts and principles set forth by James Hutton and Charles Lyell in the 18th and 19th centuries broadened Steno's original principles. Hutton's concept of unconformities (a break or hiatus in the geologic record as represented by an erosional surface) not only allows stratigraphers to determine age relations within one sequence of strata, but also to correlate unconformities across great distances. This was followed by Lyell's principle of crosscutting relationships, which showed that any geologic feature that crosscuts another is younger than that feature. For the concept of inclusions, Lyell established that fragmentary bits (inclusions) of rock contained within another rock body are older than the enclosing mass. Taken together, the work of Lyell, Hutton, and Steno provide a lithostratigraphical basis for determining the ages of beds within and across outcrops. Figure 1 shows a geological history obtained from applying those stratigraphical principles and concepts.

B. Biostratigraphy

The physical position of rock units is not the only tool for deciphering the Earth's geochronology, however. At the turn of the 18th century, William Smith noted that certain rock units often contained a particular assemblage of fossils. He used these assemblages to trace beds over short distances and also to correlate beds of different lithologies that contained the

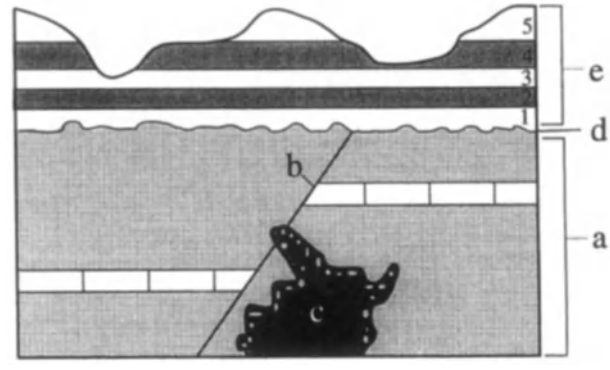

Figure 1 *Geologic crosssection and associated relative geochronology obtained by applying stratigraphic principles. Chronologically from oldest to youngest are (a) deposition of light gray and block units; (b) faulting (principle of crosscutting relationships); (c) intrusion of igneous body with inclusion of light gray unit (principle of crosscutting relationships and Lyell's concept of inclusions); (d) erosional surface (unconformity); and (e) deposition of horizontal strata (layer 1 being oldest, 5 youngest; principle of superposition). Quantitative dating methods such as radiometric or paleomagnetic dating would provide actual ages for some of the section.*

same fossils. These observations are the foundation of the principle of biologic succession, which stipulates that unique faunas characterize different periods in Earth's history, and that the identification of similar faunas in disparate deposits will allow geologists to infer chronological correlations between the deposits. Sixty years later, Charles Darwin would place Smith's biologic succession in an evolutionary context.

The use of fossils as time markers has advanced since Smith's time, and we now recognize that both assemblages of fossils and individual genera are useful in geochronologic determinations. The most effective time markers are fossils known as index or guide fossils. These taxa have a short geologic existence but are geographically widespread or cosmopolitan. Consequently, these fossils can narrow the possible age limits for the strata in which they are found and simultaneously be correlated across great distances. By using multiple overlapping ranges of index fossils, even smaller increments of time can be determined. The discipline that has developed from fossil-based stratigraphic correlations is biostratigraphy.

C. Magnetostratigraphy

A more recent method for deriving a time scale is the use of paleomagnetic analysis. The Earth's geomagnetic poles are inclined 11° from Earth's rotational axis, and studies have shown that periodically these poles reverse, therefore our "North" today was our "South" 30,000 years ago. These reversals occur roughly every half million years but are interspersed with shorter reversals at erratic intervals (such as the one 30,000 years ago). The history of reversals is recorded in both sedimentary and igneous deposits. For igneous rocks, pole orientation is recorded when iron oxide minerals such as magnetite (Fe_3O_4) align themselves parallel to the poles by crystallization in an igneous body. In the case of a cooling lava, alignment begins as the temperature nears 500° C. The magnetic declination preserved in the igneous rock on complete crystallization is known as thermoremanent magnetization. For sedimentary deposits, such as those on the ocean floor, grains of iron oxide will continually align themselves with the poles until lithification occurs; this is termed depositional remanent magnetization. The history of reversals as recorded in lava flows from around the world in combination with known radiometric dates have allowed scientists to construct a time scale based on ancient magnetism, the paleomagnetic time scale.

D. Radiometric Dating

The time scale framework established by stratigraphic and fossil studies has improved significantly over the last century with the advent of methods that allow for obtaining a quantitative geochronology. Within 10 years of the discovery of radioactivity, the physicist Ernest Rutherford suggested in 1905 that radioactive decay might be used to measure the actual age of a rock, and thus radiometric dating was born.

Decay occurs by particle emission from an atom, which results in the formation of another atom with a different composition, known as the daughter product. For example, the decay of uranium-238 will initially produce thorium-234 as its daughter product, and this process will continue until a stable configuration is obtained; in the case of uranium-238, the stable product is lead-206. Because each individual isotope has a particular mode and the length of decay that is unique, it is possible to determine the age of a particular specimen by measuring the amount of parent product versus daughter product by a mass spectrometer. For computational ease, the most useful increment to measure decay is half-life, the time required for half of the original quantity of radioisotope to decay. Half-lives are also unique for individual isotopes; for instance, carbon-14, which decays to nitrogen-14, has a half-life of 5730 years, and therefore is useful in dating recent organic materials. Whereas, uranium-238 has a half-life of 4468 million years, the isotope with the longest half-life is rubidium-87 (daughter product of strontium-87) with 48,800 million years.

II. Geochronologic Units

By applying stratigraphic and biostratigraphic principles, early geologists and paleontologists began construction of a relative geological time scale. This was based on the identification and correlation of chronostratigraphic units that represent the rocks deposited during a specific time interval. Chronostratigraphic units were then translated to geochronologic units representing increments in time. Figure 2 shows the time scale in its current form. It has been revised significantly over the last century with the use of quantitative methodologies and better stratigraphic constraint.

The largest division of the time scale is the Eon; in succession from oldest to youngest, there are three eons: the Archean, Proterozoic, and Phanerozoic. Collectively, the Archean and Proterozoic are referred to as the Precambrian and represent the largest span of Earth's history (approximately 87%). The rocks of the Archean and Proterozoic are predominantly igneous and metamorphic, although they do also contain the earliest records of bacteria, algae, and multicellular organisms.

The Phanerozoic, spanning 570 millions years ago (Ma) until today, is divided into progressively smaller units; the largest being the era, followed by the period, epoch, and finally age. The boundaries of these units indicate pronounced changes in fauna and flora or other geologic events. The oldest era, the Paleozoic, lasted 325 million years and is marked by a proliferation and diversification of shelly marine invertebrates in the early part (Cambrian through Silurian) and by bony and cartilaginous fishes, amphibians, reptiles, and mammal-like reptiles (therapsids) in the later part (Devonian through Permian).

The Paleozoic ended in a catastrophic mass extinction. Numerous marine invertebrates (rugose corals, spiny productid brachiopods, two orders of bryozoans, and many echinoderms) disappeared as well as over 70% of Permian amphibians and reptiles. It is hypothesized that the union of the supercontinent Pangaea with its associated climatic changes may be responsible for the Permian mass extinction.

The Mesozoic era spans 180 million years of geologic history and contains three periods: the Triassic, Jurassic, and Cretaceous. During this time, two new vertebrate classes evolved, the birds and mammals, and other groups experienced impressive radiations. The Mesozoic also marked the breakup of Pangaea and greater development of the Tethys Seaway. However, the Mesozoic is probably best known for the amazing reptile

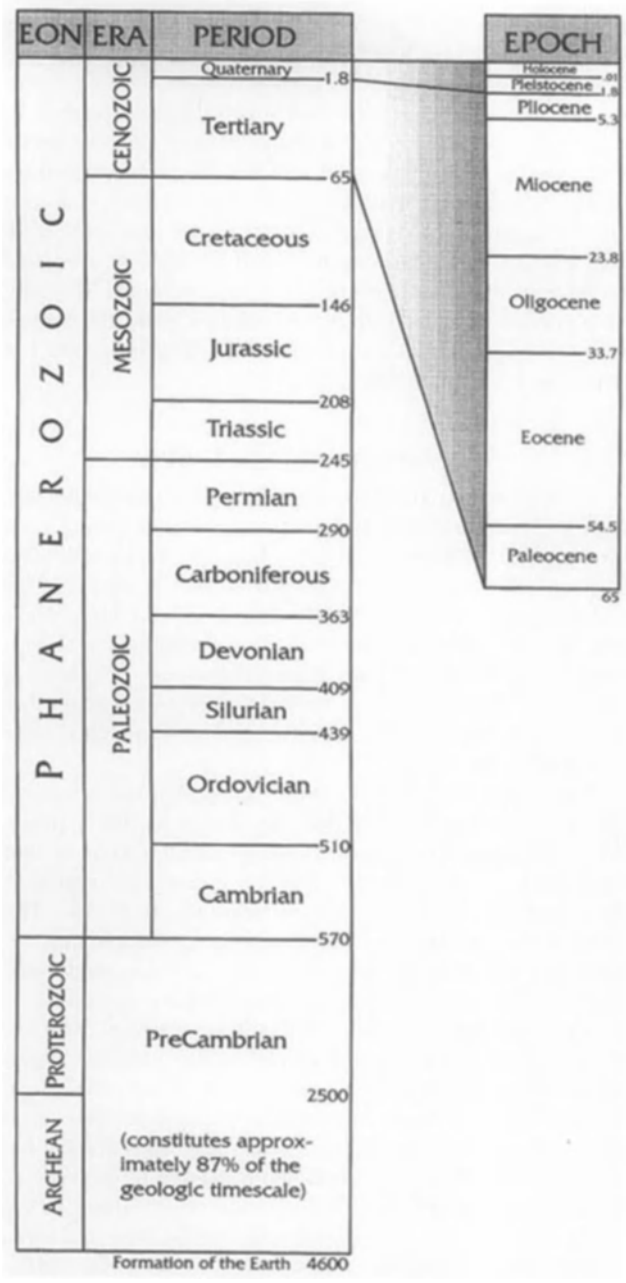

Figure 2 *Geological time scale. Dates along the right margin are millions of years before present. Geochronologic ages are not shown. Modified from Harland* et al. *(1990) and Berggren* et al. *(1996).*

faunas that dominated terrestrial and aquatic realms worldwide. The most spectacular representatives of this time are the dinosaurs.

Like the Paleozoic, the Mesozoic ended in biotic crisis with approximately 25% of all known families of animals eliminated, including dinosaurs, pterosaurs, and marine reptiles such as ichthyosaurs, plesiosaurs, and mosasaurs, as well as numerous invertebrates. This extinction occurred across what is known as the K–T boundary (Cretaceous–Tertiary boundary) and set the stage for the rapid diversification of all mammalian families during the Cenozoic era, the age of mammals.

The Cenozoic is composed of two periods, the Tertiary and Quaternary; the latter being the period in which we live today. These periods are additionally divided into epochs with the Paleocene, Eocene, Oligocene, Miocene, and Pliocene falling within the Tertiary, and the Pleistocene and Holocene within the Quaternary. Immense fossil collections have been amassed for the Tertiary and Quaternary, and comparison with studies of known environmental and geographic change has allowed scientists to paint a clearer picture of this portion of Earth history than any other period.

Like many other mammal groups, marine mammals evolved and radiated during the early to middle part of the Tertiary. The first sirenians appear in the early Eocene with the primitive genus *Prorastomus.* They underwent a radiation in the middle Eocene followed by a gradual decline through the Miocene into the earliest Pliocene. Three genera are known in recent times (*Trichechus, Hydrodamalis,* and *Dugong*). The fossil group Desmostylia appeared in the early Oligocene with the youngest representatives present in the middle to late Miocene.

Among cetaceans, the oldest representatives, archaeocetes, originate in the early Eocene, whereas the suborder Mysticeti appears in the late Eocene and Odontoceti in the early Oligocene. Within odontocetes, most of the major modern families are established by the middle to late Miocene and among mysticetes by the earliest to middle Miocene with the exception of eschrichtiids and neobalaenids, which appear in the Pleistocene. The younger geologic appearance of eschrichtiids and neobalaenids may not indicate their origin, but rather it may point to gaps in the fossil record.

For marine carnivorans, the oldest pinnipeds are late Oligocene in age. Although phocids appear in the middle Miocene, they are most abundant and diverse in recent times. Desmatophocids have a much shorter geological existence from the early to middle Miocene. Like phocids, the oldest odobenids are Miocene in age, although they enjoy their greatest diversity in the late Miocene–early Pliocene with only one species, *Odobenus rosmarus,* present today. The earliest otariids are late Miocene in age and, like phocids, the otariids are most species rich in recent times.

Giant Beaked Whales

Berardius bairdii and *B. arnuxii*

Toshio Kasuya
Teikyo University of Science and Technology, Uenohara, Japan

These two species are the largest animals of the family Ziphiidae, and their taxonomic status is still unsettled. They live in cohesive schools, feed on deep-water bottom fish, and are known to have curious life history characteristics.

I. Taxonomy

Arnoux's beaked whale, *Berardius arnuxii* Duvernoy, 1851, was described using a skull from New Zealand. A specimen of similar characters found in the Bering Sea was the basis for another species, Baird's beaked whale, *B. bairdii* Stejneger, 1883.

Characters once thought to distinguish the two species are now considered invalid, beside a few slight differences, i.e., smaller adult size (8.5–9.75 m vs 9.1–11.1 m) and possible differences in flipper size and in the shape of nasal bones and vomer. Such minor differences throw doubt on the validity of the separate species (Fig. 1).

II. Skeleton and Internal Morphology

Condylobasal lengths of skulls of adult Arnoux's beaked whales range from 1174–1420 mm, and those of Baird's beaked whale are 1343–1524 mm. Other measurements in percentage of condylobasal length are (both species combined): length of rostrum 60.7–69.5%, width of rostrum at base 64.4–82.3%, and breadth across zygomatic processes of squamosals 47.1–56.5%. Nasal bones are large but do not overhang the superior nares. Among Ziphiidae, their SKULL is the least bilaterally asymmetrical and the crest formed by nasals, premaxillae, maxillae, and frontals at the skull vertex is the least developed.

A pair of large TEETH erupt on the anterior end of the lower jaw at around sexual maturity and abrade rapidly. The tooth is flat, triangular in shape (about 8×8×3 cm) and has elements of rudimental enamel, thin dentine, massive secondary dentine filling the pulp cavity, and thick cementum that covers the root.

The vertebral formula of 3 Arnoux's beaked whales was C7, T10-11, L12-13, Cd17-19, total 47-49, and that of 49 Baird's beaked whales off Wadaura, Japan, C7, T9-11, L12-14, Cd17-22, total 47-52 (n=48.9), most of which (41) had either 48 or 49 vertebrae. There are five phalanges in the manus.

The stomach lacks an esophageal compartment, and the glandular stomach has up to nine segments. The caecum is absent. The nasal tract has three pairs of sacs.

III. External Morphology

The entire body is dark brown, and the ventral side is paler and has irregular white patches. Tooth marks of conspecifics are numerous on the back, particularly on adult males.

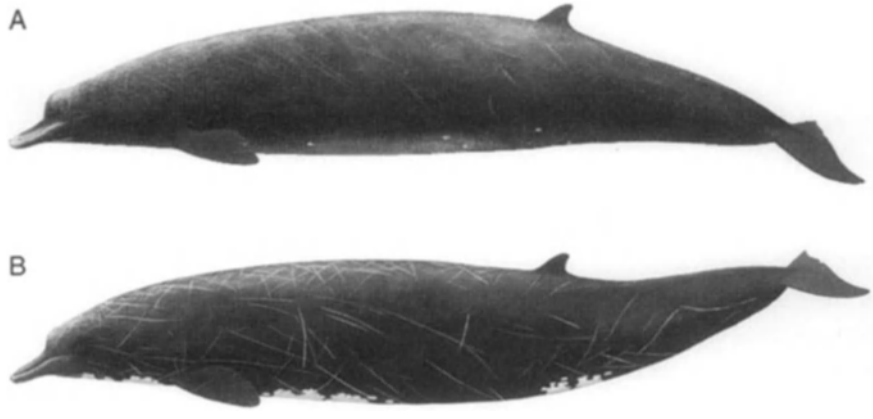

Figure 1 *Giant beaked whales in the genus* Berardius *are distributed disjunctly. (A)* B. arnuxii *occurs in waters around the Antarctic, reaching northward to the shores of the Southern Hemisphere continents. (B)* B. bairdii *ranges across the northern Pacific from Japan, throughout the Aleutians, and southward along the coast to the southern tip of Baja California (see Fig. 2). Despite this widely separated occurrence, evidence for the distinctiveness of these two taxa remains equivocal.*

They are the least SEXUALLY DIMORPHIC among the family (Table I). The body is slender and has a small head, a low falcate dorsal fin, and small flippers that fit into the depressions on the body. A pair of throat grooves and some accessory ones contribute to expand the oral cavity at suction feeding. The equation $W=(6.339\times10^{-6})\ L^{3.081}$ expresses the relationship between body weight (W, in kg) and body length (L, in cm) off Japan.

The blowhole is crescent shaped with the concavity directing anteriorly. The melon is small and its front surface is almost vertical, from which a slender rostrum projects.

IV. Distribution

Arnoux's beaked whales inhabit vast areas of southern oceans, except the tropics, from the Ross Sea at 78°S to Sao Paulo (24°S), northern New Zealand (37°S), South Africa (31°S), and southeastern Australia (29°S) (Fig. 2).

Baird's beaked whales inhabit the temperate North Pacific and adjacent seas, mainly deep waters over the continental slope. The northern limits are at Cape Navarin (62°N) in the Bering Sea and in the central Okhotsk Sea (57°N), where they occur even in shallow waters.

On the American side they occur north of northern Baja California (30°N), but there are records from the southern Gulf of California.

The southern limits on the Asian side are at 36°N on the Japanese coast in the Sea of Japan and at 34°N on the Pacific coast. They occur year-round in the Okhotsk Sea and Sea of Japan, including the drift ice area of the former.

Off the Pacific coast of Japan, the whales appear in May in waters over the continental slope at depths of 1000–3000 m and their numbers increase toward summer when hunting commences and then decrease toward October. During this period they are almost absent in waters further offshore. This reflects their food preference and DIVING ability. Their wintering ground is unknown.

V. Biology of Baird's Beaked Whales off Pacific Japan

When traveling, they form tight schools of 1–30 individuals (n=5.9). Schools of 2–9 individuals constitute 64% of the encounters and singletons 14% (Fig. 3).

Diving lasts up to 67 min (n=18.2), 39% last less than 11 min, 27% 11–20 min, and 18% 21–30 min. Time at surface is 1–14 min (n=3.9) and tends to be greater after a longer dive. During surface schooling, individuals blow continuously while swimming slowly and are easily identifiable from vessels.

Age is determined using growth layers in the teeth. The gestation time is unknown, although 17 months is suggested from interspecies relationship among toothed whales. Neonates are about 4.6 m. Females first ovulate at age 10–15 years when they are 9.8–10.7 m and live to about 54 years. Ovulation occurs throughout life at an average rate of once every 2 years. There is no evidence of significant postreproductive life.

The testis is histologically mature when it weighs 1.5 kg, which corresponds to age 6–11 years or a body length of 9.1–9.8 m, but continues growing until age 30, when it reaches 3–9 kg.

[a]Body length is in centimeters, and other figures are length from tip of upper jaw expressed as percentage of body length. Body lengths of samples are 1002–1120 cm for males and 1015–1110 cm for females.

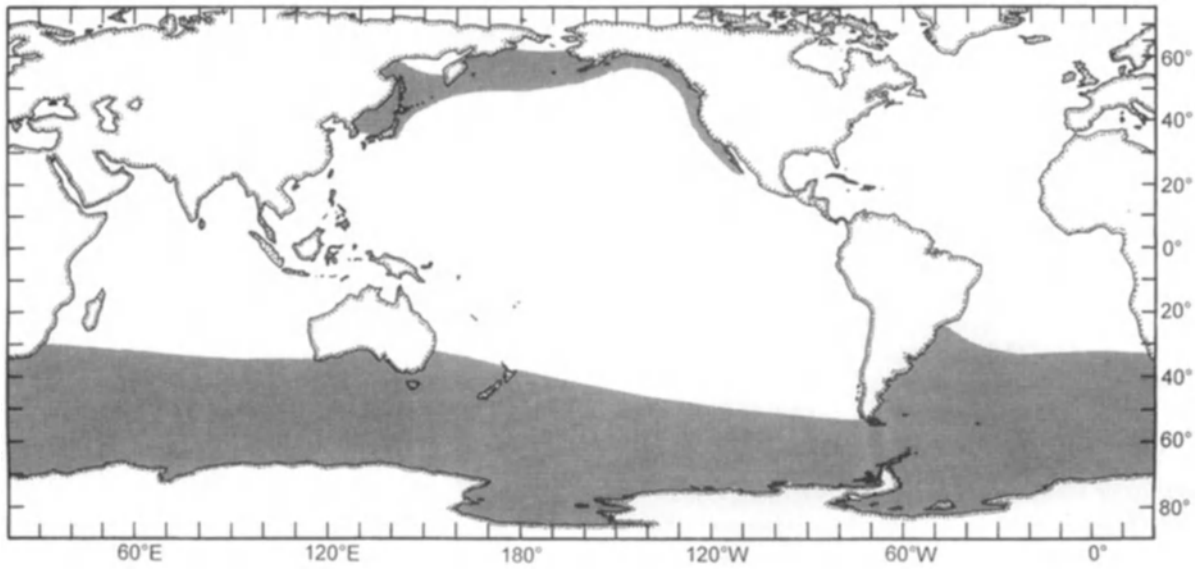

Figure 2 *Distribution of giant beaked whales in the North Pacific* (Berardius bairdii) *and Southern Hemisphere* (B. arnuxii) *(shaded areas). Precision of our current knowledge is greater in the former waters.*

Males live to about 84 years. Lack of behavioral data inhibits judgment of the age at which males begin to participate in reproduction.

Physical maturity, determined from the fusion of vertebral epiphyses to the centrum, is attained before 15 years and within 5 years from sexual maturity. Mean body lengths of samples 15 years or older are 10.45 m (SD=0.31, n=22) in females and 10.10 m in males (SD=0.35, n=66).

The male proportion is 44% at age 3–9 years and then increases with age to reach 100% at 55 years and over. Seventeen percent of samples of both sexes were old males (55–84 years). Such a sex ratio imbalance is common among whaling samples from Japan (Sea of Japan, Okhotsk Sea, and Pacific), Russia (Kuril and Aleutian Islands), and Canada (off Vancouver Island) and is believed to reflect a lower natural mortality rate of males.

The proportion of females among sexually mature individuals is 23%. This is only partially improved to 37% with the assumption that males attain reproductive capacity at 30 years when testicular growth ceases. The selective benefit for such male longevity is unknown.

Figure 3 *A school of Baird's beaked whales off Boso coasts, Japan.*

VI. Feeding, Parasites, and Predators

Squid beaks have been found in the stomach of an Arnoux's beaked whale.

Off Japan and California, Baird's beaked whales feed mainly on benthic fishes (Moridae and Macrouridae) and cephalopods, but occasionally on pelagic fish such as mackerel, sardine, and saury. Cyamids attach on teeth and skin, stalked BARNACLES on teeth, and diatoms on skin. Wounds attributable to the cookiecutter shark, *Isistius brasiliensis*, are common off Japan. Scars of killer whale teeth are common on flippers and tail flukes, suggesting PREDATION. Internally, they are heavily parasitized in the stomach, liver, blubber, and kidney, with extensive kidney pathology due to the nematode *Crassicauda giliakiana*.

VII. Abundance and Exploitation

ABUNDANCE is estimated only for Japanese waters: 5029 for the Pacific coast, 1260 for the eastern Sea of Japan, and 660 for the southern Okhotsk Sea, with 95% confidence intervals of about 50% on both sides of the mean.

Exploitation has not been reported for the Arnoux's beaked whale. HUNTING of Baird's beaked whales by USSR, Canada, and the United States was of low level. Hunting in Japan started in the early 17th century at the entrance of Tokyo Bay. The annual catch was less than 25 before 1840 and then declined. In 1891, whaling cannons were introduced and the operation moved to outer seas. After World War II, the fishery, expanded to the entire northern Pacific, reported a catch of over 300, and subsequently declined. Now the industry operates with a quota of 8 for the Sea of Japan, 2 for the southern Okhotsk Sea, and 52 for the Pacific coasts.

Gray Seal

Halichoerus grypus

AILSA HALL

University of St. Andrews, Scotland, United Kingdom

The gray seal is a highly successful marine predator of the Northern Hemisphere. This precocious and inquisitive marine mammal has had a changing relationship with humans, being exploited for its fur and blubber in the early last century but now being protected under national and international legislation. It continues to be a controversial species in relation to its interactions with fisheries where it often comes into conflict with humans for resources. However, it has sustained the vagaries of this relationship, and its population is increasing in almost every area it is found.

I. Diagnostic Characteristics

The gray seal is the only member of the genus *Halichoerus*. Its species name, *grypus*, means hook nosed, referring to the Roman nose profile of the adult male. *Halichoerus* means sea pig in Greek. This species exhibits SEXUAL DIMORPHISM with the mature males weighing between 170 and 310 kg and adult females between 100 and 190 kg. Individuals from the population in the western Atlantic are significantly larger than those from the eastern Atlantic; males can weigh over 400 kg and females over 250 kg. Genetic studies suggest that the western and eastern Atlantic populations are distinct and diverged approximately 1 million years ago (Boskovic *et al.*, 1996).

II. Selected Morphological and Physiological Data

Morphological differences between the sexes can be seen in Fig. 1. The neck and chest of the male are wrinkled and often scarred, whereas females are much sleeker. Both have the convex nose and wide muzzle, which are very pronounced in the male. Many of the females are gray in color with a distinctive cream/off-white background and markings, particularly around the neck, with generally a dark back and light underside. Males are more uniformly dark when mature, but subadults can have similar cream-colored patches on the neck and the side of the

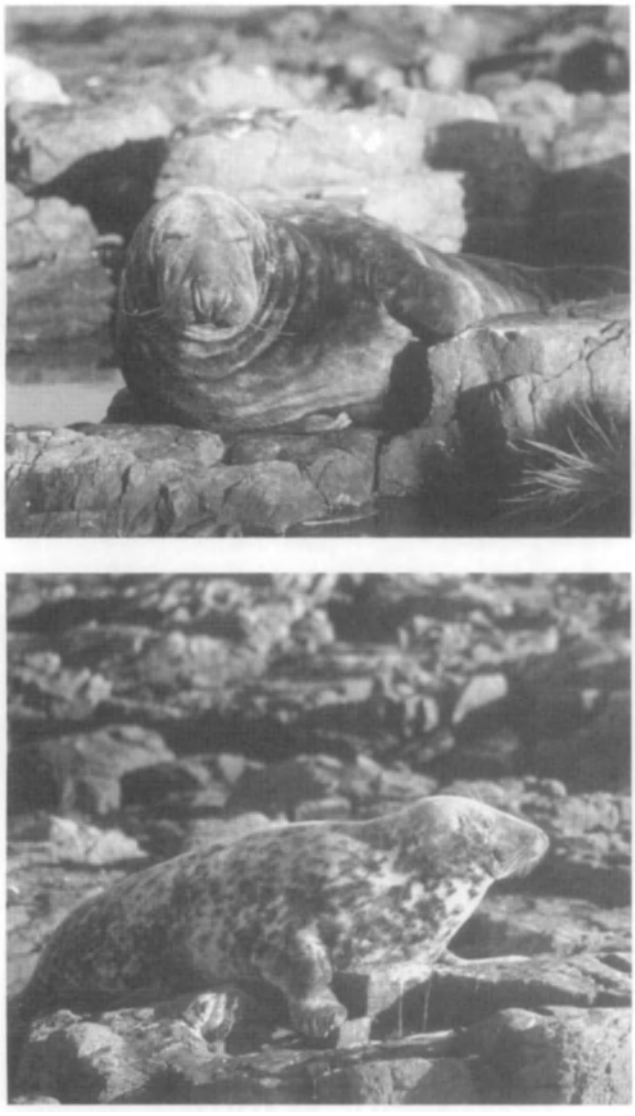

Figure 1 *Adult male (top) and female (bottom) gray seals. The female has distinct markings on the fur, whereas the male is more uniform in color and larger than the female.*

face. Females mature at between 3 and 5 years old and males around 6 years, although they are probably not socially mature until 8 years old.

III. Distribution and Geographic Variation

Figure 2 shows the geographic range of the gray seal. Breeding rookeries are on remote uninhabited islands or on fast ice. The single biggest island-breeding colony is on Sable Island (85,000, increasing at almost 12% per annum). Other major sites in the western Atlantic are in the Gulf of St. Lawrence (69,000). The northeast Atlantic population in Iceland was estimated to be 11,600 in 1987 with approximately 3000 in Norway, 2000 in Ireland, and between 1000 and 2000 in the White Sea. The Baltic population is estimated at approximately 5000 animals. The British population is surveyed annually and is currently approximately 110,000 animals, increasing at about 6% per annum.

IV. Life History and Ecology

The females give birth, on land or on ice, to a single white-coated pup between September and March. The earliest breeding colonies are those in the south of the United Kingdom and Ireland. Further north around the British Isles the breeding season is later, between October and November. In Canada, peak pupping is not until January and in the Baltic it occurs in late February–early March.

At birth the pup weighs between 11 and 20 kg and, over the lactation period, lasting an average of 18 days, can quadruple in weight to over 40 kg. The mothers' milk is very fat-rich (around 50–60% lipid) and is mobilized from her blubber stores. The pup's white coat, known as the lanugo, is shed at weaning. The pup then undergoes a postweaning fast on land for a period lasting between 10 and 28 days, during which it loses approximately 0.5 kg per day. The reason for this fasting period is not fully understood, but physiological changes during this time suggest that it is related to the development of diving ability.

Toward the end of lactation the female comes into estrus and mates. On some colonies there may be as many as 10 females to 1 male, whereas on rookeries, where access is not restricted by narrow gullies, the sex ratio may be 2 females to 1 male. Males compete for access to females but do not defend discrete territories, and matings may occur in the water as females return to the sea, as well as on land. Females fast during the breeding season and may lose up to 40% of their initial body weight during the breeding season, as they do not feed during this time. The gestation period is 8 months, and to achieve a 12-month breeding cycle the fertilized egg is not implanted until 4 months after conception. This occurs around the time of the annual molt when animals spend longer time hauled out on land. Gray seals generally return to their natal site to breed and show a high degree of site fidelity, often returning to within meters of their previous pupping sites (Pomeroy *et al.*, 1994).

Gray seals feed on a variety of fish species and cephalopods (Hammond *et al.*, 1994a,b). However, a large proportion of their diet is sand eels or sand lance (*Ammodytidae*), which can make up over 70% of the diet at some locations and in some seasons. Other prey include whiting, cod, haddock, saithe, and flatfish (plaice and flounder). They are largely demersal or benthic feeders, and foraging trips lasting between 1 and 5 days away from a haul-out site are frequently focused on discrete areas that are within 40 km of a haul-out site (McConnell *et al.*, 1999). On average, gray seal dives are generally short, lasting between 4 and 10 min with a maximum recorded duration of about 30 min. Typically, in the United Kingdom, animals dive down to the sea bed, which is largely 60 m in depth, falling to 200 m in some areas, although dives at depths >300 m have been recorded.

The family Eschrichtiidae includes a single known genus and species, the gray whale, which now is found only in the North Pacific and Pacific Arctic Oceans (though it once lived in the North Atlantic until the 17th or early 18th century). Grays are by far the most coastal of all the great whales, and inhabit primarily inshore or shallow, offshore continental-shelf waters. They tend to be nomadic, highly migratory, and are tolerant of climatic extremes. Each year, they make the longest migration of any whale (up to 15,000–20,000 km round trip) largely without FEEDING, traveling along nearshore routes between a summer feeding zone of high productivity in Arctic or subarctic waters and a winter breeding zone in temperate or subtropical southern waters. Unlike other

mysticetes, the gray is primarily a bottom feeder and influences the topography of the seabed in the Arctic (from sucking its prey out of the sediments). It is the only whale to bear its young in warm, shallow, coastal areas and lagoons.

There are two populations. The western North Pacific population (or Korean-Okhotsk) migrates along the coast of Asia. It was hunted to the verge of extirpation and is extremely rare. Another much larger, eastern North Pacific population (or California-Chukchi) migrates along the coast of North America and eastern Siberia (Fig. 1). It too was severely overexploited in the latter half of the 19th and early 20th centuries, but, following protection from commercial WHALING, has increased to about 26,600 (in 1999). The resilient eastern North Pacific gray whale is the only cetacean population that, following severe depletion, has sufficiently recovered under protection from commercial whaling to be removed from the list of endangered species. The western Pacific population, however, remains listed as critically endangered.

An active but gentle species, as long as they are not molested, the gray whale had a reputation for ferocity among the old whalers, who dubbed it "devilfish" for its habit of crashing into and staving in boats when harpooned or in defense of its young. Despite it being the trickiest and most dangerous prey, early whalemen developed a special affection for grays and found them to be the most interesting and intelligent of all the great whales. Grays seemed to learn quickly the dangers from whaling and performed a remarkable array of evasive maneuvers. They were admired for their fierce protection of their young and habit of giving assistance or "standing by" an injured companion, often reaching self-sacrificing measures. When attacked, they showed a power of resistance and tenacity of life that distinguished them from all other cetaceans. Today, many people have come to value gray whales more highly as a living resource than as one to slaughter, and they have become a WHALE-WATCHING phenomenon. Their coastal habits make them the most accessible of all the mysticetes and they can be seen most easily, often from shore. Gray whales are unusually sportive; breaching, spyhopping, LOBTAILING, and mating extravaganzas are essential elements of their migratory and breeding-grounds repertoires. Their willingness to allow whale watchers to stroke them is an added attraction, and grays are now known as "friendly" whales.

I. Systematics

A. Evolutionary History and Classification

No fossils of a direct gray whale ancestor have been found. The family Eschrichtiidae is known only from the Recent and from a single Pleistocene specimen about 50,000–120,000 years old found in California, and a less certain one from Alaska. A long-held theory proposed that gray whales could have evolved from the Cetotheridae, an extinct family of whales dating back some 38 million years, and could be their closest living relatives. Due to the lack of any fossil remains linking the modern gray whale to the far more ancient cetothere, some challenge that view and are unwilling to link them to any of the known early whales. A highly distinctive species, the gray whale has been placed in its own family: Eschrichtiidae (Ellerman and Moirrison-Scott, 1951) (=Rhachianectidae, Weber, 1904).

Most experts have considered the gray whale to be more closely related to the rorquals (Balaenopteridae) than to the right

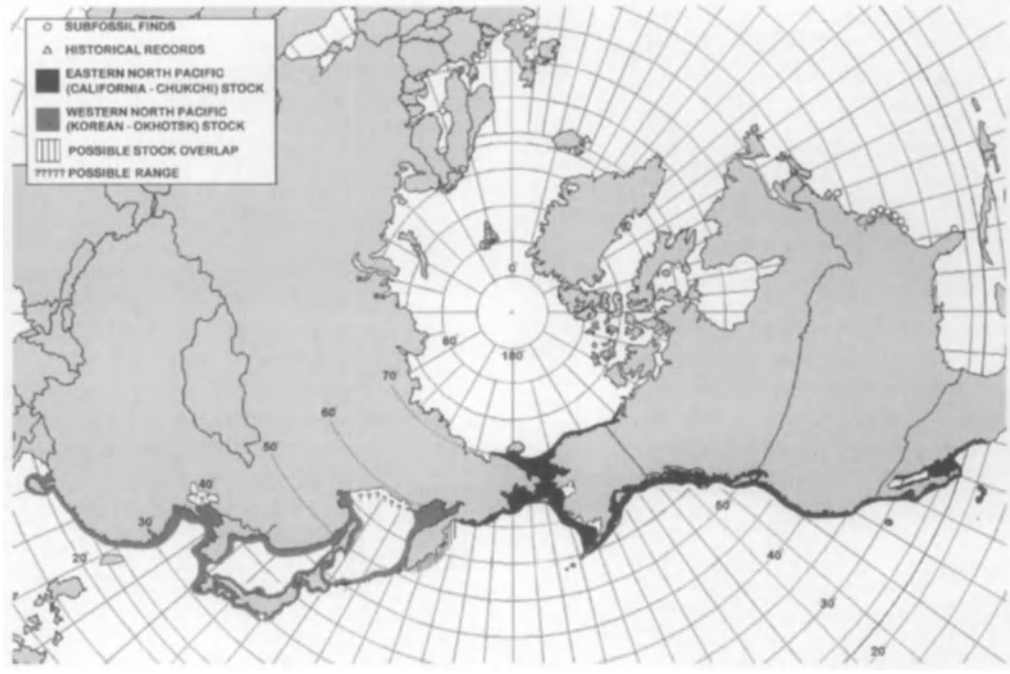

Figure 1 *Known distribution, historic and current, of the gray whale. The eastern North Pacific population (black) has recovered from depletion. The western North Pacific population (gray) remains critically endangered. The Atlantic gray whale is extinct and is known from subfossil finds (circles).*

whales (Balaenidae). Others have given it an intermediate position between the two. However, for the four modern families of baleen whales commonly recognized (Balaenopteridae: rorquals, or fin whales; Balaenidae: bowhead and right whales; Eschrichtiidae: the gray whale; and Neobalaenidae: the pygmy right whale), the pattern of phylogenetic relationships at the base of baleen whale divergence is unresolved. With respect to gray whales, analyses of their position within the Mysticeti conflict. Molecular studies position gray whales within the balaenopterids, while analyses based on morphology and including fossil and extant taxa differ in suggesting grays are linked with the balaenids and the pygmy right whale. Moreover, some biologists place the gray whale as a subfamily of Balaenopteridae.

B. Names

The gray whale has many English names, first applied by 19th century whalers. *Scrag* was used by old whalers on the Pacific coast of North America because they identified it with a whale called a scrag that was taken in the Atlantic Ocean in the 17th and 18th centuries. *Devil fish* and *hard head* were derived from the often violent reaction of the grays that commonly smashed boats with their heads and flukes when harpooned. *Mud digger* and *mussel digger* referred to the bottom feeding of the whales. *Gray* and *gray back* characterized its color. *Okhotsk* and *Korean* denoted the western population's feeding and presumed breeding grounds, and *Chukchi* and *California*, the feeding and breeding grounds for the eastern population (also the whaling grounds).

As for its scientific name, the generic name *Eschrichtius* (Gray, 1865) was given to honor a 19th century Danish zoologist, Daniel Eschricht; and the specific name *robustus* (Lilljeborg, 1861) is from the Latin for "oaken" or "strong." The gray whale first became known to science not through observations of living animals but through the discovery of subfossil skeletal remains from Europe where it had long been extinct. Conspecificity cannot be proven by purely anatomical data, but the SKELETON of the gray is distinctive and no anatomical difference has been found between extinct Atlantic and extant Pacific populations (or between the eastern and western populations of the Pacific) that would justify separating them on the basis of species, or even subspecies. Thus, the odd situation exists where the remains from the extinct Atlantic population serve as the type specimen for the Pacific Ocean (=*Eschrichtius gibbosus* Erxleben, 1777).

II. Description

The gray whale is a robust, slow-moving whale with a flexible body, more slender than the right whales and more stocky than most rorquals (Fig. 2). This species is readily identified by the mottled gray color of the skin with numerous lighter patches scattered all over the body (although color may vary from gray-brown to slate-black). Grays have more external PARASITES and epizoites than any other cetacean. The barnacle, *Cryptolepas rhachianecti*, thought to be host specific, has been found on beluga whales (*Delphinapterus leucas*). As larvae, BARNACLES are free swimming but soon settle onto calves and adults alike,

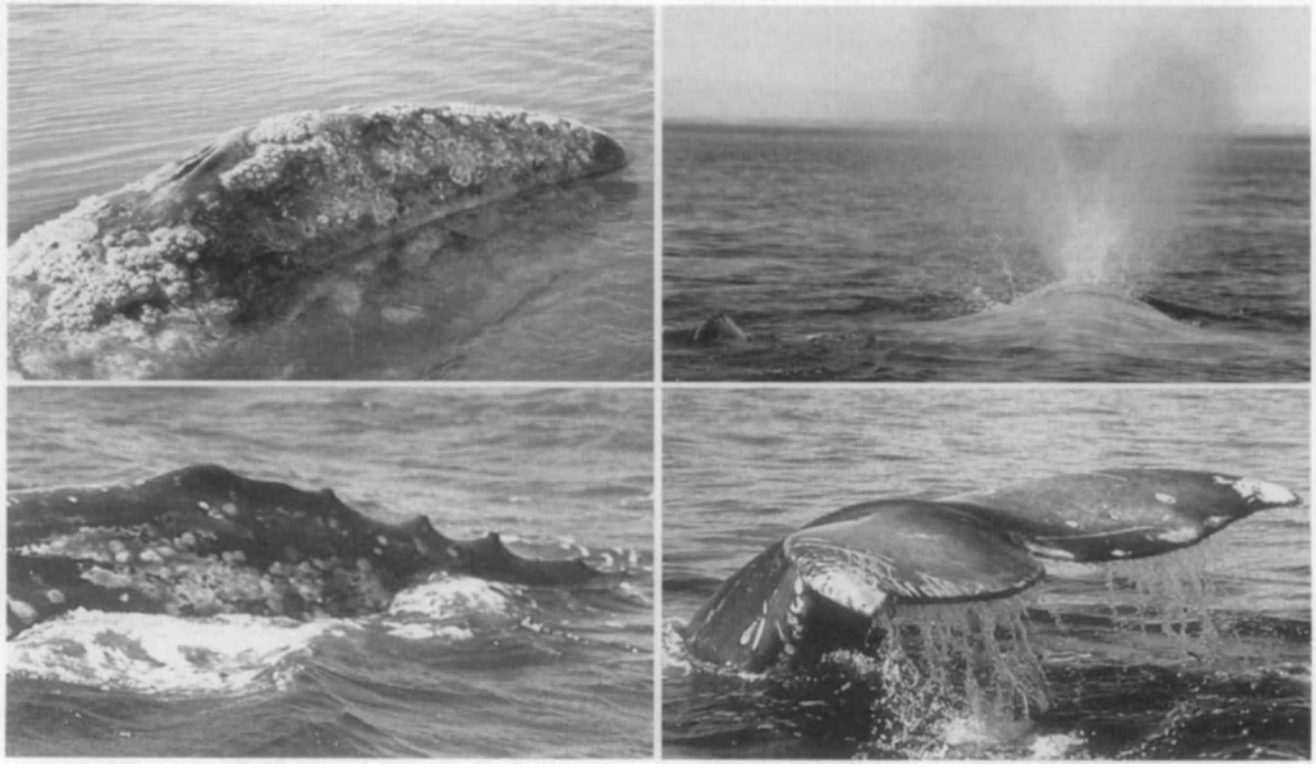

Figure 2 *The narrow head of the gray whale is usually covered with patches of barnacles and whale lice (top left). The blow is heart-shaped and 3–4 m high (top right). Instead of a dorsal fin, grays have a low hump followed by a series of bumps (bottom left). The flukes are over 3 m wide, frequently bear scars from the teeth of killer whales, and are often lifted before a deep dive (bottom right).*

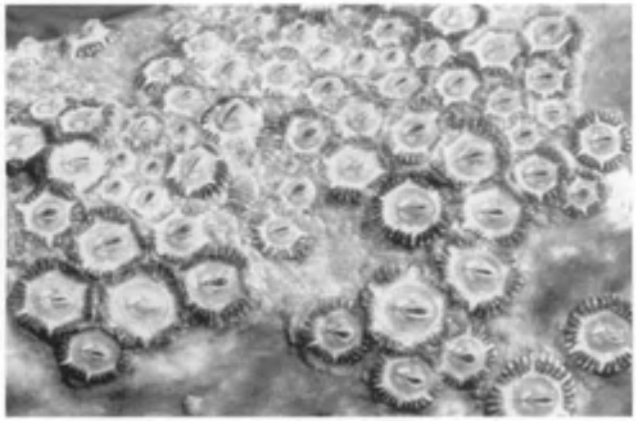

Figure 3 *Dense clusters of barnacles surrounded by whale lice develop shortly after birth. Barnacles leave white scars on the whale's skin, which slowly repigments over time.*

eventually forming large colonies that are deeply embedded in the skin. Grays also host three species of WHALE LICE (they are cyamids, not insects) that feed on skin and damaged tissue: *Cyamis scammoni* and *Cyamus kessleri* occur only on grays, whereas *Cyamus ceti* also lives on other whales (Fig. 3). The lice cling by the thousands in areas of reduced water flow, such as around barnacle clusters, blowholes, and folds of skin, and swarm into wounds. In the breeding lagoons, schools of topsmelt (*Atherinops affinis*) symbiotically clean lice and sloughing skin from the whales. Much of the whale's mottled appearance comes from the parasites or scars from previous infestations and abrasions. By photographing the skin pigmentation patterns on the backs and sides, it is possible to identify individual animals, which is important to the study of gray whales.

The gray whale's relatively short, narrow head is triangular (in top view) and moderately curved downward (in side view) (Fig. 4). It is encrusted with patches of barnacles and associated whale lice, particularly on top. Widely spaced bristles sprout from small dimples on the upper and lower jaw (no other whale has so many hairs); these short bristles, linked with sensory cells, are extra noticeable on calves. The skull comprises only about 20% of the total skeletal length. A unique feature is the presence of paired occipital tuberosities on the posterior part of the skull. Small eyes, with eyelids, are located just behind the corners of the mouth. Directly above them, on top of the head, is a pair of blowholes (nostrils). Barely visible, the ear opening is a tiny hole just behind the eye. The narrow upper jaw has 130 to 180 baleen plates hanging down on each side, separated in the front of the snout. A gray's BALEEN is the shortest (5–40 cm), thickest, and coarsest of all mysticetes and is cream-white to pale yellow. The lower jaw is broad, with a keel-like protuberance in front, and slightly arched. On the throat there are two to seven (commonly three) short, deep creases that stretch open and allow the mouth to expand a little during feeding, but they do not extend beyond the throat region and are insignificant compared with the many long ventral grooves found in balaenopterids.

Gray whales lack a dorsal fin but have a low hump followed by a series of 8–14 small bumps (knuckles) along the top of the tail stock. The ventral part of the body is smooth, without any longitudinal grooves. The paddle-shaped flippers are up to 200 cm long. Tail flukes are over 3 m wide on adults, with smooth trailing edges and a deep median notch. The flippers and flukes are often marred with tooth scars from killer whales (*Orcinus orca*). Unique to this species is a cyst-like structure (10–25 cm in diameter) beneath a swelling on the ventral surface of the tail stock, which may be similar to sebaceous glands of land mammals, or function as a track-laying scent gland, although its exact function

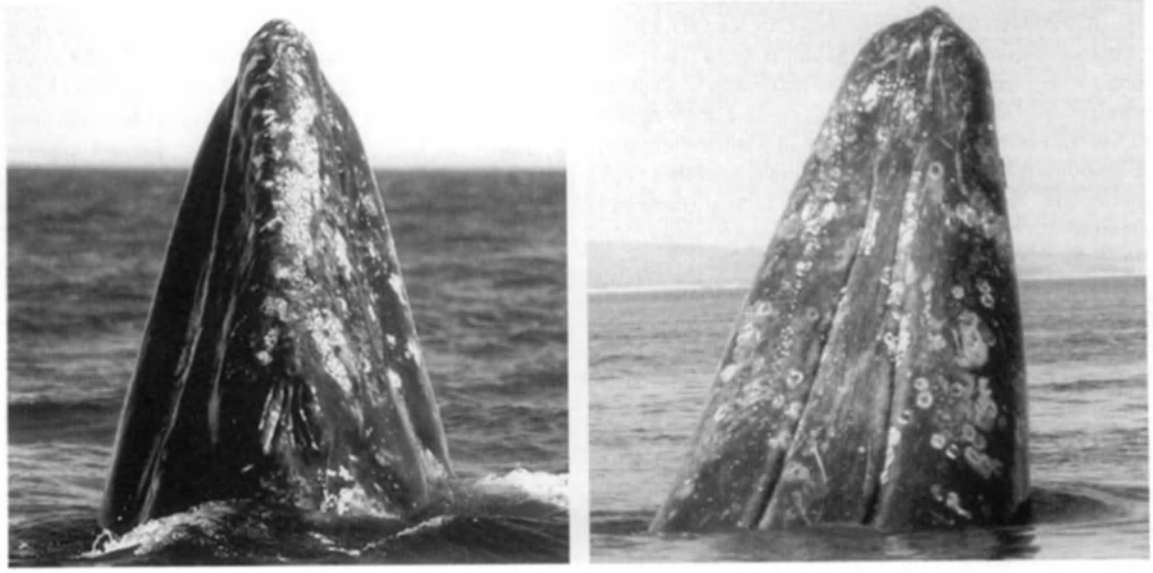

Figure 4 *Gray whales commonly spyhop, lifting the head vertically above the water. The head is narrow and triangular when viewed from the top (left), and they have from two to seven short creases on the throat (right), rather than the long, ventral throat grooves found in balaenopterids.*

is unknown. Grays, which survive in extremely cold water for about half of the year during the feeding season, are insulated with a layer of BLUBBER averaging 15 cm thick beneath the skin and can tolerate a great drop in their skin surface temperature to only a degree or so above that of the surrounding water.

Newborn grays (calves) average 4.6 to 4.9 m long and weigh about 920 kg. The sex ratio is parity at all ages. They reach puberty at anywhere from 6 to 12 years of age (average is 8), at a mean length of 11.7 m in females (called cows) and 11.1 m in males (called bulls). Adults weigh 16,000 to 45,000 kg and stop growing at about 40 years, when the average female is 14.1 m long and the average male is 13.0 m. The largest female recorded was 15 m, and the largest male 14.6 m long. Although adult females are slightly bigger than males, there is no significant difference in their appearance (the distance from the genital slit to the anus is wider in males). The maximum, as well as average, life span is unknown (age is calculated from growth layers in the waxy ear plugs that fill the auditory canal). One large female was estimated to have been 75–80 years old when she was killed and she was pregnant.

III. Ecology and Behavior

A. Social Organization

The gray whale is not a highly social species. Individuals may associate with many conspecifics, but they do not appear to form stable pairs or groups and come together for only part of the year during migration and on the winter breeding range. The only persistent social bond known is between a mother and a calf, which disappears at weaning. Now and then, short-term associations lasting several days or weeks are reported, but their significance is still a mystery to us. Very little research into the social organization of the gray whale has been done. It is possible that they communicate even over large distances, sending and receiving acoustic signals. No territoriality, dominance, or overt aggression toward conspecifics has been reported.

On the summer feeding grounds, grays are usually widely spaced, solitary (commonly pregnant females), or in pairs, and less often in small groups of 3–5, although many may be in proximity in the patchily distributed food-rich areas. Larger aggregations in tens or even hundreds can occur in a particularly rich feeding area but are likely related to a mutually available mass of food rather than to social cohesion or interaction (these aggregations fluctuate constantly). Occasionally, some grays stop feeding to form groups of 30–40 or 100–400 animals that engage in bouts of social activity (lasting 1–4 days) reminiscent of courting and mating; however, their function is unknown. During migration, singles, pairs, and trios are most common but grays sometimes form transient groups of up to 16 individuals.

On the winter breeding grounds, large aggregations of mothers with young and courting/mating whales are common, but are in constant flux (1000 or more will crowd into the largest breeding lagoon). Initially, mothers with neonates have little interaction with other mothers and calves, although many are concentrated in the nursery areas of the breeding grounds. When calves are 2–3 months old, however, they often form highly interactive social groups. In these encounters, mothers and young cavort en masse, rolling about on top of each other, rubbing and touching from head to flukes, and often emitting huge bursts of underwater air bubbles. Groups last from a few minutes to over 3 hr and involve up to 40 individuals at a time, with many others coming and going, and may play a role in the social development of the calf.

Overall, there is a low degree of cooperation among gray whales, except limited examples of joint defense against killer whale attacks and assistance or support behavior, mainly for the aid of the young and especially in the calving areas. This is evidenced by adults coming to the aid of a mother whose calf is in trouble. Standing by (whales in a pair or group assisting, supporting, or staying with an injured companion) also occurs occasionally among adults in times of distress.

B. Feeding

Gray whales do almost all of their feeding during summer and fall when they are in higher latitudes, where they forage on the ocean floor in shallow waters over continental shelves (4–120 m deep). They are adapted to exploit the tremendous seasonal abundance of food that results as the Arctic pack ice (sea ice that is unattached to land) retreats in spring, exposing the sea to the polar summer's continuous daylight, which triggers an enormous bloom of microorganisms in the water down to the sea floor. Unlike other baleen whales, the gray is mainly a bottom feeder and sucks small invertebrates and crustaceans out of the sand and mud. Their distribution in the feeding grounds coincides with the concentrations of these bottom-dwelling prey. As the summer advances and the edge of the pack ice recedes and uncovers more of the feeding grounds, the whales move. They feed heavily from about May through October, gaining enough stores of fat to sustain them during fasting or greatly reduced intake of food during the rest of the year, when the polar feeding grounds are ice covered and they migrate south to warm winter breeding grounds.

During about 5 months of intensive feeding in Arctic waters, an adult will consume roughly 170,000 kg of food. By the time the grays return to the feeding grounds (5 to 6 months later) they will have lost up to 30% of their body weight and must single-mindedly forage to replenish their fat reserves. The highest energy costs during migration are incurred by pregnant or lactating cows. For cows, the cost of reproduction includes the ENERGETIC requirements for gestation (producing a calf) and lactation (nursing young until weaning), which is far greater. During summer and fall, pregnant cows put on 25–30% more weight than other gray whales (exclusive of fetus).

An extraordinary aspect of the gray whale's feeding ecology is its apparent dietary flexibility. Over 80 species of prey have been identified, reflecting its opportunistic approach to foraging. On the summer feeding grounds, grays primarily consume benthic gammaridean amphipods (shrimp-like crustaceans that live on or buried in the sediment). Amphipods from four families account for about 90% of the food, but depending on the feeding area, 1 of 7 species is usually dominant. Four are from the family Ampeliscidae (*Ampelisca macrocephala, A. eschrichti, Byblis gaimardi, Haploops* sp.). They are tube builders that live in dense colonies or "tube mats" in the upper few centimeters of sea floor sediments. Overall, the amphipod *A. macrocephala* (up to 33 mm long) is probably the

most commonly taken species (and occurs in concentrations as high as 23,780/m^2 in the Chirikov Basin in the Bering Sea). The other three species are from separate families: Haustoriidae (*Pontoporia femorata*), Lysianassidae (*Anonyx nugax*), and Atylidae (*Atylus bruggeni*), which are mobile scavenging amphipods that rove freely over the seafloor in search of prey. In some areas, polychaete tube worms (*Travisia forbesi*) are their main food. Planktonic prey items eaten in the peripheral feeding areas south of the main feeding grounds occur in swarms or schools and include mysids, crab larvae, red crab, mobile amphipods, herring eggs and larvae, squid, megalops, and bait fish. Some plant material also occurs in their stomachs.

To bottom feed, grays roll to one side, bringing the head parallel with the seabed, sweep the side of the mouth close over the bottom a few centimeters above it, and open the jaws slightly to suck sediment containing prey into the mouth (which has flexible lips) (Fig. 5). Water, sand, and mud are strained through the comb-like baleen, leaving the food trapped on its inner margin. The suction might be created by retracting the large, strongly muscled tongue (weighing 1400 kg). The grays move slowly along the bottom, sucking up infauna in pulses, and surface with clouds of sediment (called mud plumes) streaming from the mouth. Mud plumes mark the meandering path of the feeding whales. Seabirds feed on prey brought to the surface in the plumes.

Grays impact their feeding grounds more than any other cetacean. Bottom feeding leaves mouth-sized depressions or "feeding pits" in the sea floor, from which the top layers of sediment are removed. Foraging is a major source of physical disturbance to the benthic community and plays an important role in the rate of turnover of the epibenthos. In some areas of the Arctic, over 40% of the seafloor is pock-marked with feeding pits. It is thought that by clearing space in the bottom, whales open areas for recolonization, succession, and maturing of the prey community, thus promoting the growth and diversity of life on the seafloor. Periods of nonuse are presumed to correspond to rapid recovery of the habitat. However, if the resource is overutilized and the area is stripped, it could be a one-way street leading to the permanent loss of amphipod communities and changing feeding patterns. In this way, gray whales are an integral part of the coastal community and participate in a dynamic feedback loop, termed "niche construction," whereby their feeding activities function to shape their ecological niche through alteration of the benthos.

In addition to bottom feeding, grays also occasionally feed by surface skimming and engulfing planktonic prey out of the

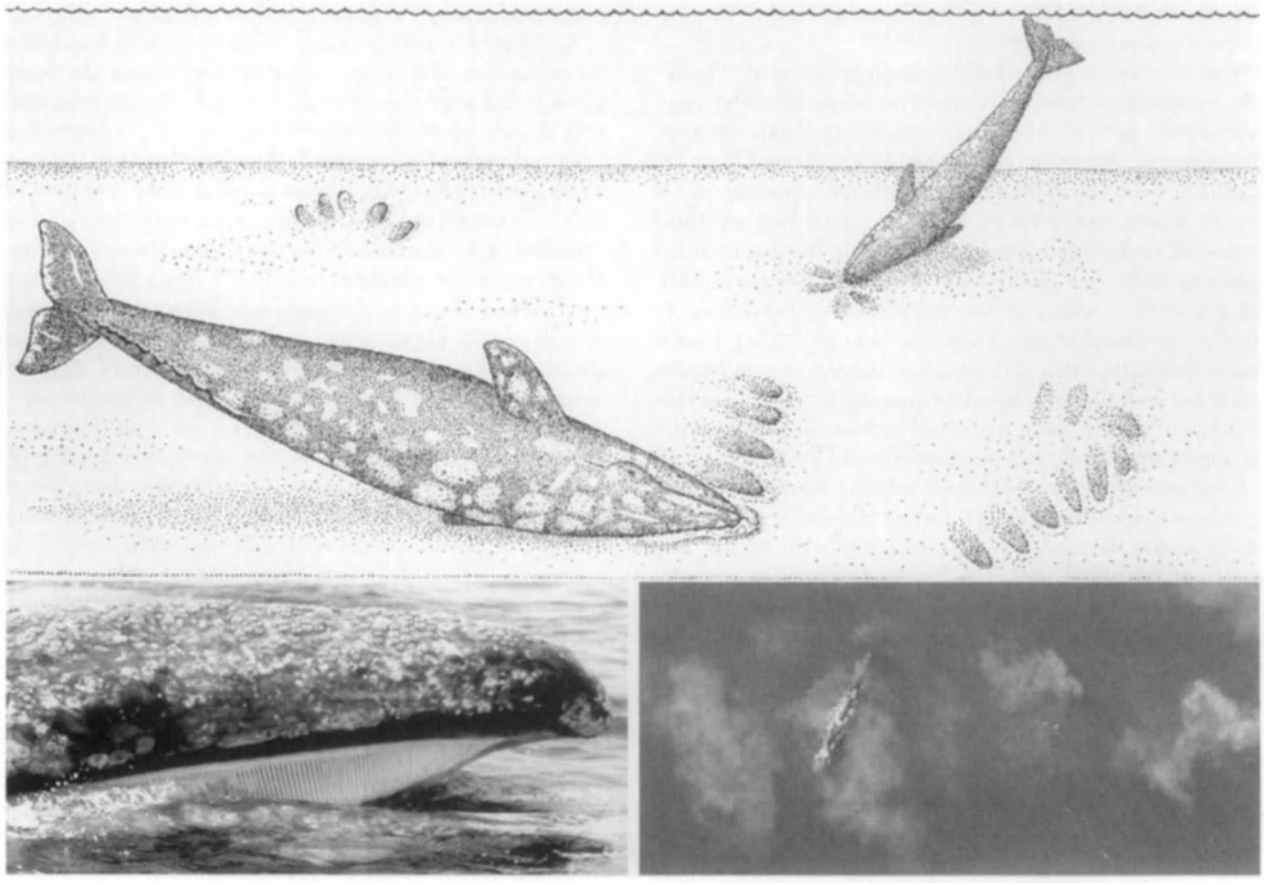

Figure 5 *A bottom feeding gray whale swims on one side to suck prey from the seafloor, creating mouth-sized depressions or feeding pits (top). The cream-white baleen plates are the coarsest, shortest, and fewest of any mysticete (bottom left). Sieving prey-laden sediments through the baleen creates billowing mud plumes (bottom right).*

water column. Zooplankton are only known to be utilized outside of the principle feeding grounds, in peripheral feeding areas throughout the migratory range. Instead of traveling the entire distance to the feeding grounds, some whales spend the summer feeding along the coast in other parts of their range. Also, whales destined for the summer grounds sometimes stop to feed periodically on the way if the opportunity arises. The importance of peripheral feeding areas is unclear. With three modes of feeding (benthic suction, engulfing, and skimming) the gray has perhaps a greater range of foraging techniques than any other of the great whales.

C. Reproduction

Gray whales are thought to have a promiscuous mating system: males and females do not form long-term pair associations and both sexes may copulate with several partners during the same breeding season. Because multiple inseminations can occur, it is proposed that *sperm competition* may be taking place in gray whale fertilization (sperm from two or more males compete to fertilize the ovum within a female). Adult males have relatively large testes weight (averaging 38 kg in mating season) to body weight ratios and presumably produce large quantities of sperm. In this mating strategy, copulating males attempt to dilute or displace the sperm of other males to increase the likelihood of being the male to fertilize the female. Their fibroelastic penis reaches 170 cm in length and is erected by muscle fibers and not vasodilation.

Reproduction in gray whales is strongly seasonal. The female reproductive cycle lasts 2 years and consists of the onset of estrus (the period of sexual receptivity), ovulation, conception, gestation, lactation, and an anestrous period. Most females bear young in alternate years, although some may rest 2 or more years between calves. In general, each year one-third to one-half of the adult females are birthing (they are not receptive to bulls after calving) and the remainder are mating, with a reversal of roles each successive year. Cows continue to breed at an advanced age. Bulls mate annually. They have a peak of spermatogenetic activity in late autumn or early winter, correlating with the time females come into estrus. Some sexual behavior on the feeding grounds and among males occurs that apparently serves nonreproductive social purposes.

Lengthy courting (precopulatory) behavior is part of the mating process, evidently requiring sufficient physical contact by the bulls to arouse the cows, but detailed information on the constituents of courtship is not yet available. Copulation occurs belly to belly. Pairs or trios of whales sometimes court and mate quite gently together. More often (or perhaps just more readily visible), there is a high level of activity, marked by whales rolling, touching, splashing, and cavorting energetically, at which times bulls with extended penises can be seen (Fig. 6). While some nudging and pushing may take place to get close to a cow, bulls do not appear to fight to keep others away. Bulls outnumber available cows by as much as two to one, leading to the belief of a ménage à trois mating group by early naturalists. In fact, although trios are common, so are pairs and groups of various sizes that can blossom into a giant free for all involving as many as 20 consorting adults at a time. The large groups constantly

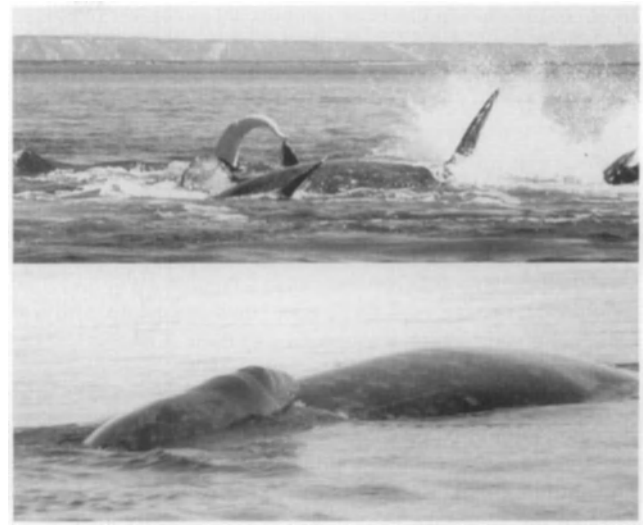

Figure 6 *Gray whales mate with multiple partners, often in large, energetic courting groups (top). Newborn calves have more uniformly dark skin and are supported on their mothers' backs for their first few breaths (bottom).*

fluctuate, with some participants departing while others join in as if stimulated by the sexual activity of the initial core group.

Conception occurs primarily in late November and December while the whales are migrating south from the feeding grounds, but some do not conceive until in the winter assembly area, or even on the northward spring migration. Length of gestation is disputed, but is generally thought to last 11 to 13 months, which means that newly pregnant females do not give birth until they have completed the following year's southward fall migration. The birth season lasts from about late December to early March (median birth date: January 27), when most near-term cows are in or near the calving grounds, although some calves are born during the migration from California south. Cows bear a single calf, unattended, and provide sole parental care. Reports of births cite head-first deliveries, with the cow supporting her calf at the surface for the first few breaths of air. Initially, its movements are uncoordinated, but swimming soon steadies (Fig. 6).

A mother's bond with her calf is especially close. She displays an unusual degree of affection, often gently stroking it with her flippers. Mothers are highly protective and will fight fiercely to defend their young from danger. While in the lagoons and on migration, calves stay close to and almost touching their mothers. They drink about 189 liters of rich milk (about 53% fat and 6% protein) each day and grow rapidly, reaching 8.7 m when weaned. The calf remains dependent on its mother until it is weaned in the summer feeding area, at about 7–8 months of age, and perhaps 1 or 2 months longer, when they have solid food in their stomachs but remain with their mother. It is thought that calves begin to forage during the latter stages of nursing and thus may gain some experience while still with the mother. After the calves are weaned, around August, cows are anestrous for 3 to 4 months. Then in November to December a new mating period begins.

D. Sensory Perception

1. Acoustics Once reported to be almost silent, it is now known that gray whales are soniferous both day and night. They create a variety of phonations that sound like rasps, croaks, snorts, moans, groans, grunts, pops, roars, quick series of clicks, belches, and metallic knocks and bongs. These low-frequency broadband signals range from about 100 Hz to 4 kHz, but may go up to 12 kHz. The most prevalent sounds for whales feeding in the Arctic and those in the breeding lagoons are pulsive signals, usually emitted in bursts, that sound like a series of metallic knocks (broadband pulses, from about 100 Hz to 2 kHz). Tonal moans are the most common phonation from migrating whales. Some behaviors may also serve an acoustic function. Grays expel huge bursts of air bubbles underwater (explosive exhalations). These emissions are often released in profusion from the blowholes in social settings. Occasionally, large quantities of air are released from the sides of the mouth as the whale swims by, producing a spectacular display of bubbles. The functions are still obscure, but the joint effect of the acoustic and visual components could create a potent short-range communication signal. Other behaviors that may have an acoustic function include percussive jaw claps, head slaps, backslaps, BREACHING, flipper slapping, and LOBTAILING.

Gray whales are not known to echolocate by means of high-frequency click trains as odontocetes do. However, some low-frequency click-like sounds resembling ECHOLOCATION (which enables a whale to detect objects by listening to the reflected echo of its own sound pulses) have been recorded. These sounds are very tentatively proposed as evidence for primitive echolocation aptitudes that may serve a long-distance function limited to large targets (such as whales) or to detecting broad topographical or oceanic features useful for orientation and navigation. The theory of echolocation in gray whales, however, is as yet unsubstantiated.

Whalers have long stood in awe of the gray's sensitivity to sound. Even the water disturbance by an oar may put a whale to flight. The relatively low upper limit of the frequency range of their vocalizations suggests that they may hear well into the low sonic or infrasonic regions (below the range of human hearing, frequencies lower than 18 Hz). The use of mostly low-frequency sounds is thought to be an adaptive strategy whereby gray whales circumvent the high levels of natural background noise prevalent in their coastal environment by producing sounds that are generally at frequencies below it. Unfortunately, much of the man-made noise in the ocean also occurs in the lower frequency range and has a high level of output, which could interfere with or mask the gray whale's sounds or possibly damage their hearing. Gray whales appear to try to get around some man-made noise by increasing their call types, calling rates, and the loudness of calls to enhance signal transmission and reception.

2. Other Sensory Perception Gray whales can see moderately well both in air and water, but color VISION is probably weak. The position of the eyes suggests that they have stereoscopic vision forward and downward permitting efficient estimation of distance. The eyes are adapted for heightened sensitivity to dim light and for improving contrast and resolution underwater. Grays have retained some sense of smell but are microsmatic at best. In water, the nares are almost always closed (but whales may smell the air as they breathe). The sense of touch is well developed. Some taste buds occur at the back of the tongue, and the possibility of chemoreception through taste has been conjectured.

E. Sleep

It is not known if gray whales sleep. Whales on migration have not been observed to stop to rest for long periods of time. One exception is mothers and calves, which stop to nurse and rest during the north migration. In polar regions during summer when daylight is continuous, most gray whales remain active continually, usually foraging or moving between feeding areas, although occasionally a few resting animals are seen. It is speculated that grays, like some delphinids, may rest one hemisphere of the brain at a time (presumably essential to a voluntary breather). In the breeding grounds, there are more obvious indications that grays sleep, particularly near-term pregnant females and those with neonates. They rest, barely awash, floating at or just beneath the surface, with head and flukes hanging down, for up to an hour, and raise the head to breathe periodically in a slow rhythmic pattern.

F. Swimming, Breathing, and Diving

Overall, gray whales are relatively slow but steady swimmers on migration, although speeds vary from the beginning to the end of the route and there are periods of wandering, resting, milling, feeding, and breeding activity in addition to directed travel along the way. They make the southward trip from the feeding to the breeding grounds in an average of 55 days, swimming at about 7–9 km/hr, and cover a distance of about 144–185 km/day. On the north migration, grays move at a slower speed, averaging 4.5 km/hr (88–127 km/day), and may socialize and feed more, which effectively slows their diurnal rate of migration. Mothers and calves travel up to 96 km/day. Speed of directed travel is about the same as that of other whales, but mothers and calves pause to rest and nurse along the migration. When pursued, grays may reach about 13 km/hr but can only maintain this pace for a few hours. Speed under duress can surge to 16 km/hr, at least for short bursts (avoiding predators). Interestingly, gray whales are very efficient swimmers. They travel mostly at speeds that minimize their energy expenditure and maximize their range, and swim at depths that minimize total drag, important factors in successfully covering the long migratory distances they travel.

Gray whales usually are not exceptionally long or deep divers. The pattern of BREATHING between dives can vary greatly for different activities, with grays averaging only 3% of the time at the surface. When migrating, whales typically remain submerged during traveling–dives for 3 to 5 min during which they may travel 300 m. They surface to blow three to five times at intervals of 15 to 30 sec during a series of short, shallow, surface dives showing only a small portion of the back. The bushy

spout is 3 to 4 m high (Fig. 2). Following the terminal blow in a series, traveling whales typically lift their flukes into the air (fluke up) to begin the next traveling dive. During prolonged dives, they may remain submerged 7 to 10 min (or longer) and travel 500 m or more before resurfacing to breathe. Usually, the longer the dive, the greater the number of blows, as the need to reoxygenate the system is greater. Their maximum known dive depth is 170 m.

Breathing and DIVING BEHAVIOR on the feeding and breeding grounds is more variable than on migration. When foraging on summer feeding grounds in shallow coastal waters of 50–60 m, grays dive to the bottom by submerging almost vertically and lifting their flukes above water, and stay under for 5 to 8 min while swimming very slowly. In the breeding lagoons, about 50% of the dives are less than 1 min and 99% are less than 6 min, whereas dives longer than 12 min are associated with resting animals. Mothers, for example, typically float at or slightly below the surface for periods of up to an hour and then submerge for 5 to 10 min, or up to 26 min. When evading detection, grays often surface cautiously, exposing only the blowholes, exhale quietly without a visible blow, and sink silently beneath the surface (called snorkeling).

The species is active at the surface; spyhopping (raising the head vertically out of the water), breaching (leaping vigorously into the air), and other aerial behaviors (head stands with tails in the air, flipper slaps on the surface, etc.) are commonly performed by adults and older calves, especially on the breeding grounds (Fig. 7, also Fig. 4). Throughout their range, grays often appear to "play" and surf in or near the breakers and shallow water along shore. Some grays regularly rub themselves on beaches and sandbars on the breeding grounds and on the rubbing beaches off Vancouver Island. They also rub on pebble beaches and rocks in the Arctic, leaving behind shed barnacles. Some enter brackish water in fjords, coastal lagoons, and the mouths of rivers and emerge cleaned of barnacles and lice. Gray whales are noted to frequent places so shallow that they appear to be lying on the bottom. Occasionally during the ebb tide, some are stranded (apparently unharmed) until the incoming tide refloats them.

G. Friendly Whale Behavior

Gray whales exhibit a sense of curiosity that appears early in life as calves investigate and "play" with floating objects such as balls of kelp and small logs. The whales, including mothers and calves, frequently approach whale-watching skiffs, particularly on the breeding grounds. Behaviors include stationing alongside the skiffs, rubbing against them, bumping, lifting, and blowing bubbles beneath the boats, and allowing the passengers to pet and stroke them (Fig. 8). This activity is popularly termed "friendly" behavior. In the lagoons, these curious grays seem to be initially attracted to the sounds made by the motors of the skiffs, which fall within the same frequency range as gray whale vocalizations. Since the first encounter with a friendly whale at the calving lagoons in the 1970s, friendly whales have become commonplace there and are also encountered to a lesser degree along the migratory route and even in the Bering Sea.

H. Predators and Mortality

Killer whales are the only predator of gray whales (besides humans), although several species of sharks, including the great white shark (*Carcharodon carcharias*) and tiger shark (*Galaeocerdo cuvier*), scavenge on carcasses and might kill a small number of calves. Pods of killer whales cooperatively pursue grays, especially calves and juveniles, and seem to attack by repeatedly ramming along their sides, grasping the flukes and flippers to immobilize and drown them, and trying to open their mouths to bite into the tongue. Killer whales have frequently been reported feeding on the tongues of gray whales and then leaving the carcasses as carrion. Sometimes grays turn on their back and slash out with a powerful tail to ward off the swift wolf-like packs of killer whales. Oddly, if cornered, they may go into "shock," floating motionless at the surface, stomach up, while killer whales bite at the tongue and flippers. Rakemark scars from teeth are often seen on living whales, indicating that many successfully ward off an attack. Some attacks may also represent practice or play by killer whales. A reduced risk of PREDATION from killer whales (more abundant at high lati-

Figure 7 *Gray whales breach frequently while migrating and on their winter breeding grounds. One animal was observed to breach 40 consecutive times.*

Figure 8 *A "friendly" gray whale cow and calf allow whale watchers to pet them (note the tip of the mother's lower jaw in the foreground).*

tudes in colder coastal seas) might be a primary benefit to females leaving polar waters to give birth in the subtropics. However, predation pressure does not appear to be a significant determinant in the gray whale's social organization.

Other known causes of gray whale mortality include ship collisions, ENTANGLEMENT in fishing gear (particularly gill nets) and man-made debris, and whaling (legal aboriginal takes and poaching). Also, calves are sometimes severely struck by whales involved in courting/mating groups, which could result in accidental fatalities. No infectious diseases have been reported. Internal parasites occur but are not known to cause death. In 1999, 2000, and 2001 an unexplained, severe deterioration was seen in the physical condition and health status of some individuals in both eastern and western populations (gray whales were unusually thin, or emaciated). In the eastern population, mortality was unusually high, and some whales appeared to have died from starvation.

IV. Distribution, Migration, and Status

A. North Atlantic Population(s) (Extinct)

The gray whale once existed on both sides of the North Atlantic. Complete and partial skeletons of grays that are subfossils (not yet mineralized) have been found on the east coast of the United States (from New Jersey to Florida) and in the eastern Atlantic from the Baltic coast of Sweden, the Netherlands, Belgium, and the Channel coast of England, the most recent dated from about 1650 A.D. (see Fig. 1). In the western Atlantic, the gray whale is thought to have migrated all along the Atlantic seaboard from Florida to Canada. The youngest North American specimen is from colonial times about 1675 A.D., whereas the oldest are around 10,000 years old. The European gray whale may have disappeared around 500 A.D., but there is a credible record for Iceland in the early 17th century. Evidently, based on written accounts, the last few gray whales in the Atlantic were exterminated by the late 17th or early 18th century, apparently by early Basque, Icelandic, and Yankee whalers. The disappearance of grays from both sides of the Atlantic coincides with the development of WHALING, supporting the idea that overhunting in Europe, Iceland, and North America was responsible for, or at least contributed to, its demise.

B. Western North Pacific Population (or Korean-Okhotsk)

1. Distribution and Migration Historic records suggest that the western North Pacific population of gray whales formerly occupied summer feeding grounds in the Okhotsk Sea as far north as Penzhinskaya Bay and south to Akademii and Sakhalinskiy Gulfs on the west and the Kikhchik River on the east (see Fig. 1). In autumn, the whales migrated south along the coast of eastern Asia from the Tatarskiy Strait to South Korea (passing Ulsan from late November to late January) to winter breeding grounds suspected to be along the coast of Guangdong Province and around nearby Hainan Island in southern China. The southern-most record was from the east coast of Hainan Island. The long-held belief that the western grays spent the winter on the south coast of Korea was unfounded. It was proposed that an additional migration corridor led down the east coast of Japan to winter breeding grounds in the Seto Inland Sea (where calving occurred) in southern Japan, but this is largely unsubstantiated. In spring, it is assumed that the whales undertook a reverse migration, passing back through the Sea of Japan to reach their summer feeding habitat in the Okhotsk Sea.

Today, the number of gray whales inhabiting the above region is severely reduced. Currently their only known summer–fall feeding ground is off the northeastern coast of Sakhalin Island, Russia. The winter calving and mating grounds are unknown, but may be in coastal waters of the South China Sea.

2. Exploitation and Population Status The western North Pacific gray whale was considered to be extirpated, or nearly so, during the 20th century but is known to survive today as a tiny remnant population. It is one of the most endangered and little-known whale populations in the world. This group was hunted intensely during the past three centuries, but its decline can be largely attributed to modern commercial whaling off Russia, Korea, and Japan between 1890 and 1960. Preexploitation abundance is unknown. Whaling pressure from the Japanese hand-harpoon fishery was underway by the 16th century. Japanese whalers continued to take grays in the 17th, 18th, and 19th centuries. A branch of the population speculated to have bred in the Seto Inland Sea of Japan was gone by 1900. Beginning in the 1840s, American and European whalers took grays in the Okhotsk Sea and western North Pacific until the early 20th century. The last major whaling period occurred between 1910 and 1933, when about 1400 whales were harvested by Japanese and Korean whalers. The fishery dwindled as the whales ran out, and many authorities thought the population was exterminated. However, catch records for 67 whales taken from the Korean coast from 1948 to 1966 indicated that some western grays remained. From 1967 to 1975, a few were continuously caught. Sightings along the coast of Korea, Japan, China, and Russia after that were rare.

During the 1990s, a small number of gray whales were found feeding during summer and fall in the Okhotsk Sea, mostly along northeastern Sakhalin Island (in Russian waters north of Japan), emphasizing its importance as a feeding ground. The population size of western gray whales was estimated to be about 100 individuals in 1999 and less than 100 in 2001. The World Conservation Union listed this population as critically endangered in 2000. Some believe it is likely that the population is below a critical size sufficient for recovery and may soon become extinct; others suggest that it may be increasing slowly. There are no data from the population's southern range off China, North Korea, South Korea, or Japan, and research is needed. It is generally agreed that the western and eastern gray whales are discrete geographical populations. Recent genetic work has documented pronounced differences between them (implying negligible levels of gene flow) and indicates that the eastern and western gray whales can be genetically differentiated at the population level.

C. Eastern North Pacific Population (or California-Chukchi)

1. Distribution and Migration From the end of May through September, most of the eastern North Pacific population is on its summer feeding grounds in the shallow,

continental shelf waters of the Bering Sea and Chukchi Sea (between Alaska and Siberia), the Beaufort Sea (east to 130°W), and the east Siberian Sea (west to 178°30′E) (Fig. 1). The range reaches its northern limit at 69°N at the edge of the zone of close pack ice (to Wrangel Island in some years). Access to the vast feeding ground is controlled by the seasonal formation, disintegration, and drift of ice (for 5–6 months it is ice covered). Gray whales are widely dispersed throughout much of the region, but the major feeding areas where they occur in greatest ABUNDANCE are the northcentral and northwestern Bering Sea, as well as the western and southwestern Chukchi Sea. Although many of the feeding areas have not been studied, those that have are underlain by dense, infaunal amphipod communities. A highly preferred habitat is the Chirikov Basin (between St. Lawrence Island and Bering Strait). It contains one of the largest and most productive amphipod beds in the world and extends over 40,000 km^2. Apparently, whales do not forage in the coastal waters on the eastern side of the Bering and Chukchi Seas, which is consistent with the lack of benthic amphipod infauna in that portion of the continental shelf. As a rule, grays are distributed in shallow waters near shore and rarely go beyond 50 km offshore, although they also aggregate on shallow flats a great distance from shore (up to 180 km). The habitat utilized averages 38 to 40 m in depth, and from 1% to 7% ice cover, but can be as great as 30%. The grays are constantly moving; their DISTRIBUTION varies yearly, and even monthly, as a result of constant ranging between feeding areas. Their foraging areas also support the largest number of bottom-feeding marine mammals in the world, including walruses (*Odobenus rosmarus*), bearded seals (*Erignathus barbatus*), and sea otters (*Enhydra lutris*).

The departure of grays from the northern feeding grounds in late summer and fall is cued primarily by shortening photoperiods and ultimately necessitated by advancing ice formation over feeding areas as the Arctic summer draws to a close. Some turn southward as early as mid-August and begin the long migration extending 7500–10,000 km to the breeding grounds, depending on where they are on the feeding range. Starting in September, grays leave the Beaufort and east Siberian Seas and converge into the Chukchi Sea. In October and November, whales move south out of the Chukchi Sea into the Bering Sea. Then, whales travel southeast and exit the Bering Sea via Unimak Pass, Alaska (in the Aleutian Islands), the easternmost prominent corridor between the Bering Sea and the North Pacific Ocean. Some pass through as early as October, others as late as January, but 90% leave from mid-November to late December. Females in late pregnancy go first, followed by other adults and immature females, and then immature males.

Once through Unimak Pass, the whales travel along the coast of North America down to central California. The migration is spread out all along the coast of Canada and the United States. The main body of the population arrives in central California by mid-January and takes about 6 weeks to pass. Beyond Point Conception, California, the majority take a more offshore route across the southern California Bight, through the Channel Islands, and reencounter the coast in northern Baja California. When the last of the southward migrants reach central California in February, they begin to overlap with the first of the northward migrants returning to the feeding grounds.

From January to early March (through May for some cows and calves), most of the population is in the winter assembly area, which extends from about central California (Point Conception) southward along the west coast of the Baja California Peninsula and continues around Cape San Lucas to the southeastern shore of the Gulf of California off Sonora and Sinaloa, Mexico. Historically, a few continued on to Guadalupe Island, whereas others reached the Revillagigedo Islands. Although a few calves are born off California, most are born along the open coast and in the calving lagoons and bays of Baja California and mainland Mexico. The principal calving areas (with 85% of the calves) are Scammon's Lagoon (Laguna Ojo de Liebre), Black Warrior Lagoon (Laguna Guerrero Negro), San Ignacio Lagoon (Laguna San Ignacio), and the Magdalena Bay complex (from Boca de las Animas to Bahía Almejas), all on the outer coast of the Baja California Peninsula. A few calves are also born on the mainland coast of Mexico at Yavaros in Sonora, and Bahía Reforma in Sinaloa.

The breeding lagoons penetrate far into desert regions through narrow entrances marked by lines of whitewater over barrier sand bars. Except for mothers and calves, however, the vast majority of gray whales in Baja California are outside the lagoons and estuaries in Bahía Sebastián Vizcaíno and Bahía de Ballenas and along the coastline, milling, courting, and wandering along the coast. Courting whales in general do not remain in the lagoons for extended periods. Rather, they are constantly passing and repassing into and out of them, and roving to other areas of the winter assembly grounds, leading to a high turnover of courting whales and subadults in the lagoons. The activity of the grays continues unabated day and night. Cows with newborns seek the quiet, inner reaches of the lagoons early in the season, away from harassment by courting whales concentrated in the areas around the lagoon entrances and outside along the outer coast, where much rolling, splashing, and sexual play can be seen. However, cows with calves also move into the ocean (often at night) and then return during darkness in morning hours, and some visit other lagoons within a season. As the consorting adults start their north migration, the mothers and calves essentially abandon the inner lagoon nurseries and occupy the area near the lagoon entrances. Some cows return to the same lagoon in successive years to bear their young, whereas others rear calves in various lagoons in different years.

The spring migration north to the Arctic feeding grounds begins in mid-February. It retraces the route of the fall migration, but is not as concentrated or as fast. Newly pregnant females migrate first, returning soonest to the Arctic to feed in preparation for the high energetic cost of gestation and lactation. They are followed by anestrous females, adult males, and then immatures. Last to migrate are the mothers and calves; they remain in the breeding area 1–1.5 months longer than most grays while the calves strengthen and grow. The first journey to the Arctic is a time of particular danger for the calves, which are occasional targets of killer whales. Cows and calves tend to travel extremely close to shore (90% are within 200 m) and are mostly alone or in pairs. Northbound whales funnel into the Bering Sea through Unimak Pass from March through June.

The north migration culminates in the dispersal of gray whales throughout their Arctic feeding grounds, which is extended in time and closely related to the ice condition (spring melt). The earliest arrivals generally reach St. Lawrence Island by May as ice recedes north or when leads or polynyas (a large area of water in pack ice that remains open throughout the year) are extensive. The main core of the population usually arrives in the Bering Strait by the end of May, where they are distributed along the cracks of ice throughout areas free of pack ice. One part of the population moves southward along the Asiatic coast and another passes through the Bering Strait into the Chukchi Sea where the whales split off in two directions: east toward the Alaska Peninsula and west toward the Chukotka Peninsula. Another smaller route possibly runs toward the Asian coast, along the Aleutian and Commander Islands. By June, grays are common in the northern Bering Sea in ice-free years, and through the Bering Strait into the southern Chukchi Sea during summer and autumn, as well as into the northeastern Chukchi and Beaufort Seas. By August and September, the ice has retreated north an average of 480 km into the Chukchi Sea. Their eastern distribution in the Beaufort Sea is limited by pack ice, as is their western distribution in the Chukchi and east Siberian Seas.

The vast majority of gray whales go to the northern feeding grounds; however, a small but perhaps increasing number do not migrate the entire distance and spend the summer feeding along the coast from Baja California to British Columbia. These whales (called seasonal residents) join the southbound migrants again in early winter. Areas where they have been observed out of season in Mexico include Bahía San Quintin and Cabo San Lorenzo, on the Pacific coast of Baja California, and Bahía de Los Angeles in the Gulf of California.

2. Exploitation and Population Status Native peoples of North America and Siberia have taken gray whales from the eastern North Pacific population for thousands of years, and a few groups continue to hunt them today. The impact of aboriginal whaling was relatively slight, however, compared to the wholesale slaughter of this population by the first American and European commercial whalers to hunt them in the Pacific. In 1846, they discovered the winter breeding grounds of the gray whale, and commercial harvests began soon thereafter in the lagoons of Baja California, then along the migration route, and spread to the feeding grounds in the Bering Sea. From 1846 to 1874, it is estimated that a minimum of 11,390 grays (not including calves) were taken. From its inception, the relentless 19th century whaling, mainly by American whalers, devastated the population. The hunt in the breeding range was largely concentrated on the cows and calves that were easily killed in the crowded lagoons and bays. Because most of the cows carried fetuses, or would have been impregnated, or had calves that were killed or died of starvation, the reproductive capacity of the population was reduced greatly. By 1900, the once abundant population was thought to be nearly extinct, and whaling all but stopped due to lack of quarry. The attention of the whalers turned to other species, allowing the gray (perhaps a few thousand remained) a brief respite before the advent of modern whaling.

With the introduction of floating factory ships on the west coast of North America in 1905, the hunting of gray whales resumed. A few were taken off Baja California and California in 1919, but mostly between 1925 and 1929. About 48 were taken annually in the Bering Sea from 1933 to 1946. All together, at least 1153 were taken from the remnant population, mainly by Norwegian, Russian, Japanese, and United States vessels. Only fear of EXTINCTION led to their official protection in 1946, except for an aboriginal harvest of about 160 whales each year that have been taken legally by Siberian Eskimos, and also a few by Alaskan natives. Since receiving protection, and the end of research harvests of about 316 grays in the 1960s, the population has increased steadily (by 2.5% per year). Based on the most recent survey (in 1997–1998), the eastern North Pacific population was estimated to be 26,600, possibly exceeding the 1846 preexploitation abundance, which most experts place at between 15,000 and 24,000. There have been indications, however, that the population is approaching, or possibly exceeding, its carrying capacity and may have become food limited (large decreases in amphipod biomass have been linked to increased predator pressure from gray whales and to detrimental effects of global warming in the Arctic). If this is correct, we can expect the gray whale population to level off or even decline.

V. Conservation and Management

A. Legal Protection

Gray whales received partial protection from commercial whaling in 1931 under the Convention for the Regulation of Whaling (which was largely ineffectual). The major whaling nations, Japan and the former Soviet Union, were not signatories to this agreement. They continued to take grays until 1946, when they joined 15 other countries and ratified the International Convention for the Regulation of Whaling, which established the INTERNATIONAL WHALING COMMISSION (IWC). The IWC was intended to provide for the proper conservation of whale stocks and thus make possible the orderly development of the whaling industry. Although it failed in its primary mission, one of its first actions was to officially halt commercial whaling for gray whales in 1946, while allowing native subsistence harvests and scientific collections. Nevertheless, there were violations of the agreement by member nations of IWC, as well as pirate whaling (whaling that is practiced by fleets that acted beyond any national jurisdiction). In 2000, Russian scientists revealed that "literally at every sighting" this prohibited species was illegally killed by the former Soviet Union from 1961 to 1979, and whaling statistics were falsified.

Gray whales were listed as endangered under the U.S. Endangered Species Conservation Act in 1969. Further protection was given by the Marine Mammal Protection Act of 1972 and the U.S. Endangered Species Act of 1973. Under the protection afforded by these and other measures, the eastern population of gray whales recovered. In 1994, it was removed from the List of Endangered and Threatened Wildlife and Plants (under the U.S. Endangered Species Act) when the population numbered 21,000. The population was also downlisted in the World Conservation Union's "1996 IUCN Red List of

Threatened Animals," from "endangered" to "lower risk: conservation dependent." However, changes to the listing of the eastern North Pacific gray whale had no bearing on the status of the western North Pacific gray whale population, which is still critically endangered.

There is no allowable commercial take of any gray whales. The IWC quota for the years 1998–2002 of 140 eastern grays annually (with an overall total of 620 in five seasons) is in response to the catch requested by the Russian Federation for its native people. It also includes an annual quota of five whales requested by the United States to satisfy the Makah Indian tribe's tradition of whaling in Washington state. No grays have been allocated to Alaskan native hunters since 1991. Further protection for eastern gray whales was given by Mexico in 1972 when two of the principal breeding lagoons, Black Warrior Lagoon and Scammon's Lagoon, were declared the world's first whale sanctuaries. The same status was extended to San Ignacio Lagoon in 1979. All lie within the Vizcaíno Desert Biosphere Reserve, Mexico's largest refuge, and entrance into the lagoons is regulated. Currently, not only is it illegal to hunt gray whales, it is also illegal to harm, harass, or even cause behavioral changes without special permits.

B. Concerns

Recently there has been a major shift in the physical environment of the Arctic region with wide-ranging effects on the biota, which may have a deleterious impact on gray whales. Over the past 20 to 30 years, there has been a trend of decreasing sea ice concurrent with increased sea surface temperatures due to global warming. Primary productivity has decreased an estimated 30–40% since 1976. Major declines of marine mammal, fish, and bird populations have occurred in the Arctic's Bering Sea. Although the effects of climate warming on grays are unknown, there are indications that the depression in primary production may lead to reductions in the benthic prey communities on which they feed. Increased predation from the growing population of whales themselves also appears to be stressing the amphipod populations. The eastern North Pacific gray whales may be expanding their summer range in search of additional feeding grounds. Moreover, it is hypothesized that the increase in gray whale mortality in 1999 and 2000 included some whales that were starving. A substantial reduction in food resources, through anthropogenic or natural causes, could have long-term effects on the future health, growth, and stability of the gray whale population.

The region of the Okhotsk Sea around Shakalin Island holds large reserves of oil and gas and is currently being developed jointly by Russian, Japanese, and U.S. companies; oil drilling and production activities plus increased shipping and aircraft traffic may cause physical habitat damage or disturb or displace the highly endangered western Pacific population of gray whales on their only known feeding ground.

Gray whales are intimately related to the coastal habitats in which they have evolved, and it is the dynamic nature of coastal regions that has shaped their unique life history and behavior. It is also precisely their coastal habits that place them in direct conflict with humans. It is not enough to stop overharvesting the whales, we must also protect their critical habitat and allow them living space. They cannot avoid exposure to our intensive coastal development, POLLUTION, vessel traffic, military activities, noise, and industrial activities associated with increased exploration and development of continental shelf, oil, and gas resources over virtually their entire range. Additional concerns include disturbance from ecotourism along migration routes and within the calving grounds, entanglement in fishing gear (particularly gill nets), ship strikes, pollution from salt extraction facilities in Mexico's gray whale refuges, and commercial developments in the breeding area of Magdalena Bay, Mexico. In a world where the human population is expected to double in the next century, the pervasive effects of the population explosion will lead to additional regional and global environmental problems and further approbation of living space and resources that the gray whale requires to sustain itself.

Group Behavior

ALEJANDRO ACEVEDO-GUTIÉRREZ
University of California, Santa Cruz

Many animals spend part or all of their lives in groups. A group may be viewed as any set of individuals, belonging to the same species, which remain together for a period of time interacting with one another to a distinctly greater degree than with other conspecifics. Thus, the study of group living is the study of social behavior, and marine mammals societies can be remarkably diverse (Fig. 1).

Groups can be classified based both on the amount of time individuals interact with each other and on the benefits that individuals receive. Schools last for periods of minutes to hours whereas groups last months to decades. Aggregations (or nonmutualistic groups) do not provide a larger benefit to individuals than if they were alone, whereas groups (or mutualistic groups) do provide such a benefit to their members. Aggregations are formed because a nonsocial factor, e.g., food, attracts individuals to the same place, and groups are formed because they provide a benefit to their members.

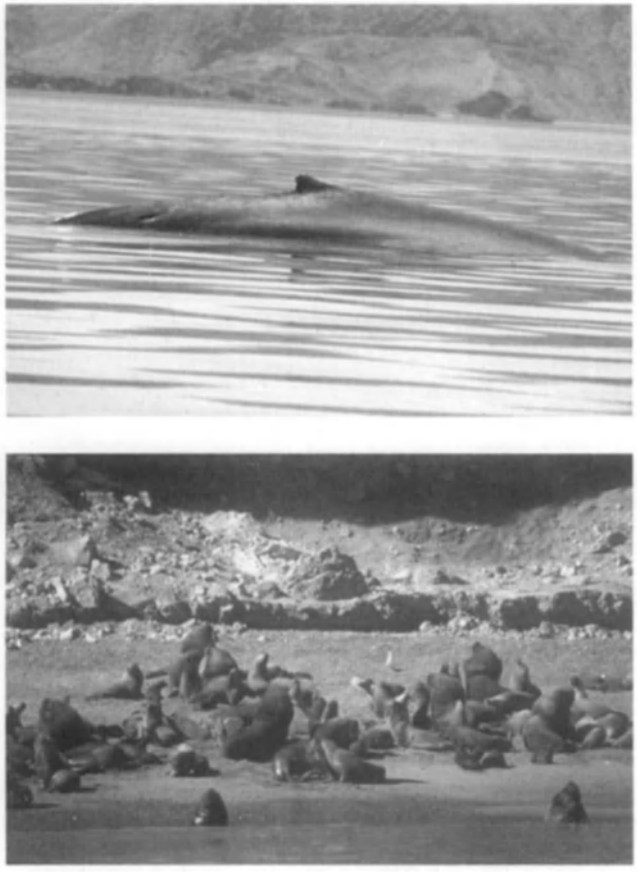

Figure 1 *(Top) Blue whales are usually found alone or in small numbers. Photo by B. Tershy. (Bottom) South American sea lions aggregate in large numbers during the breeding season. Photo © A. Acevedo-Gutiérrez.*

I. Group Living

There appear to be three conditions under which group living will evolve: the benefits to the individual outweigh the costs, the costs outweigh the benefits but strong ecological constraints prevent dispersal from the natal territory, and the area where the group lives can accommodate additional individuals at no cost.

A. Benefits and Costs of Group Living

Group living is explained in terms of benefits to the individual group members—direct fitness, kin selection, reciprocity, and mutualism—and to the groups themselves—group selection. Kin selection and reciprocity are perhaps the arguments employed most frequently to explain benefits of group living. For instance, kin selection explains the generalities of cooperative breeding in mammals and birds and the evolution of cooperation among male chimpanzees. However, these traditional explanations are, in some cases, inadequate and some behaviors are best explained in terms of direct fitness. Delayed direct benefits to the subordinate male explain the occurrence of dual-male courtship displays in long-tailed manakins, and direct benefits from the early detection of danger explain the sentinel behavior of meerkats.

Reduction of predation and increase of foraging efficiency and the number of individuals that can be supported by the available local resources have been typically viewed as important factors shaping group living. However, the reduction of predation and increased foraging efficiency can be accomplished through a myriad of different mechanisms (Table I). In addition, these two benefits are sometimes inadequate to explain group living: in African lions, female-grouping patterns are best explained as facilitating the cooperative defense of cubs against infanticidal males and the defense of territory against other females, not as increasing foraging efficiency. Group living can also impose several costs to individuals (Table II). The magnitude of these costs may be important in shaping group living; it has been suggested that differences in group size between primate and carnivore species may be related to the differences in their costs of locomotion. Marine mammals reduce the costs of locomotion by developing energy-conserving swimming behaviors such as routine transit speeds, wave riding, porpoising, and gliding. It has been hypothesized that this reduced cost of locomotion, coupled with a lack of restriction to a particular territory, has allowed some populations of killer whales (*Orcinus orca*), and possibly long-finned pilot whales (*Globicephala melas*), to develop societies in which females and males remain with their natal group for life (Fig. 2). In this manner, males traveling with their mothers can have large home ranges and thus find potential mates.

Studies have documented novel strategies followed by individuals living in groups, including the complexity of intra- and intergroup interactions. Female African lions cooperate to defend their territory from intruders; however, some individuals consistently lead the approach, whereas other individuals lag behind without being punished by the leaders. One potential explanation for this tolerance is that females need to defend their territories against other groups and their success depends in part on the number of defending females, even if some individuals

TABLE 1
Benefits of Group Living

Reduction of predation
- Enhanced ability to detect predators: sensory integration[a]
- Enhanced ability to deter predators, even larger than group members[a]
- Enhanced ability to escape, including predator confusion and coordinated evasion behavior[a]
- Reduced individual probability of being selected as prey
 - By associating with conspecifics: dilution effect[a]
 - By hiding behind conspecifics: selfish herd[a]

Allocation of time to other activities
- Reduced individual vigilance time
 - Because of group vigilance (many eyes)[a]
 - Because of decreased individual predation risk[a]
- Increased foraging time for mothers by having babysitters[a]

Enhanced detection and capture of prey
- Foraging in risky, but profitable, areas.
- Finding prey or reducing variation in food intake through cooperative searching: sensory integration[a]
- Following more knowledgeable animals in the group to a food source: information transfer[a]
- Following other species with more specialized senses to a food source[a]
- Joining resources uncovered by others, also known as conspecific attraction, kleptoparasitism, area copying, scrounging, or tolerated theft[a]
- Acquisition of innovative feeding behaviors from another group member
 - Social learning through social facilitation (contagion of motivational states)
 - Directing attention to particular locations or objects: local enhancement
 - Imitation of knowledgeable tutors[a]
 - Information sharing and cultural transmission[a]
- Increased diversity and size of prey that is captured
 - Due to more individuals foraging[a]
 - Due to prey flushed by movements of group members[a]
 - Due to individuals with different skills or abilities foraging together: skill pool effect
- Increased food intake as a result of communal foraging[a]
- Lower risks of injury while hunting[a]

Acquisition or defense of resources
- Large groups defend, occupy, or displace small groups from better territories
- Large groups acquire or defend localized food sources, including carcasses, from conspecifics or other species[a]

Improved reproduction
- Caring and protection of offspring[a]
- Learning to be a parent[a]
- Finding mates in isolated or vast areas[a]
- Enhanced reproductive synchrony[a]
- Enhanced survival when there is prevention of dispersal to neighboring territories
- Males benefit from cooperative displays, subdominant males receive the payoff later in time
- Males in large groups gain access to females[a]

Reduction of parasitism
- When number of hosts in a group increases more rapidly than the number of mobile parasites, reduced individual probability of being parasitized by associating with conspecifics: dilution effect

Other
- Huddling to survive cold temperatures[a]

[a]Suggested or documented benefits in marine mammals.

never lead the charge. Complex social behaviors have also been reported in marine mammals. In a breeding colony of gray seals (*Halichoerus grypus*) at the island of North Rona, Scotland, a few large males monopolize matings on the breeding beaches; however, females over the years give birth to full siblings not sired by the dominant male. Fathers of the pups are nondominant males that mate with the same females in different seasons. Thus behavioral polygyny and genetic fidelity seem to operate simultaneously in this colony. It has been suggested that this strategy of partner fidelity is maintained in the population because it may diminish aggressive interactions between dominant males and thus reduce the pup mortality originated by these clashes. Male Indian Ocean bottlenose dolphins (*Tursiops aduncus*) in Shark Bay, Australia, exhibit very complex levels of alliances that are only matched by humans. Males form strong and stable bonds for over 10 years with one or two other males, and males

TABLE II
Costs of Group Living

Increased predation
Large groups more attractive to predators
Larger groups more likely to be detected by a predator: encounter effect
Reduced foraging efficiency
Increased amount of food needed for group[a]
Increased energy spent, distance traveled, or area covered to find food for group[a]
Increased conspicuousness: prey able to detect predators sooner than if predators are alone
Reduction in food intake due to sharing of prey, scramble competition, scrounging, and individual discrepancies in foraging success
Reduction in food intake due to interference by the behavior of other individuals[a]
Reduce ability to learn innovative foraging skills due to scroungers in the group
Increased conflicts for resources due to the presence of more conspecifis or other species
Individuals from other groups or species following: social parasitism[a]
Individuals from other groups or species attracted to feeding parties: local enhancement[a]
Reduced reproduction, increased competition for mates or other limited resources
Individual discrepancies in number or quality of mates obtained[a]
Extrapair copulations and loss of fertilizations to other members of group[a]
Increased intraspecific competition for limited resources[a]
Increased infant mortality[a]
Increased risk of exploitation of parental care by conspecifics
Theft of nest material
Increased risk of infection
Increased contagious parasitism
Increased disease transmission

[a]Suggested or documented costs in marine mammals.

in these first-order alliances cooperate to form aggressively maintained consortships with individual females. Each first-order alliance forms moderately strong bonds with one or two other alliances (these second-order alliances do not endure for more than a few years) and males cooperate to take or defend females from other alliances. A different strategy is for males to form a large but loose superalliance that competes with the smaller and more stable first-order or second-order alliances. Members of the superalliance split into smaller alliances of pairs and trios that are constantly changing but that are always composed of males from the superalliance. These pairs and trios join conflicts involving members of the superalliance and are always victorious. It is hypothesized that the large size of the superalliance allows individuals to compete with the smaller alliances and that the fluidity of individual associations within the superalliance allows males to maintain affiliative bonds.

Figure 2 *In certain populations, male and female killer whales remain with their natal groups throughout their lifetime. Photo by B. Tershy.*

B. Female Social Behavior

One previously neglected area of research is the study of female social behavior. Because females and males frequently have different interests, female relationships are important in understanding social evolution independently of the behavior of males. For instance, dominant female chimpanzees have a higher reproductive success than subordinate ones, apparently because they are able to establish and maintain access to good foraging areas, competing in extreme cases as intensely as males. Females may also influence behaviors that affect the interests of males. Female bird song appears to have evolved in part to compete for males; however, this behavior has the potential consequence of preventing polygyny by deterring rival females.

The study of females is also essential to understand group living in marine mammals. Captive female common bottlenose dolphins (*Tursiops truncatus*) maintain dominance hierarchies and also compete aggressively against each other. However,

unlike chimpanzees, it is unknown if female dominance hierarchies in free-ranging dolphins translate into differences in reproductive success. The preference and fidelity of female gray seals at North Rona toward nondominant males undermine the polygynous strategy of dominant males and result in a different mating system from that inferred by behavioral observations. The large number of females in colonies of certain pinnipeds, such as elephant seals (*Mirounga* spp.), has permitted the existence of alloparenting and the appearance of a distinct suckling strategy by calves: milk stealing. Male and female sperm whales (*Physeter macrocephalus*) have different grouping strategies: females aggregate in complex groups whereas adult males are less social. The function of the female groups is to provide care for calves that are too young to follow their mothers during their deep foraging dives (Fig. 3). It has been suggested that alloparenting in sperm whales reduces the period in which the calf is unaccompanied and thus provides protection from predators and also perhaps provides communal nursing. Thus key features of the sperm whale society are explained solely by the behavior of females.

II. Social Behavior of Marine Mammals

There are several differences between terrestrial and marine environments that have allowed the evolution of distinctive strategies in marine mammals. Drag, heat loss, and density of the water generate differences in scaling and costs of locomotion, allowing many marine mammals to have large body sizes and large home ranges. Sound is the form of energy that best propagates in water and, not surprisingly, marine mammals employ it for social COMMUNICATION and many species employ ECHOLOCATION to navigate. Marine mammals must find food that is for the most part dispersed and patchy, thus they appear to have no territories outside of the breeding season. Due to the global effects of the atmosphere and the ocean in the marine environment, marine mammals are affected by both global and local processes as exemplified by the impact of El Niño–Southern Oscillation events on different populations.

A. General Strategies

Sirenians, sea otters (*Enhydra lutris*), and polar bears (*Ursus maritimus*) are solitary animals that have few social interactions beyond mating and mother/offspring pairs. The time that these pairs remain together is 1 to 1.5 years in sirenians, 5 to 7 months in sea otters, 2.5 years in polar bears. When a female becomes receptive, sirenians form aggregations that have as many as 17 males physically competing for access to the female or defending display territories. During the breeding season, male sea otters establish territories that include the areas occupied by several females, whereas male polar bears mate with only one partner because females have a dispersed distribution.

Most pinnipeds aggregate in colonies during the breeding season. A major factor influencing the size of these colonies is the distribution of habitat available for parturition. All pinnipeds give birth out of the water and thus the areas favored for parturition are oceanic islands, ice, or isolated mainland regions not easily accessible to terrestrial predators. When available space is limited, females become densely aggregated in large colonies that favor mating systems in which males defend either aggregations of females or areas occupied by females, or aggregate and display before aggregations of females (Fig. 4). When parturition space is dispersed, females are isolated, males usually have access to only one female, and no colonies are formed. The strongest association found in pinnipeds is formed by a mother and her offspring and lasts from less than 1 week to almost 3 years, depending on the species. Pinnipeds haul out together outside of the breeding season. Although this nonreproductive social behavior is poorly known, evidence shows that it increases vigilance for predators in harbor seals (*Phoca vitulina*). It is believed that hauling out together also allows pinnipeds to rest, avoid predators, molt, or warm themselves. For instance, walruses (*Odobenus rosmarus*) in large numbers may decrease the rate of body heat loss, particularly in calves, when on land or ice.

The complexity of cetacean societies appears to be related to the amount of time invested in lactating and in rearing the calf after weaning. Baleen whales are found in schools of varying size, from single individuals to more than 20 whales. Pairs of mothers and their offspring form stable associations that last less than 1 year. It is currently unclear if long-term associations exist among adult whales. Most females give birth every 2 to 3 years and have the potential to produce more than 20 calves throughout their lifetime. Schools of baleen whales have been observed in both feeding and breeding grounds. For instance, feeding humpback whales (*Megaptera novaeangliae*) forage alone, in aggregations, or as a group, depending on prey type, whereas aggregations of breeding males display acoustically or compete directly for access to females. Odontocetes are the most social marine mammals and have different types of societies as suggested by the large variation in school size among species (Table III). Short-term associations between adults characterize several porpoises (Phocoenidae). Associations between mothers and their offspring last 8 to 12 months. Females breed every 1 or 2 years and may give birth to 15 calves or more during their life span. In medium-sized delphinids, such as bottlenose dolphins, associations between adults are varied: they last a short amount of time in some individuals and several years in others; long-term associations appear to be common between males in certain populations. Calves remain with their mothers 2 to 11 years (Fig. 5). Females give birth at least every 3 years and may produce close to 10 calves throughout their lifetime. Baird's beaked whales (*Berardius bairdii*) apparently employ a novel social strategy. Males live longer than females and thus there is an excess of mature males over females. It has been hypothesized that these traits indicate a society in which males provide significant parental care by rearing weaned calves: protecting them from predators and teaching them foraging skills. In the case of the sperm whale and large-sized delphinids (pilot whales, *Globicephala* spp., and some populations of killer whales), females appear to spend their entire lives within their natal group, forming strong matrilineal societies. Females usually breed every 3 to 6 years and may give birth to about 5 calves throughout their lifetime, more in the case of long-finned pilot whales. Females may live over 20 years past their reproductive years. It has been suggested that this strategy allows old females to transmit and store cultural information and provide alloparental behavior. In the case of short-finned pilot whales (*G. macrorhynchus*), it is possible that nonreproductive females even provide alloparental nursing. Male killer whales in some populations, and perhaps male long-finned pilot whales, remain in their natal group for life but mate with females from other groups when they meet. Male sperm whales, and perhaps male short-finned pilot whales, leave their nursing group when they reach puberty; however, the former, after they have reached their late 20s, roam among nursery groups looking for mates, whereas the latter appear to join other nursery groups. It has been suggested that adult male short-finned pilot whales remain in the nursery group that they join and engage in few clashes with other males because they are able to engage in nonreproductive mating with old

TABLE III
School Sizes of Odontocetes

Species[a]	*Average school size*	*Maximum school size*
Phocoenoides dalli (7)	2.3–7.4	5–500
Neophocaena phocaenoides (1)	2.0	13
Phocoena phocoena (6)	1.2–5.7	15–100
P. sinus (1)	1.9	7

females, as apparently occurs in bonobos. A recent hypothesis that remains to be tested suggests that the cultural transmission of behaviors, i.e., learned behaviors passed onto family members, is being conserved within matrilineal groups of odontocetes, affecting the course of genetic evolution. This modification of the course of genetic evolution through culture has thus far been documented only in humans.

B. Foraging

Increased foraging efficiency is considered to be one of the principal roles of group living in cetaceans. However, thus far transient killer whales provide the only clear example supporting the argument that marine mammals live in groups because of foraging benefits. Transient killer whales live in the Pacific Northwest and prey on harbor seals and other small marine mammals. Individuals maximize their caloric intake if they feed in groups of three, which is the size of the group in which they live. The small size of these groups is apparently maintained by the departure of all female offspring and all but one male offspring from their natal group.

Two benefits of group living through foraging efficiency are the ability to search for prey as a group and to forage communally (Fig. 6). Searching for prey as a group allows individuals to combine their sensory efforts, which should be an advantage when prey has a dispersed and patchy DISTRIBUTION. Communal foraging allows individuals to combine efforts to pursue and capture prey. This behavior has been reported in dolphins, baleen whales, including fin whales (*Balaenoptera physalus*) and bowhead whales (*Balaena mysticetus*), and pinnipeds, such as fur seals and sea lions. However, in some instances it is unclear whether individuals combine efforts to pursue and capture prey or merely aggregate in an area where food is concentrated. A particular type of communal foraging behavior, termed prey herding, has been observed when feeding on shoaling fish. Individuals encircle shoals of fish and thus create a tight, motionless ball of prey from which they can grab individual fish; in some cases, individuals release bubbles to further tighten the ball of prey. This herding of prey has been well described in humpback whales, dusky dolphins (*Lagenorhynchus obscurus*), and killer whales. However, it has also been reported in other species, such as bottlenose dolphins, common dolphins (*Delphinus* spp.), Clymene dolphins (*Stenella clymene*), and Atlantic spotted dolphins (*S. frontalis*). It is difficult to document this behavior, and only one study has quantified the success of cetaceans in herding prey. This study noted that common bottlenose dolphins off Costa Rica seldom herd prey into a ball when it is scattered, rather they pursue the individual fish. Perhaps evasive maneuvers of prey or interference by hunters from other species feeding on the same prey prevents dolphins from herding.

Figure 6 *Communal foraging allows dolphins to combine pursuing efforts. Photo © A. Acevedo-Gutiérrez.*

C. Predation

The reduction of PREDATION is considered to be another principal function of group living in cetaceans. Certain shark species and some large delphinids attack cetaceans, and calves suffer higher mortality than adults. However, pinnipeds apparently also form groups in response to predation. Walruses sometimes form groups lasting throughout the year in the water and on haul-out sites. It has been suggested that this may be a female strategy for pup defense against predation by polar bears.

Thus far no conclusive evidence shows that group living in cetaceans is driven because of benefits in reduction of predation, although it has been suggested that this could be the case in sperm whales. Nonetheless, group living may provide several benefits to reduce predation. Groups are able to mob and chase away predators, as has been observed in humpbacked dolphins (*Sousa* spp.) when attacked by a shark. It is believed that other dolphins also employ this antipredatory strategy. Sperm whales, and perhaps humpback whales, employ the marguerite formation, in which adults surround young individuals by having their heads toward the center (horizontal formation) or toward the surface (vertical formation). Adults have their flukes toward the periphery and employ them to slap at predators, which in the majority of observations have been killer whales.

Group living appears to be related to food and predation in terrestrial and marine mammals. Thus it has been argued that the variation of group sizes among dolphin species is related to food availability, to prey habitat, or to the need to defend against predators. Data have been compiled on the average school size from 24 species of the family Delphinidae (Table III). Because definitions of school vary among researchers, the author has attempted to make values comparable by selecting only studies with at least 30 observations throughout a season and defined schools as the number of individuals engaged in similar activities regardless of distance between them. The author averaged the values from species belonging to the same genus and related them to crude measures of predation pressure and prey habitat, measures obtained from the literature. Results indicate that regardless of the body weight of the species, average school sizes are larger when predation pressure is high rather than low and when prey is found in open rather than in enclosed waters (Fig. 7). School sizes are largest when both pressure from predators is high and prey lives at depth in oceanic waters. Thus it appears that the average school size of dolphins is related both to the predation they experience and to the habitat where their prey lives. In turn, reproductive success might also be related to these two environmental factors. The reproductive success of female bottlenose dolphins is highest in shallow waters, either because calves and their mothers are able to detect and avoid predators or because prey density is highest.

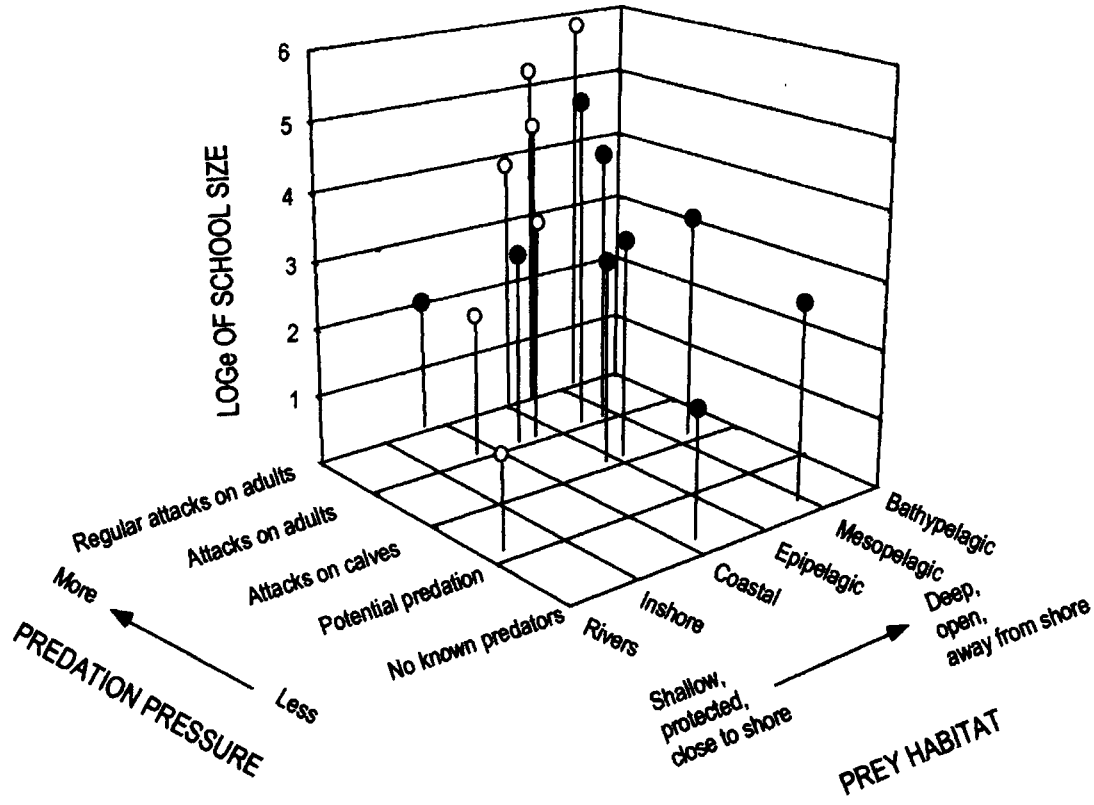

Figure 7 *Relationship among predation pressure, prey habitat, and average school size of 16 genera of the family Delphinidae. Open circles indicate small species (females weigh less than 150 kg) and solid circles indicate large species (females weigh more than 150 kg).*

III. Conclusion

Group living involves benefits and costs, and the resultant society represents a balance between the different interests of all group members. The aquatic environment has allowed marine mammals to pursue complex and sometimes unique social strategies. At the same time, the basic needs of finding food, ensuring reproduction, and evading predators are also found in terrestrial environments. This convergence provides interesting parallels between the social strategies of marine mammals and those of terrestrial mammals: chimpanzees and bottlenose dolphins, elephants and sperm whales. Although many questions about the group behavior of marine mammals remain unanswered, long-term studies and research on poorly known species will provide a more profound understanding of their societies.

Habitat Pressures

PETER G. H. EVANS
University of Oxford, United Kingdom

Like other animals, marine mammals may have preferred locations in which they spend the majority of time or where they engage in particular important life history activities such as giving birth, calf rearing, or feeding. The array of physical and oceanographic features that typify those locations forms the habitat of a species or local population. Often these are difficult to define. An ice-breeding seal clearly depends on pack ice upon which to give birth and that constitutes its breeding habitat, and a gray whale may seek out a sheltered tropical lagoon to calve, but for a large open-ocean baleen whale such as the blue whale, identifying its habitat requirements for breeding can be a difficult task. The same applies to feeding habitats: manatees and dugongs, for example, require specific habitats such as shallow seagrass beds for feeding, but oceanic dolphins may range the high seas in pursuit of shoaling fish, making it hard to identify whether they have specific habitat requirements. Human activities impinge upon the lives of marine mammals if they damage or destroy those habitats that may be important to them. Our knowledge of habitat pressures facing marine mammals is therefore limited to particular species and especially to locations nearshore where animals have been studied more intensively and their ecological requirements better defined.

Habitats formed by eddies, thermoclines, and fronts may shift from one locality to another during the life span of a marine mammal, leading to shifts in their geographic distributions. Habitats determined by geomorphological features, such as depth, topography, and available haul-out or den sites [in the case of pinnipeds and polar bears (*Ursus maritimus*), respectively], are relatively stable over time in relation to location. Strong site fidelity may lead a population to have difficulty adjusting to changes in local food availability.

Habitat pressures on marine mammals from anthropogenic influences may be grouped into five categories: (1) physical damage to their environment: a river or seabed and its constituent communities; (2) contamination from chemical pollutants; (3) direct removal of important prey through fisheries; (4) disturbance from human activities either by the introduction of sound into the environment or through ship strikes; and (5) physical and oceanographic effects from global climate change.

I. Physical Damage

Human population pressures frequently lead to direct changes to coastal and riverine environments. Estuaries are turned into industrial harbors, wetlands are drained for agricultural purposes or for tourism, and coastal waters are modified often irreversibly by dredging of the seabed and input of a wide variety of pollutants. Some of the most obvious detrimental changes to a habitat come from the alteration of rivers inhabited by particular dolphin species. Water is often taken out of rivers for other uses, such as for drinking, flood control, or irrigation agriculture. In Pakistan, for example, most of the annual flow of the Indus River is diverted into canals, and this, along with dam construction, has resulted in the Indus river dolphin (*Platanista gangetica minor*) losing probably at least half of its historical range. Dams modify water flow and affect the sedimentation of rivers; they also block traditional movement patterns of marine mammals, which can lead to population fragmentation. The construction of large dams (such as the Ghezouba Dam and the Three Gorges Dam) along the Yangtze Kiang river system thus poses serious threats to the already endangered Chinese river dolphin or baiji (*Lipotes vexillifer*), which now numbers only a few hundred (or fewer) individuals. It may also restrict movements of more widespread species such as the Amazonian manatee in Brazil.

On land, one of the greatest habitat pressures leading to mass extinctions of fauna and flora is that of deforestation, particularly in the tropics. In the 1980s, Latin American countries are estimated to have eliminated 7.4 million hectares of tropical forests annually, with Brazil sustaining the greatest annual loss with 3.2 million hectares per year. This deforestation directly affects the freshwater habitats of the boto or Amazon river dolphin (*Inia geoffrensis*), as well as the Amazonian manatee (*Trichechus inunguis*).

After centuries of direct exploitation, pinnipeds have largely sought sites remote from human activities to give birth to their pups. They therefore are less likely to experience direct physical damage to those breeding habitats.

II. Chemical Pollution

Nearshore environments in particular are exposed to a potential wide range of pollutants as a result of industrial and agricultural activities. Those pollutants may concentrate in the food web and either degrade the habitat by removing important prey populations or cause health deficiencies in the local populations of marine mammal species. Although high levels of potentially damaging pollutants have been detected frequently in marine mammals, particularly seals and coastal small cetaceans inhabiting nearshore environments, direct causal links with health status have rarely been demonstrated. Baltic ringed (*Pusa hispida*) and gray (*Halichorus grypus*) seals during the 1970s had lesions of the reproductive system attributed to high PCB and DDT levels in their tissues. By the late 1980s–1990s, as levels in those pollutants declined, the proportion with lesions had declined substantially, along with an increase in their pregnancy rate. In an experimental study with harbor seals (*Phoca vitulina*), females fed with fish from the heavily polluted Dutch Wadden Sea had poorer reproductive success than those fed less contaminated fish from the North Atlantic. The effects were attributed to PCBs or their metabolites, and seals with the highest PCB intake were found to have reduced blood levels of thyroid hormones and vitamin A, both of which are known to be important in reproduction, including spermatogenesis.

Belugas (*Delphinapterus leucas*) in the highly polluted St. Lawrence estuary in North America had a high prevalence of tumors that had been attributed to carcinogenic compounds, such as polycyclic aromatic hydrocarbons, and other toxic compounds, such as PCBs. These were thought to account for low reproductive success in this population. However, although both sets of compounds occurred at high levels in this population, it remains difficult to demonstrate a direct link, and the population in fact appears to have increased in the 20 years since hunting ceased in 1979.

Harbor porpoises (*Phocoena phocoena*) inhabiting the continental shelf around the British Isles on postmortem are significantly more likely to be diseased when they have high hydrocarbon concentrations. Mass mortalities of striped dolphins (*Stenella coeruleoalba*) in the Mediterranean, common bottlenose dolphins (*Tursiops truncatus*) in the eastern United States, harbor seals in the North and Baltic Seas, and Baikal seals (*Pusa sibirica*) in Lake Baikal all showed significantly high concentrations of PCBs, which was thought to have reduced resistance to disease, thus making these populations more susceptible to virus infection.

Despite examples like these of apparent links between contamination and health status, the biological significance and the nature of effects remain uncertain, and it has been impossible to demonstrate conclusively that demographic changes to a population can be attributed to pollution. The only exceptions are where POLLUTION can be shown to lead directly to mortality. After the *Exxon Valdez* went aground in Price William Sound, Alaska, in 1989, releasing large volumes of crude oil, several thousand sea otters (*Enhydra lutris*) and about 300 harbor seals died as a result of their oiled pelts losing vital insulation properties.

III. Competition with Fisheries

Habitats comprise animal and plant communities in an often complex web of interaction. When one or more members of the community are removed in large numbers this can have repercussions throughout the food web, altering PREDATOR–PREY RELATIONSHIPS and competition for resources. Following the intense exploitation of large baleen whales in the Southern Ocean during the first half of the 20th century, it was estimated that their overall biomass was reduced from 43 million tons to about 6.6 million tons, and that this made available a "surplus" of about 153 million tons of KRILL. These massive changes to the food web of the Southern Ocean had important effects on the remaining members, with individual whales growing faster, reaching sexual maturity at an earlier age, and exhibiting increased pregnancy rates. Similar changes in life history parameters were seen in other marine species, such as the Antarctic crabeater seal (*Lobodon carcinophaga*) and several seabird species.

During the 20th century, fisheries around the world intensified to such an extent that major changes in fish stocks have been observed for many species. Rarely, however, is it possible to show that prey depletion has reduced the numbers of a particular marine mammal species. Many marine mammals have catholic diets and appear to respond by switching prey. The relative ease of capture and nutritive contents of different prey species may vary, but it has scarcely ever been possible to demonstrate that these have affected reproductive or survival rates, and hence led to a decline in that population. More often than not, the species appears to respond by shifting its DISTRIBUTION.

On both sides of the North Atlantic, fishing activities have reduced the stocks of Atlantic mackerel and herring markedly, resulting in other fish (upon which they prey), such as sand lance, sprat, and gadoid species, becoming very abundant locally. Not only did some cetacean species such as harbor porpoise and humpback whale (*Megaptera novaeangliae*) switch their diet to include those prey in greater amounts, but some also showed geographic shifts in distribution. Gray seals, feeding largely on sand lance, increased in number in the North Sea at around 7% per year, whereas right whales (*Eubalaena glacialis*), feeding largely on plankton (the prey of sand lance) in the northwest Atlantic, showed local declines. When some local sand lance and sprat populations crashed a few years later, further changes were witnessed. In the Gulf of Maine, for example, fish-eating humpback and fin whales (*Balaenoptera physalus*) were replaced by plankton-eating right and sei (*B. borealis*) whales, harbor porpoises moved nearer to shore, and Atlantic white-sided dolphins (*Lagenorhynchus acutus*) became abundant and white-beaked dolphins (*L. albirostris*) rare.

In the Bering Sea and Gulf of Alaska, substantial declines in the numbers of Steller sea lions (*Eumetopias jubatus*), harbor seals, and northern fur seals (*Callorhinus ursinus*), as well

as several species of fish-eating birds, have occurred since the 1970s. Although other factors may also be involved, most of these declines have been attributed to a decline in food availability resulting from the development of the walleye pollock fishery, a key prey species for many of these marine mammals following the demise of local herring stocks. Similarly, the collapse of productivity of the Barents Sea ecosystem, brought on partly from excessive fishing mortality, has had far-reaching effects on a range of species from seabirds to marine mammals.

IV. Disturbance

Sounds are introduced into marine and freshwater environments from a wide variety of sources: motor-powered vessel traffic of various sizes; active sonar for object detection, including fish finding; seismic exploration and subsequent drilling and production for oil and gas; explosions from military exercises and ocean science studies; and marine dredging and construction. Most of the sounds produced are concentrated between 10 and 500 Hz frequency. However, speedcraft of various types generate noise mainly between 2 and 20 kHz by cavitation of the propellor, and sidescan and military sonar generate sounds between 2 and 500 kHz.

Among cetaceans, baleen whales appear to have rather different hearing sensitivities to those of toothed whales and dolphins. The former are thought to be most sensitive at low frequencies below 5 kHz, and the latter above 10 kHz. Thus baleen whales are likely to be most vulnerable to large vessels, oil and gas activities, marine dredging, and construction, whereas toothed whales and dolphins may be more susceptible to recreational speedboats and most forms of active sonar.

Changes in behavior (e.g., movement away from the sound, increased dive times, clustering behavior) are often recorded in the vicinity of loud sounds. Few experimental studies have been conducted to test the nature and duration of negative responses. One such study in relation to low-frequency regular ATOC (acoustic thermometry of ocean climate project) sound pulses was conducted west of California. Aerial surveys showed no significant differences in numbers of marine mammals of any species between control and experimental surveys, but humpback and sperm whales (*Physeter macrocephalus*) were on average further from the sound source during the experimental periods. Although many other studies have reported negative reactions, there is very little information concerning the long-term impact of sound disturbance. In Hawaii, humpback whale mothers with their calves are thought to have shifted their distribution offshore in response to the high volume of recreational traffic. Whale and seal watching itself can impose pressures on marine mammals, disturbing seals from haul-out or breeding sites, and whales (and dolphins) from favored feeding areas.

In addition to those indirect effects where sound disturbance may interfere with or frighten marine mammals, there is some evidence that loud sounds can cause physical damage. Temporary or permanent shifts in hearing thresholds may occur that could affect auditory acuity, and postmortem examination of humpback whales found dead in the vicinity of drilling operations has revealed ear damage.

Powered vessels pose an obvious threat to marine and freshwater mammals through direct damage. Collisions have been reported in a wide variety of species, and in some, such as the Florida manatee (*Trichechus manatus latirostris*) and the North Atlantic right whale, they are regarded as the major threat to their survival. With the advent of high-speed ferries in many parts of the world, ship strikes are being reported with increasing frequency, affecting especially the slower swimming species such as sperm and pilot whales.

V. Climate Change

As a result of emissions by humans of substances that deplete the ozone layer, our increasing use of hydrocarbons for energy and fuel, and large-scale deforestation and desertification, the world is experiencing climate change such that it is predicted that, in the next hundred years, temperatures will rise by 1.0–3.5°C and the overall sea level will rise by anywhere from 15 to 95 cm. Obvious consequences will be the melting of polar ice, drowning of coastal plains, and changes to shallow seas. Other less direct implications include an increase in the frequency and velocity of storms, and more extreme seasonal fluctuations in local climate (including, for example, El Niño Southern Oscillation events). Shifts in areas of primary productivity may lead to distributional changes for many marine mammal species, but some, such as the polar bear (*Ursus maritimus*), land-breeding pinnipeds, and coastal cetaceans and sirenians, may find it difficult to adjust to the loss of important feeding or breeding habitats. Already there is concern that less stable ice in some parts of the Arctic has reduced the availability of ringed seals (*Pusa hispida*) to polar bears, thus reducing the breeding success of the bears, which in those areas depend on this species for food.

During recent El Niño events, there has been reproductive failure in many seabird populations and some colonies of fur seals. During the 1982 El Niño, for example, all Galapagos fur seal (*Arctocephalus galapagoensis*) females lost their pups due to starvation. However, many pelagic toothed whales and dolphins, being less tied to a particular locality, simply shifted their distributions: short-finned pilot whales (*Globicephala macrorhynchus*), for example, left southern Californian waters following the departure of a species of squid, their main prey. Such changes can affect other members of the ecosystem. When the squid returned some years later, the temporarily vacant niche became occupied by another cetacean species, the Risso's dolphin (*Grampus griseus*).

Despite the many pressures on their habitats, marine mammals appear to be remarkably resilient, often living in highly modified coastal and riverine environments. Of course, because demographic changes may be slow and difficult to detect, we rarely know whether these are having negative effects. In the case of small local populations of endangered species such as the North Atlantic right whale, vaquita (*Phocoena sinus*), various river dolphins, monk seals (*Monachus* spp.), and manatee populations, the dangers of habitat pressures are all to obvious. However, even for other species, a precautionary approach would be prudent, and there is hope for the establishment of protective areas where human activities can be zoned.

Hair and Fur

PAMELA K. YOCHEM AND BRENT S. STEWART
Hubbs-SeaWorld Research Institute, San Diego, California

I. Structure and Function

The presence of hair is one of the characteristics that distinguishes mammals from other vertebrates. Hair consists of keratinized epidermal cells, formed in hair follicles located in the dermal layer of the skin. Pinniped and sea otter (*Enhydra lutris*) hairs are flattened in cross section rather than round as in other carnivores. This is evidently an adaptation for enhancing streamlining of the body and reducing drag during swimming. Pinnipeds and sea otters have diffuse smooth muscle in their dermis, but they lack true arrector pili muscles. Pinnipeds, sea otters, and polar bears (*Ursus maritimus*) possess sebaceous glands and sweat glands, but these are absent in cetaceans and sirenians. Cetacean skin is hairless except for a few vibrissae or bristles occurring mostly on the rostrum or around the mouth. These are usually lost before or soon after birth. Sirenians have widely scattered hairs. The integument of pinnipeds, sea otters, and polar bears generally has two layers of hair. The outer protective layer consists of long, coarse, guard hairs and the inner layer is composed of softer intermediate hairs or underfur. Polar bear, sea otter, and otariid guard hairs are medullated (having a sheath), whereas phocid and walrus hairs (*Odobenus rosmarus*) are not. The hairs typically grow in groups or clumps, with a single guard hair emerging cranial to one or more underfur hairs. Each hair grows from a separate follicle, but the underfur follicles feed into the guard hair canal so that all hairs in a particular clump emerge from a single opening in the skin. Some pinnipeds have a relatively sparse hair coat [walrus, elephant seals (*Mirounga* spp.), and monk seals (*Monachus* spp.) with a single guard hair per hair canal], whereas others have a lush, thick coat (fur seals, with dozens of underhair or fur follicles feeding into each guard hair canal). Sea otters have the densest fur of any mammal, with approximately 130,000 hairs/cm^2, about twice as dense as that of northern fur seals (*Callorhinus ursinus*).

The appendages of some pinnipeds and the pads of sea otters are hairless, allowing these species to readily lose excess body heat by conduction to the environment. Although most marine mammals rely on blubber for insulation, a layer of air trapped within the hair or fur serves as the primary insulator in fur seals and sea otters and keeps the skin dry when the animals are submerged. Sea otter pelage is coated with squalene, a hydrophobic lipid that aids in waterproofing the fur.

II. Molt

Many phocid seals possess a white lanugo coat *in utero;* this may be lost before birth or may persist for several weeks (as in some arctic and antarctic species). This pelage provides insulation for neonates of ice-breeding seals until they develop a

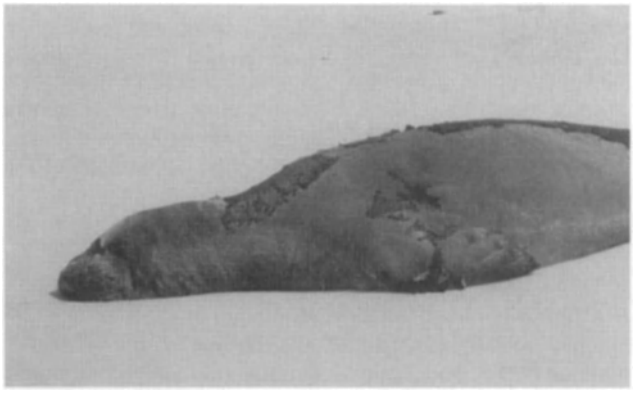

Figure 1 *Catastrophic-type molt in the Hawaiian monk seal* (Monachus schauinslandi) *where the upper epidermis and hairs are shed in large patches within a few weeks. Photograph by B. S. Stewart.*

blubber layer and also may serve as camouflage or protective coloration. Other examples of distinct neonatal pelage include the wooly black coat of elephant seals, which is replaced by a silvery hair coat after the pup is weaned, and the fluffy buff-colored pelage of sea otter pups, which persists for several months. The signals for initiation and control of the annual pelage cycle are not known for most species but are thought to include endocrine (thyroid, adrenal, and gonadal hormones), thermal, and nutritional influences. Molt is generally seasonal, beginning shortly after breeding. Sea otters may molt year round, although more hairs are generally replaced in summer than in winter. The duration of molt in pinnipeds ranges from a very rapid and "catastrophic" shedding of large patches of epidermis and associated hairs (elephant seals, monk seals) (Fig. 1) to the more gradual pattern seen in otariids, with hairs replaced over several months.

Harbor Porpoise

Phocoena phocoena

ARNE BJØRGE AND KRYSTAL A. TOLLEY

Institute of Marine Research, Bergen, Norway

The harbor porpoise (*Phocoena phocoena*) is a small odontocete inhabiting the temperate and boreal waters of the Northern Hemisphere. The harbor porpoise derives its common English name from the Latin for pig (*porcus*) and is sometimes referred to as the "puffing pig" in parts of Atlantic Canada. Harbor porpoises have a short, stocky body resulting in a rotund shape, an adaptation that helps them limit heat loss in the cold northern climes. On average, adult females reach 160 cm in length and 60 kg. Males are smaller than females, growing only to about 145 cm and 50 kg (Fig. 1). The largest recorded size for this species was from a female who was over 200 cm and 70 kg.

I. Distribution and Variation

The dorsal side of the harbor porpoise is dark gray, while the chin and underbelly are a contrasting white, which sweeps up to the midflanks in a mottled pattern. Gray stripes originate

Figure 1 *Two immature harbor porpoises swim side by side in the murky waters of the Irish sea. The characteristic stripe running from the mouth to the flipper is clearly visible, as is the mottled gray pattern on the flanks. Photograph by Florian Graner.*

on each side of the head near the back of the mouth and run back toward the flippers. The small triangular-shaped dorsal fin makes this species easily recognizable at sea, as does its characteristic swimming pattern of several short, rapid surfacings followed by an extended dive of several minutes. Occasionally, harbor porpoises are known to "log," or lie at the surface, while they move their head about in a sweeping motion.

Harbor porpoises are distributed throughout the coastal waters of the North Pacific, the North Atlantic, and the Black Sea (Fig. 2). Although sightings of porpoises occur in deep waters between land masses, they generally prefer the shallower inshore waters of the continental shelves. Porpoises in each ocean basin are reproductively isolated, resulting in the classification of harbor porpoises into two subspecies: *Phocoena phocoena vomerina* in the Pacific Ocean and *Phocoena phocoena phocoena* in the Atlantic Ocean, plus a third possible subspecies, *Phocoena phocoena relicta*, in the Black Sea. These subspecies differ from each other morphologically as well as genetically, as their cranial size and proportions are different. Pacific harbor porpoises have smaller skulls but longer jaws than Atlantic porpoises. Although the fossil record containing porpoises is poor, recent genetic investigations have made it possible to reconstruct the most probable relationships among the porpoises. Early morphological studies suggested that harbor porpoises are related to Burmeister's porpoise (*Phocoena spinipinnis*) and the vaquita (*Phocoena sinus*), and therefore these three species have been placed in the same genus. However, genetic information suggests that the harbor porpoise's closest relative is the Dall's porpoise (*Phocoenoides dalli*), a species endemic to the Pacific Ocean.

II. Ecology and Behavior

Harbor porpoises are normally found in small groups (1–3 animals) often consisting of at least one mother–calf pair. Groups of 6–8 animals are not uncommon and, on rare occasions, harbor porpoises may form much larger aggregations. Their SWIMMING and surfacing movements are quick, but harbor porpoises rarely leap out of water. When surfacing, their dorsal side is exposed for a few seconds; due to their short body length and blunt shape, their movement at the surface resembles a forward roll. Often, harbor porpoises can be seen resting at the surface with their body tilted slightly backward.

Porpoises are fish and squid feeders, often foraging near the sea bottom in waters less than 200 m in depth. Bottom-dwelling fishes and small pelagic schooling fishes with high lipid content

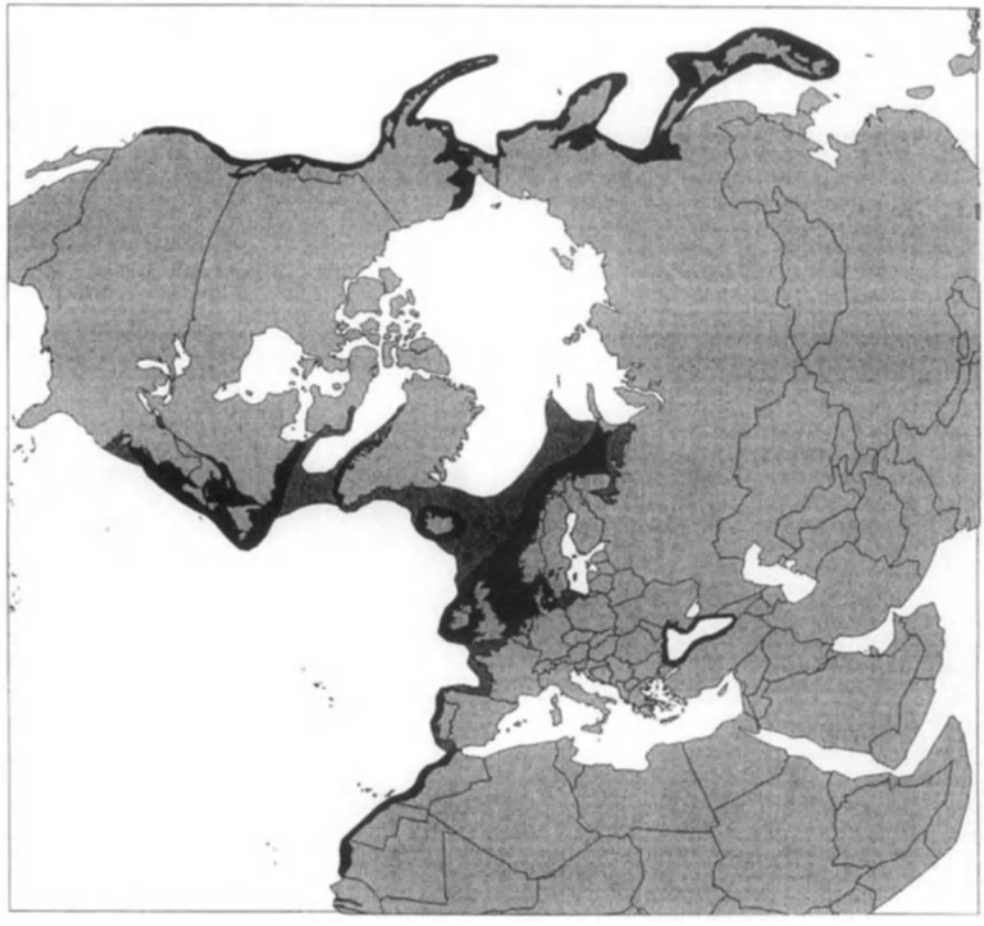

Figure 2 *The primary worldwide distribution of the harbor porpoise* (Phocoena phocoena) *is shown in dark gray. The secondary distribution of harbor porpoises is shown in light gray.*

such as herring, sprat, and anchovy are common prey items. Occasionally, porpoises occur in deeper waters where their diet includes midwater fish such as pearlsides.

Some studies have demonstrated that porpoises may reside within an area for an extended period of time. However, onshore/offshore migrations and movements parallel to the coast are thought to occur. These movements may mirror seasonal changes in DISTRIBUTION and availability of important prey species, and some studies indicate that these movements may correspond to underwater ridges and banks. In some coastal areas, porpoises migrate offshore to avoid ice during winter, but in the long and narrow fjords of Norway, where porpoises live year-round, fresh water input from rivers may freeze within a few hours. Under such circumstances porpoises can be fatally trapped.

III. Anatomy, Physiology, and Life History

Harbor porpoises have spade-shaped teeth, a characteristic that distinguishes them from the dolphin family, which have conical teeth. A characteristic feature of harbor porpoises are tubercles, or small hard bumps on the leading edge of the dorsal fin. The function of the tubercles is not yet known. Harbor porpoises have extremely thick blubber, an adaptation that aids in THERMOREGULATION in cold waters. Calves have thicker blubber and are more rotund than adults, providing them with an excellent capacity to conserve heat. Dive telemetry data have shown that porpoises can dive to depths of at least 220 m. The majority of dives usually last just over a minute, although dives of over 5 min have been recorded.

Harbor porpoises have an average life span of about 8–10 years, although some have been documented to have lived longer than 20 years. They become sexually mature between 3 and 4 years but are not physically mature until they are 5 (males) to 7 (females) years old. Harbor porpoises exhibit reproductive seasonality, whereby all porpoises give birth in a contracted calving season lasting only a few weeks. The calving season varies from region to region, but in most areas, calving takes place within a time period from May to August. The gestation period is approximately 10.5 months. Calves are weaned before they reach 1 year but begin to take small solid food items (e.g., euphausiids) when they are just a few months old. Calves are usually about 70–75 cm and 5 kg at birth but grow rapidly in their first year with males reaching about 120 cm and females 125 cm in length.

Mating takes place approximately a month and a half after the calving season. In the Atlantic, most females produce a new calf every year, but in the Pacific it appears that the calving interval may be every other year. Harbor porpoises likely have a promiscuous mating system, whereby each individual mates with several other individuals. Further, they are thought to be "sperm competitors" because males produce large quantities of sperm, presumably in order to mate with several females in an effort to reproduce. The testes undergo an exceptionally large seasonal change in size where they enlarge up to 800 g just prior to the mating season but regress in winter to a total weight of about 200 g.

IV. Human Interactions

Because harbor porpoises inhabit coastal waters, they are affected by the activities of modern man. POLLUTION, NOISE, ship traffic, and overfishing of prey species are just a few of the human-induced disturbances on this species. In the past, harbor porpoises were harvested for their meat and blubber, but at present, porpoises are given legal protection in nearly every country. However, legal protection does not protect them against accidental deaths in fishing nets, and entanglement in fishing nets is the most significant human-induced threat to porpoises. In many areas this incidental mortality may exceed sustainable levels, and modifications in fishing practices are urgently needed to ensure the long-term survival of some porpoise populations. In some areas, knowledge of porpoise movements and habits has aided in setting fishing regulations designed to help protect this species.

Although porpoises may be able to detect fishing nets through the use of echolocation, they do not always echolocate and may blunder into nets without ever detecting them. The use of specialized highly visible nets may help porpoises detect fishing nets. "Pingers," or devices that emit warning sounds, also may be attached to nets to make known the location of fishing nets. However, testing of these special nets and devices over a long period of time is required to verify if these are adequate solutions to this problem.

Harbor Seal and Spotted Seal

Phoca vitulina and *P. largha*

JOHN J. BURNS
Fairbanks, Alaska

The harbor seal is also widely known as the common seal. It occurs over a great latitudinal range and in many different coastal and insular habitats around the rims of both the North Atlantic and the North Pacific regions. Spotted seals, in contrast, occur only in seasonally ice-covered seas of the Western Hemisphere. The name larga seal is sometimes used for the spotted seal and is derived from *largha*, which is part of the scientific name. These two sibling species are the most closely related members of the subfamily *Phocinae* and are fascinating examples of adaptations to vastly different environments. Most harbor seals occur in habitats that are sea ice free throughout the year, or at least where their coastal haulout sites are clear of sea ice during the breeding season. Spotted seals utilize sea ice during the breeding season. In this context, it is important to distinguish between sea ice and freshwater icebergs calved from tidewater glaciers. Both species are of medium size. In some areas of the North Pacific their distributions overlap.

I. General Appearance

Based on external appearances, harbor and spotted seals older than weaned pups are not readily distinguishable from each other. Body size of spotted seals falls within the range of that for all but the largest harbor seals.

The pelage pattern and coloration of harbor seals is variable (Fig. 1). Background color ranges from yellowish or yellowish-gray (light phase) to blackish (dark phase). Light-phase seals are usually more pale on the flanks and belly than on the back, are covered with small black spots, and often show small pale rings, usually on the slightly darker dorsum. Dark phase harbor seals also have dark spots that are largely masked by the background COLORATION. Usually the dark seals show obvious light rings, especially on the dorsum. Seals of intermediate coloration are common. Throughout their broad range there are regions within which a particular pelage type predominates. Ungava seals are of the dark phase, as are most western Pacific harbor seals. Spotted seals are more uniform in color and pattern (Fig. 2). They tend to resemble light-phase harbor seals, which has contributed to the confusion about these two species.

II. Diagnostic Characters

There are morphological, ecological, and behavioral differences between harbor and spotted seals. The breeding habitat of harbor seals is coastal and insular. They give birth mainly on shore ROOKERIES, although in some parts of Alaska and Greenland they utilize icebergs calved from tidewater glaciers in protected fjords. Spotted seals use seasonal sea ice, mostly far

Figure 1 *Adult harbor seals from the eastern Pacific region. The uppermost seal is of the dark color phase.*

Figure 2 *A female spotted seal with pup in the Bering Sea. The pup is nearly weaned and is beginning to shed lanugo around its hind flippers.*

from shore. During the breeding season, harbor seals occur in herds with no obvious social organization. Spotted seals occur as widely scattered adult pairs, usually with a pup (triads). In the areas where they occur together, harbor seals breed about 2 months later than spotted seals (reproductive separation). The pelage of newborn harbor seals is like that of adults because the lanugo is shed before birth (*in utero*). Occasionally, especially in the northern parts of their range or in the case of premature pups, the lanugo is retained for up to a few days after birth. The pups usually enter the water shortly after birth, often within an hour. Spotted seal pups retain their whittish woolly lanugo, which is important for thermoregulation, for about 4 weeks. After the lanugo is shed the pelage resembles that of adult animals (Fig. 3). They remain on the ice during the nursing period and are abruptly weaned (abandoned).

There are no individual cranial measurements that consistently separate harbor from spotted seals. As with body size, skull measurements are within the range of those in harbor seals. The ratios of some measurements are useful for differentiating between the two species. Those ratios include jugal length/condylobasal length; nasal length from maxillo-frontal suture/condylobasl length; and interorbital width/mastoid width. Several nonmetrical characters, used in combination, do permit differentiation between the species. In harbor seals the skull is more massive, the bullae are more flattened and angular, the premolar teeth of adults are mostly obliquely set (straight in spotted seals), the posterior margin of the jugal bone is mostly angular (as opposed to rounded), the glenoid fossa is more flattened and angular, the bony process of the external auditory meatus is mostly straight and blade like (as opposed to mostly blunt and rounded), the shape of the posterior edge of the bony palate is mostly acute (as opposed to mostly rounded), and the hyoid arch is mostly incomplete, having abbreviated stylohyals that are not attached to the bullae (as opposed to complete and attached in spotted seals). Unfortunately, none of these diagnostic characteristics are useful for differentiating live seals under field conditions.

Very experienced observers can distinguish between these two seals, even those with similar pelage, based on behavior when hauled out together on land, on general facial features of adults, and on behavior when frightened into the water.

Figure 3 *A weaned spotted seal pup that has almost completely shed its lanugo.*

III. Distribution and Movements

The distribution of harbor and spotted seals is shown in Fig. 4. Harbor seals occur over a latitudinal range from about 30°N to 80°N in the eastern Atlantic region and about 28°N to 62°N in the eastern Pacific region. They have the broadest distribution and occur in most different habitats of any other pinniped. Although the centers of abundance (greatest numbers of breeding animals) are in the northern temperate zone, breeding colonies of these seals occur north or south of that zone, depending on the presence of required environmental conditions created by regional oceanographic and climatic conditions. The high latitude distribution in the Atlantic region is due to relatively warm oceanographic features, including the so-called North Water in Baffin Bay (eastern Canada–West Greenland), and the strong influence of warm water carried across the Atlantic to northern Europe by the Gulf Stream and associated gyres.

There are five presently recognized subspecies of harbor seals: *P.v. vitulina* Linnaeus, 1758; *P.v. concolor* (DeKay, 1842); *P.v. mellonae* (Doutt, 1942); *P.v. richardii*[1] (Gray, 1864); and *P.v. stejnegeri* Allen, 1902. The spotted seal, *P. largha* Pallas, 1811, is considered to be a monotypic species. The different subspecies of *P. vitulina* were originally recognized on the basis of geographical separation and skeletal morphology. Recent studies of their genetics sustain those conclusions. Boundaries

[1]Editorial protocol for this book requires the nomenclature of Rice (1998), which is *P.v. richardii*. The correct nomenclature, in the authors opinion, is *P.v. richardsi* in accordance with the explanation in Shaughnessy and Fay (1977). The person in whose honor this subspecies of seal was named was Capt. Richards, not Capt. Richard.

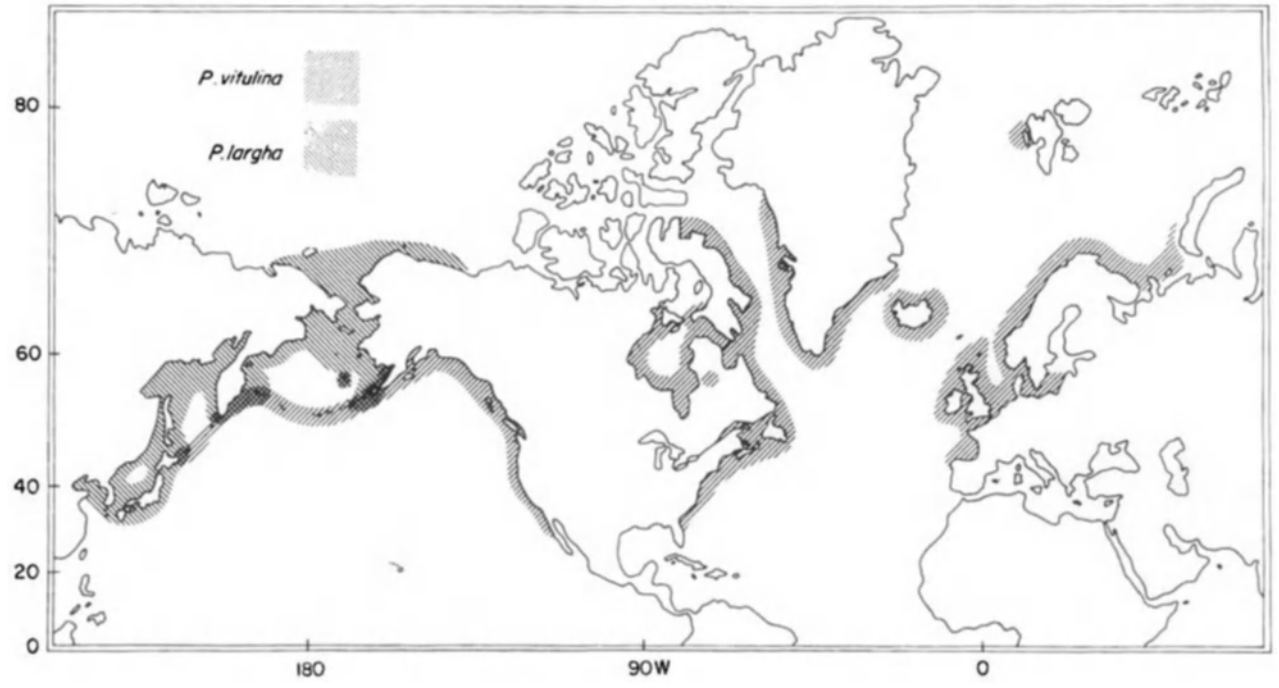

Figure 4 *The distribution of harbor seals (five subspecies) and spotted seals.*

between the eastern and the western subspecies within both the North Atlantic and North Pacific oceans are not known with certainty.

In the eastern Atlantic, *P.v. vitulina* normally occurs from the French coast bordering the English Channel, throughout the North Sea and northward to Finmark on the Barents Sea, including into the southern Baltic Sea and waters of Ireland and Great Britain. Stragglers occur to Portugal in the south and to the eastern Barents Sea in the northeast. The northernmost breeding population (here assumed to be *P.v. vitulina*) is in western Svalbard (Spitsbergen) at 78°30′N.

The boundary between *P.v. vitulina* of the eastern Atlantic and *P.v. concolor* of the western Atlantic is not known. However, harbor seals extend across the North Atlantic as a series of widely separated populations that occur at Svalbard, the Faeroe Islands (uncertain), Iceland, southern East Greenland, and West Greenland northward to about Upernavik (72°N). In Greenland the seals are considered to be *P.v. concolor*, as are those in most of eastern North America.

In the western Atlantic region the normal range of *P.v. concolor* extends from about 40°N (New Jersey) to about 73°N (northern Baffin Island, Canada), including into Hudson Bay and southern Foxe Basin. Stragglers have occurred as far south as Florida. The resident freshwater seal of the Ungava Peninsula in eastern Canada, *P.v. mellonae*, was first described and recognized as a separate subspecies by Doutt (1942), mainly on the basis of skull features and apparent isolation. It occurs in several drainage systems that empty into eastern Hudson Bay, where *P.v. concolor* is found. The subspecific designation of the Ungava seals was in doubt for several reasons, including their close proximity to saltwater harbor seals; the fact that in general harbor seals occur frequently in rivers and lakes; and because the freshwater drainages in which it occurs flow into Hudson Bay. However, passage to and from salt water is blocked by numerous obstacles resulting from isostatic uplifting (rebound) of the peninsula since the last Pleistocene glaciation. The distinct status of this rare freshwater seal has been upheld on the basis of genetic differences.

In the North Pacific region the distribution of harbor seals extends from Cedros Island near the west-central coast of Baja California, Mexico (about 28°N), northward to the Gulf of Alaska and southeastern Bering Sea, across the entire Aleutian Ridge (the Aleutian and Commander islands) to the Kamchatka Peninsula of eastern Russia, southward in the Kuril Islands and beyond to Hokkaido island in northern Japan. *P.v. richardii* is the subspecies of the eastern North Pacific region, and *P.v. stejnegeri* occurs in the western Pacific. The boundary between these two subspecies is currently thought to be in the western Alaska Peninsula–eastern Aleutian Islands, although uncertainty about that question still exists. The northernmost pupping colonies in the Pacific region are in Prince William Sound, Alaska, at about 61°13′N. That is some 1920 km farther south than the northernmost breeding group in the Atlantic region.

Great distances separate the Atlantic and Pacific forms. There are no breeding colonies between Baffin Island in northeastern Canada and the Pribilof Islands of southeastern Bering Sea, nor between northern Norway and the Pribilof Islands.

Seasonal and annual movements of harbor seals are quite varied depending on the environments in which they occur. They are usually considered to be relatively sedentary, with a high degree of fidelity to one or a few haul-out sites. This view, although perhaps applicable to some populations, is a gross oversimplification. It is now recognized that they move, in

some cases quite extensively. Generalizations are inappropriate in view of this seals' wide distribution and differences in stock sizes, population dynamics, and the varied environments they occupy. In most instances, some individuals are likely more sedentary and show stronger site fidelity than others. Kinds of movement include migrations, juvenile dispersal, seasonal shifts, shifts related to breeding activity, responses to seasonal habitat exclusion, responses to acute or chronic disturbance, and immigration/emigration, occasionally on a relatively large scale.

The spotted seal was, until recently, considered to be a subspecies of the harbor seal. It is now recognized as a distinct species that includes several widely separated breeding populations. The centers of abundance during the breeding season are mainly in the temperate/sub-arctic boundary regions. The seal is well adapted to exploit the "front" and broken ice zones of seasonal sea ice that overlies continental shelves during winter and spring. Spotted seals resort to haul outs on land during ice-free seasons of the year. There are great seasonal expansions and contractions of range, commensurate with the annual cycle of sea ice advance and retreat. Their distribution in all areas is most restricted during the period of maximum ice cover. They occur in the Bering, Chukchi (in summer), Beaufort (in summer) and Okhotsk seas, Tartar Strait, the Sea of Japan and the northern Yellow Sea/Bo Hai (Bohai Sea), and adjacent embayments that border the Korean Peninsula and China. The most southern breeding populations (about 38°N) are in the Sea of Japan and the Yellow Sea. Their occurrence at these southern latitudes is because of a cold winter climate, dominated by the so-called Siberian high pressure system, that results in a limited sea ice cover during midwinter.

In all areas, as the seasonal ice cover recedes and disintegrates, spotted seals expand their range and haul out on land. Some animals of the population that winters and pups on ice in the Bering Sea migrate northward into the Chukchi and Beaufort seas during the ice-free months. Their summer–early autumn distribution extends as far north as 71°30′N near Point Barrow, Alaska, and to about 70°N on the northern shores of Chukotka, Russia. Thus, the total range of the Bering Sea population extends over 15° of latitude, or about 1665 km.

Spotted and harbor seals are sympatric (have overlapping ranges) in the southeastern and southwestern Bering Sea, on the Kamchatka Peninsula, in the Kuril Islands, and northern Japan. Similarities in general appearance and occurrence on land (sometimes in close proximity) have long contributed to the confusion about these two different species.

IV. Population Size

Populations of harbor and spotted seals fluctuate in size due to both natural and anthropogenic causes, including hunting, incidental taking, competition for food with commercial fishers, habitat alteration, disturbance, protective measures, diseases, climate regime shifts, and other factors. Some populations are small and isolated, persisting in what may be marginal habitat. These may be the ones most vulnerable to changes in environmental factors and to direct exploitation. In general, direct exploitation has now been reduced greatly. Most populations are currently protected from HUNTING except under terms of special licenses or in areas where they are taken by indigenous peoples for subsistence purposes. Population estimates are fragmentary and, in many cases, outdated.

Estimates of the size of harbor seal populations provide useful indications of regional abundance and further illustrate this seals' coastal and insular distribution, primarily in the northern temperate zone. In the middle 1980s there were perhaps 98,000 eastern Atlantic harbor seals. By then populations had recovered after prolonged and sometimes intensive hunting and control programs. The largest numbers were and still are around the rim of the North Sea and Iceland. Areas of greatest abundance were in Great Britain (up to 47,000), Iceland (28,000), the Wadden Sea (10,000), and Kattegat/Skagerrak (6000). The smallest known populations are in the Baltic Sea (perhaps 200) and around Svalbard (500 to 600 in 1990). In 1988 a large proportion of some populations died from a viral epidemic: up to 48% in parts of southeastern Great Britain and an estimated 60% in the Wadden Sea and Kattegat/Skagerrak. These affected populations recovered rapidly and by 1992 there were an estimated 7250 seals in the Wadden Sea and perhaps 5200 in Kattegat/Skagerrack.

The number of western Atlantic harbor seals is not known, although in 1993 there were reported to be between 40,000 and 100,000, of which 30,000 to 40,000 were in Canadian waters. In some parts of northern Canada and Greenland these seals are harvested for meat and for their beautiful hides, which are made into clothing and other articles of Native handicrafts. The population in the United States was about 4700. There is no estimate of the number in Greenland. Fewer than 60 were harvested there in 1989. Apparently they were never abundant and have declined or disappeared in several locations.

Estimates (unreliable) of the number of Ungava seals range from 120 to perhaps 600 animals. The actual number is probably closer to the lower value. This includes the entire subspecies. Ungava seals are considered to be possibly endangered, vulnerable, and rare because of a lack of information, a very limited range, low numbers, and potential threats from proposed development in the region. This subspecies may well be a relict in habitat that has been altered drastically and unfavorably by natural geological processes during Holocene and Recent times.

In the eastern Pacific region, harbor seals are abundant, although as elsewhere numbers have fluctuated greatly. There is no estimate for the number in Mexican waters. From California to southeastern Alaska, these seals have increased greatly during the past three decades. Estimates during the mid-1990s were: California, 34,500; Oregon and coastal Washington, 29,900; inland waters of Washington, 13,800; British Columbia, 100,000 (with increases of about 12.5%/year through 1993); and southeastern Alaska, 35,000. In south-central and southwestern Alaska the population trend has been the opposite of that farther south, with an 85% decline in the Gulf of Alaska between 1976 and 1988. These opposite trends in the southern and northern parts of their range are apparently mainly responses to a major oceanic regime shift that began about 1976, although factors such as protection, continued hunting and incidental taking are also involved. At present the estimated

number in the Gulf of Alaska region, including Prince William Sound, is about 20,000 animals. In southwestern Alaska, primarily Bristol Bay, there are an estimated 15,000 seals not including animals in the Aleutian Islands, which are herein considered to be a different subspecies.

The range of the western Pacific harbor seal extends across the Aleutian Ridge to Asia. These seals are predominately of the dark color phase, they tend to occur in very small groups (as opposed to large aggregations), and they mainly occupy rocky islands and shorelines. Regional estimates of numbers are: Aleutian Islands, about 3400 (in 1994); Commander Islands, 1500; Kamchatka Peninsula, 200; Kuril Islands, 1900; and northern Japan, 300. Estimates for the latter four areas are from the early 1990s. They are classified as rare in Japanese and Russian waters and are now protected.

There are no reliable recent population estimates for the spotted seal, except perhaps in the Bohai Sea. Indirect and anecdotal information suggests that since the early 1980s the population in the Bering Sea has declined, perhaps due to changing climate and therefore more unfavorable sea ice conditions and changed food-web dynamics. This is also in accord with trends of harbor seals in the northern part of their Pacific range. For the Bering Sea population, estimates (educated guesses) were 200,000–250,000 in the early 1970s and 100,000–135,000 in the 1980s. The actual current size of the population is unknown, although these seals remain of common occurrence and are important to Native subsistence hunters in coastal areas of the Bering and Chukchi seas. Fewer than 5000 per year are thought to be harvested annually. Vessel-based commercial hunting by the Russians ended in 1995. The population in the Okhotsk Sea was placed at 130,000 in 1982. There is essentially no subsistence hunting there and, as in the Bering Sea, commercial harvests have stopped. The current size of populations in the Sea of Japan and Tartar Strait is not known. In the Bohai Sea, including Liaodong Bay, there were an estimated 4500 in 1990. This compares with estimates of >7000 in the 1930s; >8100 in 1940; and 2269 in 1979 (after a period of intensive harvesting). These seals were accorded protection from hunting in the 1980s.

V. Behavior and Life History

As already noted, harbor and spotted seals are superficially quite similar in appearance. Harbor seals haul out mainly on land, although in some areas of mainland Alaska and Greenland they use icebergs calved from tidewater glaciers. Also, in the northern parts of their range, where labile sea ice occurs to or very near shore, they haul out on it until the land sites are accessible, usually long before the pupping season. They use haul outs throughout the year, although most frequently and in greatest numbers during the pupping and molting seasons. Regardless of season, haul-out activity is strongly affected by the stage of the tide, air temperature, wind speed, precipitation, and time of day. They lay close to the water when hauled out and usually flee when disturbed, although habituation is not uncommon near large human population centers, if they are not harassed unduly. The substrate at natural haul outs on land is diverse and includes mud flats, sand and gravel bars and beaches, rocks, glacial icebergs, and occasionally sea ice. Depending on the region, haul outs can be on lakes, rivers, estuaries, bays, ocean shorelines, islands, islets, ledges, and any other setting where the seals can rest, undisturbed, with immediate access to deep water. They may, on occasion, haul out on man-made structures such as docks, floats, and log rafts.

Spotted seals use sea ice starting with its formation in autumn. They often concentrate in large numbers on the early ice that forms near river mouths and estuaries (freshwater freezes at a higher temperature then seawater) and feed on autumn spawning fishes. As the ice thickens, becomes attached to land, and extends farther from shore, spotted seals move seaward into the drifting ice. Their association is mainly with the highly labile marginal areas and they migrate (southward in the Chukchi/Bering sea region) to maintain an association with that habitat. During the cold weather of winter they rarely haul out. Peak haul out on the ice is during the pupping and molting season.

As the sea ice cover retreats and disintegrates in late spring–early summer, spotted seals again move shoreward and, in the Bering Sea, northward. Again, large aggregations can often be seen close to shore on the last remnants of former shorefast ice and on ice flushed from rivers and estuaries. At this time of year they feed extensively on the dense schools of spawning herring and smelt. They haul out on shore when the ice is gone. Between haul-out bouts on land, some seals travel long distances in the open sea, even between Alaska and Siberia, and use multiple haul outs (as they also do when migrating). Shore haul outs are mostly on isolated mud, sand or gravel beaches, or on rocks close to shore. They are often on river bars, tidal flats, and barrier islands. Spotted seals are especially vigilant on land, where they may be subjected to attack from a variety of predators. Their association with sea ice starts again as soon as it begins to form in the autumn.

A. Food Habits

Feeding forays of harbor seals can be close to haul-out sites or many miles distant, either along the coast (including rivers) or seaward. They are capable of FEEDING at considerable depths (to 500+ m) and are generalists that prey mainly on abundant and easily available foods, with diets varying by season and region. There are long-term changes in foods that are associated with environmental changes, and therefore dynamic changes in the abundance of different prey species. Primary food items are small to medium size fishes (or age classes), such as various members of the codfish family, hake, mackerel, herring, sardines, smelts, shad, capelin, sandlance, sculpins, a variety of flatfishes, salmonids, and many others. Their propensity for cod, salmons, and other commercially important species has resulted in long-standing conflicts with fishermen in many areas. Cephalopods (squid and octopus) are usually reported as being next important after fishes, followed by crustaceans, including mainly shrimps and crabs. Several studies have reported that shrimp may be particularly important to recently weaned pups. Although there is great diversity in foods, a few items usually comprise the majority of seasonal diets in an area. As examples, in Atlantic Canada, 23 different food items were identified but 4 accounted for 84% of the estimated biomass of prey consumed. In the Gulf of Alaska, fishes comprised 73.8% of the

diet and 27 different species were eaten. The four most important foods were pollock, cephalopods, capelin, and flatfishes. In the western Aleutian Islands the main food items, at least in 1958 and 1962, were Atka mackerel (*Pleurogrammus monopterygius*) and octopus. The main foods of the Ungava seals are thought to be resident brook and lake trout. Seals in Lake Iliamna, Alaska, feed on the variety of salmonids (charr, trout, and salmon) that occur there in large numbers.

Spotted seals are also generalist feeders that primarily utilize similar types of abundant fishes, crustaceans, and cephalopods. Because they have a pelagic distribution in winter–spring and a different coastal and pelagic distribution during ice-free months, there are major seasonal and regional differences in food habits. Additionally, there are age-related differences. Most reports about food habits are based on seals examined during spring (mainly April and May) when they are associated with sea ice. A few samples are from animals collected in the coastal zone during autumn, and there are anecdotal observations of summer feeding, especially in areas where subsistence and commercial fishing activities occur. There are few data from the late autumn and winter months, although in the Bering and Okhotsk seas these seals occur where pollock, herring, eelpout, flounders, shrimp, and crabs are abundant.

Independent feeding by spotted seal pups begins about 10 to 15 days after they are abruptly weaned. During the time of fasting and early independent feeding they live on their accumulated fat reserves and lose between 18 and 25% (sometimes up to 30%) of their weight. The first food consumed is frequently small amphipods or euphausiids. Abundant schooling fishes are the main foods of older seals and, in the Okhotsk Sea, occurred in 89% of seals 1–4 years old and 70% of seals >5 years old. Cephalopods were next in importance, followed by decapods. Amphipods were still consumed by the 1–4 year olds but were not found in older animals. The frequency of occurrence of cephalopods was higher in older age animals. Spotted seals were reported to feed more in the morning and evening than at other times of the day. During spring the main food items in the Bering Sea, depending on the region, were pollock, arctic cod, sand lance and capelin. In the Okhotsk Sea, pollock were most important. In Peter the Great Bay (Sea of Japan), the dominant fishes were saffron cod, flounders, and rockfish and in Tarter Strait they were saffron cod, flounders, and salmon. In all areas crustaceans and cephalopods were also important. There has been little sampling in coastal habitats during summer when anadromous and coastal spawning fishes such as charr, salmon, capelin, smelt, herring, flounders, saffron cod, and other species are abundant. According to traditional local knowledge, those foods are utilized intensively by the seals.

B. Size

The average length of harbor seals varies among populations. The smallest and largest seals occur in the North Pacific region and therefore they bracket the size of animals from other regions. Those from the northern Gulf of Alaska, members of the *P.v. richardii* complex, are the smallest. The average standard length and weight of adult males from that area is about 160 cm and 87 kg, while that of adult females is about 148 cm and 65 kg. Newborn pups average 82 cm and 10 kg. The largest seals are of the *P.v. stejnegeri* complex from northern Japan. Length and weight of adult males range from 174 to 186 cm and 87 to 170 kg and that of adult females from 160 to 169 cm and 60 to 142 kg. newborn pups were up to 98 cm and 19 kg.

Spotted seals are about the same size as most harbor seals and there are slight differences among populations. Adult males from the Bering Sea range from 161 to 176 cm and 85 to 110 kg. Adult females are 151 to 169 cm and 65 to 115 kg. Near-term fetuses and newborn pups from the Okhotsk Sea are 78 to 92 cm long and 7 to 12 kg. Healthy pups usually double and sometimes triple their birth weight during the 3- to 4-week nursing period.

C. Reproduction

In general, female harbor seals reach sexual maturity at ages 3 to 4 years and physical maturity by age 6 or 7. Males obtain sexual maturity at 4 to 5 and physical maturity by 7 to 9. The maximum life span is around 35 years, although few animals live that long in the wild. All harbor seal populations have a similar reproductive cycle. However, over their very broad range the specific timing of events varies. Depending on the region in question, births occur in late spring or summer. Within a specific population the peak of pupping can change slightly over time, apparently in response to significant environmental shifts. Additionally, there is some interannual variability. In general the pupping season extends over a period of up to about 10 weeks, within which there is about a 2-week peak. Females bear a single pup, although twinning has been recorded. In most regions, pups are born on land, usually between the high and the low tide water lines. In some parts of Alaska (and presumably also in Greenland), pups are born on floating icebergs calved from tidewater glaciers in protected fjords.

Newborn pups can and do enter the water, often being forced to do so by tidal inundation of birth sites or because of disturbance by birds scavenging afterbirth. Mother–pup bonding is a critical phase of behavior within the first hour of birth, as mutual recognition is required to locate and/or remain with each other on rookeries and in the water. A young pup often clings to its mother's back in the water. Mothers feed during the approximately 4-week nursing period (some reports indicate as long as 6 weeks). Pups start to catch their own food during the late stages of the nursing period.

Mating occurs in the water at about the time that pups are weaned, although females mating for the first time or that have not given birth in a specific year may breed outside of the peak period of the postparturient animals. There is intermale competition for receptive females and no obvious social organization during the breeding season. As with all other pinnipeds, fertilization is followed by a prolonged period of delayed implantation (embryonic diapause) that lasts about 2.5 months, after which the embryo implants and resumes development. The total gestation period, from fertilization to birth, is about 10.5 months. In most populations, pregnancy rates exceed 85%; in other words, most sexually mature females bear a pup every year.

To put the timing of this generalized reproductive cycle into a regional context, the peak period of pupping can be used as

the benchmark event. In Europe, most pupping occurs during late June and early July. In most of eastern Canada and Greenland, births are mainly during mid-May to mid-June, slightly later at higher latitudes. However, the Ungava seals reportedly pup during late April or early May. There are considerable differences among populations of the Pacific region. Births occur during early February in Mexican waters; in March–April in southern California; in May along the outer Washington coast; between late June and September in Puget Sound and southern British Columbia; during May to late June in northern British Columbia, most of Alaska and Japan; and early June to late July (peak around July 1) in the Aleutian and Pribilof Islands.

Spotted seals have the same basic reproductive cycle as harbor seals, although the timing of events is directly related to the most favorable sea ice conditions at the time of birth and weaning. Pups are born exposed on the ice and, during the first 2 or 3 weeks, are more like land mammals. They spend most of the time on ice floes until weaned. Unseasonably early disintegration of ice is thought to result in a high mortality of nursing pups. During early life the dense coat of lanugo provides the required insulation for maintaining body heat, although that important function is assumed by the rapidly increasing blubber layer acquired during the 4-week nursing period. At weaning, most pups are heavier than at any other time during their first year of life. They are so fat and buoyant that they are poor divers. This large energy store provides sustenance during the early stages of adjustment to independent life.

Timing of the birth period has evolved to coincide with the average period of greatest extent and stability of the seasonal sea ice cover and varies by region. Weaning, which is abrupt, coincides with the normal seasonal onset of ameliorating spring weather and disintegration of the seasonal ice cover. The use of sea ice as a platform on which to bear and nurture pups is central to the ecology of spotted seals. These events (birth, dependence during the nursing period, weaning, and early independence) are more restricted in time than is the case with harbor seals. Pups are born earlier in the more southerly parts of this species' range. In the Yellow Sea the peak period is during late January; in the Sea of Japan it occurs during February and March; and in both the Okhotsk and Bering seas the peak is during the first half of April. Mothers feed during the nursing period, although the pups remain on the ice, sometimes wriggling over brash ice to move between closely adjacent ice floes.

Mating occurs at about the time that pups are weaned, and most females breed annually. The MATING SYSTEM is quite different than that of harbor seals. Spotted seals begin to form pairs early during the pupping season. They are considered to be annually monogamous and territorial. Triads consisting of a female, her pup, and an attending male can be seen lying on the ice. These triads are widely spaced, although there are regions of high abundance. Females frequently attend their pups on the ice, especially during the early nursing period, and the males stay with the females. Pairs that include an adult female that did not pup are also formed. In the Bering and Okhotsk seas, such pairs are seldom seen on the ice in early April (prior to the molt in adults), probably because there is no pup to attend. As with all aspects of the breeding cycle, there is a latitudinal element to the mating period that relates to the regional seasonality of sea ice, and the timing of birth and lactation.

Nursing and recently weaned pups remain on the ice flows without benefit of snow lairs. Their only protection from wind is that provided by their mothers or the shelter of ice ridges. The exposed and relatively immobile pups are not subjected to significant predation by polar bears or arctic foxes because the labile marginal ice in which they occur during spring is well south of the normal range of those predators. Polar bears and arctic foxes do not occur in the Okhotsk Sea of farther south.

D. Molt

In harbor seals the molt generally occurs during midsummer to early autumn, within 2 or 3 months of the pupping season. During the molt, seals haul out more frequently than at any other time of the year except for the pupping season. There are differences in timing among age and sex cohorts. Usually yearlings begin and end the molt earliest, followed by subadults, then adult females, and last, adult males. There is overlap among these general age groups. Throughout their extensive range the molt occurs after cessation of the breeding season. Accordingly, it occurs later in the year in the late breeding populations of harbor seals such as those in Europe, British Columbia, and Puget Sound.

Spotted seals of the Okhotsk and Bering seas molt mainly in late spring. Pups, as mentioned, have the color and pelage pattern of adults after their lanugo is shed. Older seals begin the molt after the breeding season and show an overlapping age-related sequence similar to that of harbor seals. The period of intensive molt is during May and June, during which time the sea ice is retreating rapidly and deteriorating. In areas where the ice disappears early, or in minimal ice years, the molt is completed on shore haul outs.

VI. Mortality Factors

Excessive overexploitation, large-scale die-offs due to epizootic diseases, and natural long-term population changes are known to occur in harbor seals. As examples, in late 1979 and 1980 an estimated 500 seals died along the New England coast from an influenza virus of avian origin. Another less severe disease-caused die-off occurred in the same area in 1982. The largest known incident of mass deaths occurred in northern Europe, during 1988–1989, when an estimated 18,000 harbor seals died due to a viral infection that spread rapidly among some colonies in the North Sea region. In all areas the populations had previously reached high levels after cessation of control programs. In the eastern North Pacific south of the northern Gulf of Alaska there has been a sustained long-term increase in numbers. Farther north they declined about 85% between 1976 and 1988. These changes in the eastern Pacific are probably mainly related to natural large-scale climatic regime shifts now known to have occurred. Nothing is known about natural fluctuations in spotted seals, although it is probable that they have also been affected by climate change and therefore changes in the carrying capacity of their more remote environment.

The reported predators of harbor seals include killer whales, sharks, Steller sea lions, eagles, ravens, and gulls. Spotted seals

are preyed on by those same animals and also by walruses, polar and brown bears, wolves, and arctic foxes. Humans hunt both species of seals, especially in the north, and also occasionally take them incidentally in the course of other activities, particularly fishing.

VII. Conservation Concerns

There are similar conservation concerns relevant to both harbor and spotted seals. The general problem of pollution from military, agricultural, and/or industrial activities (including coastal and off-shore oil and gas development) is of particular concern because of its direct and indirect effects on seals and the foods they eat. Oil spills are a chronic problem. Recent disease outbreaks may have been intensified because of suppressed immune responses caused by a variety of pollutants. Hunting may still be an important factor in limiting or reducing some of the small breeding populations of harbor seals in Greenland and northern Canada. Fishing activities can affect both species adversely by causing incidental mortalities and by competing for fish the seals depend on for food. FISHERY INTERACTIONS are probably limiting any increase of the small populations of harbor seals in northern Japan and parts of Greenland. Development projects can alter or eliminate important habitat or displace seals by increased disturbance near haul outs. The Ungava seal may be particularly vulnerable to proposed hydroelectric projects.

Climate change, specifically warming, will have major impacts on harbor and spotted seals. The contentious aspect of that important issue is the extent to which natural change is being exacerbated by anthropogenic effects. Climate has changed many times in the past and has been an important force affecting zoogeography, population fluctuations, extirpation, and EXTINCTION. Global warming is definitely causing later formation and earlier breakup and reducing the extent and thickness of seasonal sea ice. It might well result in an increase of suitable habitat for harbor seals in the north and an overall decrease of spotted seal habitat, especially in the southern parts of its range.

Harp Seal

Pagophilus groenlandicus

David M. Lavigne
International Fund for Animal Welfare, Guelph, Ontario, Canada

The harp seal is one of the most abundant and best known of all pinniped species. Commonly referred to by scientists in recent decades by the Latin name *Phoca groenlandica*, the Greenland seal (following Burns and Fay 1970), it is more correctly named *Pagophilus groenlandicus* (Erxleben, 1777)—the ice lover from Greenland (Rice, 1998). Its most popular common name, the harp seal, comes from the black, wishbone marking found on the backs of adult animals, which is reminiscent of the musical instrument of the same name (Fig. 1). Another common name—the saddleback seal—refers to the same marking. The faces of adults are also black whereas the remainder of the body appears silvery-gray when dry. Young pups, which have a characteristic white pelt at birth, are known as "whitecoats" (Fig. 1).

Adult harp seals are about 1.7 m in length, with females being marginally smaller, on average, than males. Adults weigh about 130 kg early in the pupping season, but their mass (weight) varies considerably throughout the year and from year to year.

I. Distribution and Populations

Harp seals inhabit the North Atlantic and Arctic Oceans from northern Russia in the east to Newfoundland and the Gulf of St. Lawrence (Canada) in the west (Fig. 2). Although some authors recognize two subspecies (see Rice, 1998), it is more common to refer to three distinct populations (Reijnders *et al.*, 1993; Reeves *et al.*, 1992), based on small morphological, genetic, and behavioral differences. One population, which is found largely in the Barents Sea, reproduces on the "East Ice" in the White Sea off the coast of northwest Russia. (This population is designated by some Russian scientists as *P.g. oceanis.*) A second population lives off the east coast of Greenland and breeds on the "West Ice" near the island of Jan Mayen. The third lives in the northwest Atlantic off the east coast of Canada and breeds in two locations: on the "Front" off the coast of Newfoundland and Labrador, and in the Gulf of St. Lawrence (Fig. 2). (The latter two populations are assigned to *P.g. groenlandicus* by some scientists.)

The northwest Atlantic harp seal population is the largest of the three. The Canadian government now estimates that the population stabilized in the late 1990s (Department of Fisheries and Oceans, 2000). Pup production in 1999 was estimated at 998,000 ± 200,000 (mean ± 95% confidence limits). The year 2000 population was estimated to number 5.2 million animals (95% confidence interval = 4.0–6.5 million).

The most recent assessment for the West Ice population estimated 1994 pup production and population size to be 59,000 and 286,000, respectively (Anonymous, 1994).

A 1998 aerial survey in the White Sea found pup production on the East Ice to be on the order of 300,000–400,000, higher than previously thought (see Anonymous, 1999). These results are consistent with a total population size of about 1.5 to 2.0 million animals.

The harp seal is a highly gregarious and migratory species that lives in close association with pack ice. Its annual range (Fig. 2) is essentially defined by the southern and northern limits of pack ice and is largely coincident with the subarctic region of the North Atlantic (Dunbar, 1968).

II. Growth and Reproduction

From late February to mid-March, female harp seals congregate near the southern limits of their range (Fig. 2) to give birth to their pups. Each female gives birth to a single pup (although twin fetuses have been reported). Newborn pups weigh

Figure 2 *Harp seal distribution in the North Atlantic Ocean. The four black circles indicate pupping areas (see text for details).*

about 11 kg at birth and lack the thick insulating layer of BLUBBER found in older seals. They are nursed on a fat-rich milk for about 12 days, during which time they deposit a thick (ca. 5-cm) blubber layer and grow about 2.2 kg per day. During this time they pass quickly through a number of recognizable developmental stages (Lavigne and Kovacs, 1988; Hannah, 2000). At weaning the pups weigh on average 36 kg. At this stage they are known as "graycoats" because their spotted, gray juvenile pelage has grown in and can be seen beneath the white neonatal coat. Shortly thereafter, the white coat becomes loose and, within a few days, it begins to fall out. Once the white coat is completely molted, exposing the black-spotted, silvery-gray pelt of the young harp seal, the animal is called a "beater" (Fig. 3).

At the age of about 13–14 months, young harp seals undergo their second molt. It is at this time that the "beater" pelt is replaced by a similar spotted pelt and the animals are renamed "bedlamers." They will retain this spotted pelt through successive annual molts until the spots start to disappear and

Figure 3 *Molted harp seal pup or "beater," aged about 4 weeks. Photo courtesy of International Fund for Animal Welfare.*

the dark, harp-shaped pattern of the adult coat begins to emerge. Older harp seals with a combination of the spotted bedlamer pelt and the distinct adult "harp" are called "spotted harps." The transition from the bedlamer pelt to the adult pelt begins with the onset of sexual maturity, at the age of 4 or 5 years (possibly later in males). Most male harp seals develop the black "harp" marking abruptly, whereas in females the transition is more gradual and may take many years. Indeed, some female harp seals never lose all their spots or develop a complete "harp." Any seal with the complete harp and black face may be aged anywhere from about 5 to 30 years—the life expectancy of the species.

Weaning in harp seals is abrupt. The adult females simply leave their pups on the ice and turn their attention to mating and the production of next year's pup. Mating usually occurs in the water (Lavigne and Kovacs, 1988), but has also been photographed on the ice (F. Bruemmer, personal communication). The fertilized egg, which results, divides several times, forming a spherical embryo, which floats freely in the womb for more than 3 months before being implanted in the wall of the uterus. This type of suspended development—known as delayed implantation—ensures that all females give birth to their pups at the same time each year when short-lived pack ice is available as a whelping platform.

Meanwhile, the weaned pups remain on the ice and undergo a postweaning fast, during which they may lose up to half of their body mass as they draw on their thick blubber layer for sustenance. The entire fast may last upward of 6 weeks, but they eventually enter the water and begin feeding on their own.

Following the breeding season, older harp seals congregate once again on pack ice farther north to undergo their annual molt. Following the molt, in which the pelt and surface layers of skin are replaced, the animals MIGRATE to summer FEEDING areas in subarctic and arctic waters to the north. All three populations exhibit similar patterns of annual migrations, although the timing of specific events, such as pupping, mating, and molting, varies slightly among populations.

III. Ecology

By pinniped standards, harp seals are modest divers. The average maximum dive depth is 370 m and the average dive duration is about 16 min (Schreer and Kovacs, 1997).

Harp seals exhibit catholic feeding habits, which vary with age, season, location, and year. While at least 67 species of fin fish and 70 species of invertebrates have been recorded in their stomachs over the past 50 years (Wallace and Lawson, 1997), harp seals tend to concentrate on smaller fishes, such as capelin (*Mallotus villosus*), arctic cod (*Boreogadus saida*), and polar cod (*Arctogadus glacialis*), and a variety of invertebrates, including euphausiids (*Thysanoessa* sp.). Contrary to many popular reports, harp seals rarely eat commercially important Atlantic cod, *Gadus morhua*. Harp seals are themselves prey for polar bears (*Ursus maritimus*), killer whales (*Orcinus orca*), and sharks (e.g., *Somniosus microcephalus*), but their major predator would appear to be *Homo sapiens*.

IV. Conservation Status

All three populations of harp seals have been hunted by humans for centuries; all three have undergone documented declines in numbers as a result of overexploitation; and all three populations continue to be hunted today. The commercial hunt for northwest Atlantic harp seals remains the largest hunt for any marine mammal population in the world, with over 460,000 animals acknowledged killed in each year between 1996 and 1999 (Department of Fisheries and Oceans, 2000, also see Johnston *et al.*, 2000). The seals are hunted in Canada during and after the spring breeding season in what was once called "the greatest hunt in the world." The same population is also hunted off the west coast of Greenland during the summer months.

Overexploitation, particularly in the northwest Atlantic (Johnston *et al.*, 2000), and an expanding and largely unregulated trade in seal products (especially seal skins, seal oil, and penises) remain potential threats to the species. Other potential threats include continued proposals to cull harp seal populations, ostensibly to benefit commercial fisheries; reduced food availability due to human overfishing or climate change; incidental catches in fishing gear; and environmental contaminants (Reijnders *et al.*, 1993).

Health

JOSEPH R. GERACI AND
VALERIE J. LOUNSBURY
National Aquarium in Baltimore, Maryland

The health of any animal is affected by age, behavior, and environment. Like terrestrial species, marine mammals are subject to infection, injury, and metabolic disturbances. Our understanding of marine mammal health has been impeded not only by the difficulties inherent in studying these species in the wild, but also by their unique biology. In recent decades, the challenge has been compounded by human impacts on the health of marine mammals and their environment.

I. Adaptations to Life at Sea

Cetaceans, sirenians, pinnipeds, and sea otters, although taxonomically distant, have evolved similar biological mechanisms to cope with a marine existence. These functional adaptations include strategies for controlling body temperature, diving, maintaining salt and water balance, and promoting reproductive success—adaptations vital to health and survival.

A. Thermal Balance

Except for some areas in the tropics, the sea is almost always cooler than mammalian body temperature. Even a few

degrees difference is enough to drain a mammal's thermal reserves, as water steals body heat about 20 times faster than air. To cope with this drain, marine mammals have generally evolved mechanisms to conserve body heat. Of these, blubber has arguably been the key to evolutionary success. This coat of fat provides cetaceans and certain pinnipeds with mechanical protection, warmth, buoyancy, nutrients when food is scarce, and fresh water in reserve. Otariid pinnipeds have thinner blubber and less body fat than phocids or the walrus (*Odobenus rosmarus*) and are thus less tolerant of cold and depend to a certain extent on their pelage for insulation. This is especially true for otariid pups, which may not acquire an adult coat or adequate fat until they are about 3 months old and, in the meantime, are prone to hypothermia when they become wet. Species with less blubber rely on other strategies. The sea otter (*Enhydra lutris*) depends entirely on a high metabolic rate (and high caloric intake) to generate heat and on its dense, well-groomed fur to prevent heat loss. The living sirenians, with low metabolic rates and little ability to control surface heat loss, are functionally restricted to tropical and subtropical waters.

Environmental temperature has more than a subtle bearing on health. To survive in a cold climate, a marine mammal must be robust, appropriately insulated, and have all surface heat control mechanisms operating. If not, the only recourse is to increase the metabolic rate and either eat more or borrow fat from vital fat reserves. Ironically, as a last measure to conserve heat, pinnipeds and sea otters may haul out on land where the prospect of feeding is hopeless.

Overheating is rarely a problem for a marine mammal in water. In a warming environment, a whale may eat less and metabolize blubber, which effectively reduces insulation, and shed excess heat by increasing blood flow to the skin, particularly of the extremities. Losing heat on land is not as easy. A wet seal or sea otter may get some comfort from evaporative cooling, but once it is dry, it depends mostly on circulatory and behavioral adaptations (e.g., seeking shade, sleeping, moving to the surf zone) to avoid hyperthermia. These strategies work to a point. A sea otter out of water can become distressed at air temperatures as low as 10°C and die within hours at 21°C. A cetacean stranded on a sunny beach can literally cook inside its own blubber.

B. Breathing and Diving

Marine mammals forage at all depths. While sea otters and sirenians may have little need to dive deeply or for more than just a few minutes, some species of phocids and odontocete cetaceans make prolonged dives to 2000 to 3000 feet or more. Such deep diving is made possible by a suite of adaptations for coping with pressure and potentially deadly nitrogen, and for storing and utilizing oxygen efficiently. During a prolonged dive, circulation to the skin and viscera may almost cease, allowing oxygen to be channeled to organs that need it most, such as the heart and brain.

Deep dives may require a shift to anaerobic metabolism. Such dives may be useful for escape and exploration but are costly in terms of time and energy. For most animals, survival depends on obtaining sufficient prey within the depth and time limits imposed by aerobic diving capacity, which in turn depends on the species and the size, age, and health of the individual. Because of their relatively greater capacity to store oxygen, large animals tend to be better divers. It is not surprising that juveniles may find it difficult to reach prey that is easily accessible to adults.

C. Salt and Water Balance

The osmotic concentration of the sea is nearly four times greater than that of mammalian body fluids. Chemical equilibrium thus favors loss of body fluids into the sea and encroachment of salts into the animal. Marine mammals have evolved a number of strategies to prevent this from happening: (1) external surfaces are impermeable to seawater; (2) body water is highly conserved—sweat glands are either reduced or absent and the kidneys efficiently concentrate urine; (3) they drink little seawater and acquire most of their fresh water from food (water makes up about 70% of a fish, 80% of a squid, and over 90% of aquatic plants, and each gram of dietary fat or metabolized blubber yields close to its weight in fresh water). In pinnipeds and cetaceans, the physiological response to stress is also designed to conserve water. Secretion of aldosterone, a hormone produced by the adrenal cortex, promotes the resorption of sodium from the kidney, thereby drawing water back into the body. Maintaining electrolyte balance thus depends on adequate blubber, well-functioning kidneys, proper hormonal balance, and a healthy, intact epidermis.

D. Strategies for Rearing Young

The social, physical, and biological conditions that together create a healthy environment are especially critical during the period of an animal's life when it depends totally on its mother. Vulnerabilities can often be predicted on the basis of species, location, patterns of maternal care, and environmental conditions. For example, many pinnipeds have evolved strategies to ensure breeding opportunities for animals that may be dispersed for much of the year, with the result that pupping and mating occur at predictable times and locations. While an effective strategy for the population, consequent crowding on rookeries can increase the risk of injury, infection, and disease transmission for individuals.

II. What Can Go Wrong?

Body systems work together, each complementing the others. Impairment of one system can disturb the entire equilibrium, leading to secondary problems, which then become a threat. For example, blubber is a source of energy, insulation, water reserves, and buoyancy. If it becomes depleted because food is unavailable, the animal may eventually be unable to rest at the surface, maintain body heat, forage, escape predators, or keep up with a group. The ensuing stress may open the door to infection, further reducing the chance of survival.

Injuries and illnesses are not always apparent and are often detected only after analyzing blood or tissue samples from a living animal or dissecting a dead one. Even careful study might not reveal serious biochemical and physiological conditions. Stress is poorly understood and difficult to quantify. What little is known about the process in marine mammals shows that it can disrupt thyroid and adrenal cortical function, water and electrolyte balance, and metabolism and reproduction, and can decrease

circulating levels of certain blood cells, perhaps reducing resistance to parasitic infection and compromising immune responses.

A. Reproductive Failure and Death of the Newborn

An orderly, coordinated progression of biological and behavioral factors is required for an animal to reproduce successfully. Weakness or disruption at any point can result in reproductive failure, evident as abortion, stillbirth, premature birth, or death of the newborn. The causes of reproductive failure are often obscure, particularly in species that cannot be studied from shore.

In some species, the risk of abortion or stillbirth appears to be greater for first-time mothers. Young mothers are also often smaller and give birth to smaller offspring, which are more vulnerable to hypothermia and injury. The health and nutritional condition of any mother, regardless of age or size, affects the fetus. Decreased prey abundance, such as associated with El Niño events, may be associated with decreased fertility, increased abortions, and reduced pup production. Infectious disease [e.g., morbillivirus in harbor seals (*Phoca vitulina*) in Europe] may also lead to increased premature births and abortions. In fact, a rise beyond the expected level of reproductive failure may be one of the first signs of an environmental disruption, such as a viral epidemic, reduced prey stocks, or high levels of certain anthropogenic contaminants.

A successful birth is no guarantee of prolonged survival. Neonates that are weak at birth or suffer from serious congenital defects soon die. Healthy neonates may, for one reason or another, be abandoned by their mothers or face an early death if the mothers fail to provide proper care, whether due to illness, injury, disturbance, or simply to inexperience.

B. Starvation

Marine mammals spend much of their time searching for food of the appropriate type, size, and quality to satisfy needs that may vary seasonally and with age. Some animals, e.g., dependent young, the sick, and the very old, can starve even when food is plentiful. Many factors determine how long an animal can survive without food: its age, fat reserves, metabolic rate, energy demands, and general health. Large animals with low metabolic rates survive longer than those with high energy demands, such as small species, newborn, and growing pups. Baleen whales may feed very little for 6 to 8 months of the year, but a sea otter without food for even 2 days can die from gastroenteritis and shock. Starvation is a major cause of death in pinniped and sea otter pups.

Throughout the period of dependency, a young animal's survival hinges on the health of its mother. Before giving birth, a phocid seal or baleen whale must develop ample fat reserves to carry it through a period of fasting or reduced feeding during lactation. The pup or calf born of a malnourished mother is at risk from the moment of birth and its longevity is compromised early in its development. The young of species in which females feed continuously during lactation face a different threat. A bottlenose dolphin (*Tursiops truncatus*) calf depends on the state of its mother's nourishment throughout what may be a year or more of nursing. An otariid pup risks starvation if a shift in prey abundance forces its mother to spend longer periods away from the rookery.

Weaning frees a young animal from dependence to face the challenge of providing for itself. Manatees (*Trichechus* spp.) and some cetaceans and otariids remain with their mothers long enough to learn foraging skills. Not so for all sea otters. Newly independent juveniles, handicapped by high metabolic demands and inexperience, and at a time when erupting TEETH create problems with chewing, often starve. Females may be especially vulnerable because they tend to remain in established areas of the range even when prey become depleted.

Depletion of food stocks, whether from overexploitation, overfishing, or climatic or oceanographic fluctuation, can affect entire populations. Food scarcity in one area may cause some animals to move elsewhere. When food abundance changed during the El Niño of 1982–1983, California sea lions (*Zalophus californianus*) moved northward, and many northern fur seals (*Callorhinus ursinus*) may have emigrated from San Miguel Island to rookeries in the Bering Sea. Some animals are unable or unwilling to make such excursions, e.g., females with pups, territorial males, or populations in remote ranges. When fish disappeared from surface waters around the Galapagos Islands during the 1982–1983 El Niño, widespread starvation among the islands' fur seal population (*Arctocephalus galapagoensis*) soon followed.

Starving animals eventually die—some quickly, as would a pup deprived of milk or a sea otter overcome with hypothermia and exhaustion. Others die after a period of illness triggered by malnutrition and mediated by factors such as hypothermia, dehydration and electrolyte imbalance, hormonal disturbances, and infection by parasites and opportunistic pathogens. Some starving seal pups may ingest whatever is nearby—gravel, stones, or grass—and consequently die of an impacted stomach.

While a sudden shortage of prey may cause outright starvation of large numbers of animals, the more subtle effects of nutritional stress, including low productivity and decreased juvenile survival, may prove equally damaging to a population.

C. Direct Environmental Effects

Extreme weather conditions can take a toll on all age classes. Among Florida manatees (*Trichechus manatus latirostris*), intense or prolonged cold weather can cause mortality equivalent to 1.5–2% of the estimated population, with the greatest impact on juveniles. Storms hitting a crowded pinniped rookery at the peak of breeding season can be disastrous: pups become hypothermic, are battered on rocks or drowned, are separated from their mothers and starve, or become victims of adult aggression. Unusual ice conditions can be hazardous for cold-water species. Sea otters trapped out of water by heavy ice soon die of starvation, stress, and shock. An untimely freeze in polar waters can trap cetaceans in ice, where they may ultimately suffocate or starve. Ice-breeding seals can drown or be crushed in large numbers if their ice floes are broken up by storms or unseasonably warm temperatures.

D. Trauma

For most marine mammals, the risk of injury is continual, whether from natural sources, such as storms, predators, and

aggressive encounters, or human activities, such as fishery operations and recreational boating. For example, injuries are common on pinniped ROOKERIES, where pups are often trampled accidentally or attacked by adults, fall into gullies or crevices, or wash off unprotected beaches into pounding surf. Adults can be victims as well, as bulls compete for territories and females, and females compete for space.

Historically, commercial hunting had serious impacts on certain species or stocks of marine mammals. Today, more animals die in accidents; interaction with fishers is a leading cause of death and injury. Pelagic odontocetes die in purse seines and drift nets, coastal cetaceans and pinnipeds in gill net and trawl fisheries, and some river dolphins by fishing methods that employ electricity and explosives. Marine mammals thought to compete with commercial operations may be killed deliberately.

Entanglement in discarded net fragments, ropes, packing bands, monofilament line, and other debris is a risk for many species. The effects on populations vary; some suffer no appreciable impact, whereas others may be seriously threatened. For the individual, the problem is always serious. An animal that does not drown immediately may escape with fractures and internal injuries or may carry net fragments, ropes, or bands that increase drag, impede swimming ability, or become snagged. A seal pup growing into its packing-band "collar" will eventually die, either from suffocation or from deep cuts and infection.

Coastal dwellers are vulnerable to injury from a variety of human activities. For example, many dugongs (*Dugong dugon*) in Queensland (Australia) waters have died in shark nets set to protect public beaches. Right whales (*Eubalaena glacialis*) in the northwest Atlantic and manatees in Florida are injured or killed by collisions with vessels at rates that jeopardize these populations.

E. Predation

There are times in a marine mammal's life when it draws the attention of predators. Probably the easiest meal is a small, inexperienced animal that can be found in a particular place on schedule—criteria often met by young pinnipeds, whether on land or ice or at sea. As some examples, arctic foxes and polar bears break into ringed seal (*Pusa hispida*) birth lairs to take pups and, sometimes, their mothers. Steller sea lions (*Eumetopias jubata*) on the Pribilof Islands eat young northern fur seals that venture into the water, whereas southern sea lions (*Otaria flavescens*) raid South American fur seal (*Arctocephalus australis*) rookeries, driving away the adults and killing pups. Leopard seals (*Hydrurga leptonyx*) consume large numbers of crabeater seals (*Lobodon carcinophaga*) from the time the weaned pups leave the safety of the ice until they are several months old and large enough to escape attack. Killer whales (*Orcinus orca*) patrol some pinniped rookeries and may work vigorously to wash a seal into the water or even chase one onto the beach; other pods may attack baleen or sperm (*Physeter macrocephalus*) whales. Sharks pose a danger to many species or populations, including sea otters along California and Hawaiian monk seals (*Monachus schauinslandi*).

The impact of a predator can extend beyond its effect on the individual prey. Killing a pregnant mother with a dependent young removes not one, but three animals from the population. A female northern elephant seal (*Mirounga angustirostris*) may recover rapidly from a shark attack, as many seem to do, but may be less able to nurse her pup and is unlikely to mate in the compressed breeding season. In this case, a single attack, while only injuring the mother, may have cost the population two pups.

F. Parasites

Almost all marine mammals are infected by parasites by the time they are weaned or shortly afterward. Most of these parasites have evolved with their hosts and, under normal circumstances, cause little damage to otherwise healthy animals. Among these are the amphipods and copepods that eat bits of whale skin, seal lice that normally occur in small numbers and consume insignificant amounts of blood, and gastrointestinal helminths ("stomach worms"). Others are harmful enough to affect the well-being of individuals and even segments of a population. For pinnipeds, these include heartworms, some lungworms, and the hookworm *Uncinaria lucasi;* and in cetaceans, the nematodes *Crassicauda* spp. (in the mammary glands, cranial sinuses, and kidneys) and the trematodes *Nasitrema* spp. (in the cranial sinuses) and *Campula* spp. (in the liver and pancreas). However, any parasite can become destructive when the mechanisms that maintain the host–parasite balance break down, as they do when an animal is ill or starving. Prolonged stress, by retarding wound healing and destroying protective blood cells, can set the stage for a parasite to do the most harm. Debilitated animals that come ashore often suffer from serious parasitic conditions.

An animal's parasite burden can offer clues to its overall health and to changes in its environment, such as alterations in prey abundance. Seal lice are transmitted and proliferate on the animal only on land. A heavy infestation requires that the animal be on shore a long time, one sign that it may be ill. A fast-swimming odontocete offers barnacles little opportunity to attach; the presence of species such as *Lepas* sp. or *Xenobalanus* sp. on a dolphin's flukes or dorsal fin suggests that the animal has been moving unusually slowly, a common sign of illness. Differences in parasite fauna can indicate differences in feeding habits. For example, walruses feeding on benthic invertebrates have few if any nematodes in their stomachs, whereas those that eat fish have more. The relationship between diet and parasitism is predictable enough that variations in parasite burden may be used to distinguish populations and help identify segregated social groups.

G. Microorganisms

Microorganisms of all kinds—bacteria, fungi, and viruses among them — abound in the sea. Some are of the types found on land and in land dwellers; others, including certain *Vibrio* bacteria, thrive only in aquatic habitats. Like terrestrial mammals, marine mammals harbor many organisms that may be regarded as normal. Few of these are necessarily pathogenic, meaning they do not always cause infectious disease, but some are more threatening than others. The fine line between infection and infectious disease depends on both the virulence of the organism and the susceptibility of the host, which is determined

by the history of previous contact with the organism and the health of the animal's immune system. Age is also a factor. A very young animal may be protected by maternal antibodies, which protect it against organisms with which the mother has earlier come into contact. The pup or calf then develops its own active immune capability, which affords increasing protection until its declining years, when immune function once again weakens. For these reasons the very young and the very old are more likely to acquire infections. Of course, natural and human-related stresses may compromise immune function in animals of all ages.

1. Bacteria The nature and severity of bacterial infections can be influenced by the animal's behavior and age, and environmental conditions. Habitat also plays a determining role. A phocid pup born on clean sand is less likely to acquire a serious navel infection as it drags its unhealed umbilicus across the rookery than a pup born in areas fouled by feces, stagnant water, or decaying vegetation. For pups in fouled environments, bite wounds provide another route for infection by bacteria such as *Streptococcus* sp. and *Corynebacterium* sp.

Infections are sometimes predictable. During molt, seals slough skin and hair. In northern elephant seals the process is exaggerated and large sheets of epidermis are lost; many animals, particularly yearlings, come ashore with skin infections during this time. Weddell seals (*Leptonychotes weddellii*), which use their teeth to maintain breathing holes in ice, and sea otters that feed on hard-shelled prey grind down their teeth to such an extent that they develop abscesses and bone infection.

A few bacteria are inherently pathogenic. Leptospirosis, caused by the spirochete *Leptospira* sp., occurs in domestic and wild animals worldwide. Infection in California sea lions has caused kidney disease in juvenile and subadult males and abortion in females. *Mycobacteria* of the complex associated with tuberculosis (*M. bovis, M. tuberculosis*) are of growing concern. An outbreak in a captive colony of New Zealand fur seals (*Arctocephalus forsteri*) and Australian sea lions (*Neophoca cinerea*) was the first indication that this disease, subsequently found in free-ranging pinnipeds from Australia, New Zealand, and South America, may be endemic in certain wild populations. Bacteria representing an apparently new strain or species of *Brucella* have been found in a number of marine mammal species, primarily from the North Atlantic and Artic oceans. Although implications for marine mammals are uncertain, infection in terrestrial mammals commonly leads to abortion.

The impact of an infection on animal health depends on the organ involved. An isolated abscess in a muscle may have little apparent effect, while a similar infection in the lung can be seriously debilitating. Bacterial pneumonia, often associated with lungworms, can be serious enough to cause death or stranding. Infections that increase metabolic stress or disturb water and electrolyte balance, such as gastroenteritis with vomiting and diarrhea, can be rapidly fatal.

2. Mycotic Infections Fungal organisms rank low on the list of primary pathogens of marine mammals. They tend to infect animals that are weakened, perhaps by other chronic debilitating disease. Infections are usually acquired from soil-, dust-, or water-borne fungi and enter the body through the skin or by inhalation. A wide variety of organisms have been isolated from marine mammals, including *Candida, Aspergillus, Coccidioides, Blastomyces, Histoplasma, Fusarium, Nocardia,* and *Loboa.*

Lobomycosis, a skin infection caused by the yeast *Loboa loboi,* has an unusual range. The disease occurs in free-ranging and captive bottlenose dolphins from Florida waters and in tucuxi (*Sotalia fluviatilis*) in South America. Curiously, other than in cetaceans, Lobo's disease occurs only in people inhabiting low-lying wetlands of Central and South America.

Coccidioidomycosis, generally a rather innocuous fungal disease of domestic animals, was until recently considered rare in marine mammals. What might be described as outbreaks of infection in California sea lions and sea otters between 1986 and 1994 coincided with a rise in human infections, attributed to environmental conditions that favored the growth of *Coccidioides imitis.*

3. Viruses First recognized in the late 1960s, viral infections in marine mammals have emerged as the greatest cause of large-scale mortality. To spread rapidly, a virus requires a naive host population of a minimum density, which can arise either through population growth or changes in social behavior. Once infected, a migrating or wandering animal may carry the virus to new habitats.

More than 450 harbor seals (*Phoca vitulina*) died in a disease outbreak in New England during the winter of 1979–1980. The cause was found to be an influenza virus of avian origin that had infected the seals, probably as they hauled out on the rookeries of Cape Cod. Seals of all ages developed pneumonia, which forced many out of the water and onto crowded beaches where the virus could spread easily from seal to seal by aerosol transmission. This was the first marine mammal die-off of demonstrated viral origin.

More devastating were the outbreaks of morbillivirus infection that swept through populations of pinnipeds and cetaceans in Europe in the late 1980s and early 1990s. The series of epidemics began with the outbreak of canine distemper virus infection that killed thousands of Baikal seals (*Pusa sibirica*) in 1987–1988. A related morbillivirus (phocine distemper virus) killed about 17,000 harbor seals and a few hundred gray seals (*Halichoerus grypus*) in Europe in 1988–1989. Between 1990 and 1992, another morbillivirus (dolphin morbillivirus) killed thousands of striped dolphins (*Stenella coeruleoalba*) in the Mediterranean Sea. Infected animals developed pneumonia, fever, and neurological disorders associated with encephalitis. The immunosuppressive effect of these viruses led to the development of secondary, often overwhelming, infections by bacteria, fungi, and other viruses.

Studies since 1988 indicate that morbillivirus infection, often without recognized illness, is common in many marine mammal species and may have occurred in many North Atlantic marine mammal populations prior to the European epidemics. The outbreaks in European seals may have been the result of viruses, perhaps introduced by infected migrating harp seals (*Pagophilus groenlandicus*) entering naive popula-

tions that were dense enough to support transmission. The epidemic in striped dolphins showed that the brief periods during which dolphins surface in unison, and perhaps some behaviors underwater, may be enough for a viral infection to spread rapidly from one cetacean to another.

The morbillivirus outbreaks offered clues to past events, such as the unexplained die-off of crabeater seals along the Antarctic Peninsula in 1955. Serological studies have tentatively linked that event to morbillivirus, perhaps transmitted from sled dogs. The 1990–1992 epizootic in striped dolphins suggested that morbillivirus infection, which was observed in some bottlenose dolphin carcasses examined during a die-off along the U.S. mid-Atlantic coast in 1987–1988, may have played an important role in that event. Indeed, retrospective studies present strong evidence that morbillivirus outbreaks have occurred sporadically in coastal bottlenose dolphin populations along the southeast United States since the early 1980s.

A number of viruses are associated with less serious health conditions. Poxviruses, for example, commonly cause skin lesions in pinnipeds and cetaceans; pox disease often appears in conjunction with other illnesses or stress. Herpesviruses are also common in cetaceans and pinnipeds and, although not usually serious, have been associated with fatal pneumonia and hepatitis in harbor seal pups and encephalitis in one stranded harbor porpoise (*Phocoena phocoena*). Calicivirus infection is common among many marine mammals in the North Pacific; clinical disease, which in California sea lions appears as vesicular lesions on the skin of the flippers and mouth, may accompany stress, debilitation, or other infectious conditions, particularly leptospirosis.

Numerous other viruses have been found in marine mammals, many without recognized effect. The list will undoubtedly grow, as will our understanding of their significance, as investigators become more alert to the presence and effects of viruses, and as techniques to isolate and identify them continue to improve.

H. Metabolic Disorders

Metabolic processes sometimes break down. Environmental and biological factors that control hormonal regulation may fail to become synchronized, demands on the system may be overtaxing, and organ function, under the influence of a genetic clock, deteriorates with age and illness. The animal becomes incapacitated, but the underlying reason may be evident only at the molecular level and therefore is difficult to detect. Not surprisingly, little is known about metabolic diseases in aquatic species.

In marine mammals, salt and water balance is regulated in part by the adrenal gland. Aldosterone, secreted from the adrenal cortex, normally acts on the kidney tubules to conserve sodium and thereby maintain salt and water balance. In pinnipeds, conditions that lead to prolonged stress, including molt, malnutrition, and disease, can exhaust the gland of aldosterone, resulting in loss of sodium from the body, a condition known as hyponatremia. Affected animals lose their appetite, become weak and disoriented, and eventually die. Aldosterone features in the stress response of cetaceans as well, only it does not become depleted and the animals do not develop hyponatremia. Quite the contrary, in severe stress following a stranding, a cetacean may eventually begin to drink seawater and develop a condition of salt overload, or fatal hypernatremia, that dehydrates tissues, including the brain.

I. Tumors

Marine mammals develop all kinds of tumors, from benign lipomas that are little more than fatty lumps in the great whales to highly malignant lymphomas in young seals. As studies on marine mammals have increased, so have the numbers and variety of tumors reported.

In other mammals, tumors have been associated with a variety of factors, including hormones, viruses, congenital and hereditary defects, and physical and chemical agents. Establishing these links has generally required years of investigation on large populations and a systematic consideration and elimination of other possible contributors. These requirements are difficult to meet in marine mammal studies. Hence it may never be possible to prove the assumption that environmental contaminants are responsible for the unusually high incidence of tumors in beluga whales (*Delphinapterus leucas*) in the St. Lawrence River, however tempting the link. One study may be more fruitful. Recent investigations suggest that a virus may be responsible for the high incidence of urogenital tract carcinomas observed in stranded California sea lions.

J. Biotoxins

Certain species of dinoflagellates and algae produce toxins that accumulate in some fishes and invertebrates, eventually poisoning animals further up the food chain. Prior to the late 1980s, such biotoxins had been suspected, but not proven, to play a role in several events involving marine mammals. For example, ciguatoxin, a dinoflagellate neurotoxin, was implicated in the illness of about 50 Hawaiian monk seals on Laysan Island in 1978; the weak, lethargic seals eventually became emaciated, suffered from severe parasitic infections, and died. Fourteen humpback whales (*Megaptera novaeangliae*) died in Cape Cod Bay (Massachusetts) in the winter of 1987 after eating mackerel containing saxitoxin, a neurotoxin that even in minute quantities causes respiratory paralysis.

In 1988, brevetoxin, a neurotoxin produced by the dinoflagellate *Gymnodinium brevis*, the organism responsible for "red tides," was implicated in a die-off of several hundred Atlantic bottlenose dolphins along the U.S. mid-Atlantic coast. Although the extent of the role of brevetoxin in that event remains unclear, this toxin has since been linked to the mortality of bottlenose dolphins and Florida manatees in the Gulf of Mexico, where red tides are a recognized threat to the manatee population. Red tide outbreaks in southwest Florida in 1983 and 1996 killed about 37 and 155 manatees, respectively; these animals died from the acute and chronic effects of ingestion of toxins and inhalation of toxic brevetoxin aerosols.

In 1998, California sea lions along central California were poisoned by domoic acid, a neurotoxin produced by the diatom *Pseudo-nitzschia* sp. It caused convulsions, loss of coordination, and vomiting. While more than half of the stranded sea lions died, others were brought to rehabilitation centers and recovered. The similarity of this event to previous episodes in

California sea lions and northern fur seals in the same area suggests that blooms of this diatom could have an effect on discrete populations.

Marine mammals may be particularly susceptible to the neurological action of biotoxins for several reasons: (1) during a dive, blood is channeled to the heart and brain, effectively concentrating toxin there, and away from the liver and kidney where it is normally metabolized and excreted; (2) a short period of disorientation may be enough to impede an animal's ability to reach the surface for a vital breath of air; and (3) animals that remain in the area of a bloom may be subject to the cumulative effects of toxins ingested or toxic aerosols inhaled over a period of days or weeks.

K. Strandings

Stranding is defined as having run aground. The term here describes any marine mammal that falters ashore ill, weak, or simply lost. Most animals die at sea and only a fraction reach the shore. Those that do generally reflect the age, sex, and density of the animals in the area. Any change in the expected profile may be a signal that something unusual is happening, such as a toxic event, a disease outbreak, intensive local fisheries operations, or a change in prey abundance.

Pinnipeds and, to a lesser extent, sea otters normally spend time ashore, but only those unwilling or unable to return to sea are considered stranded. These would include pups that become separated from their mothers prematurely or fail to make a successful transition to independence. Most strand in the vicinity of the rookery, although some may stray far from their normal range. Other than in spring, when pups come ashore in large numbers, and in the absence of unusual events such as disease outbreaks, pinnipeds normally strand alone.

Many cetaceans that strand singly are debilitated in some way. Some offshore species strand with characteristic illnesses. Short-beaked common dolphins (*Delphinus delphis*) along California, for example, develop parasite-related brain damage, and dwarf (*Kogia sima*) and pygmy (*K. breviceps*) sperm whales along the U.S. Atlantic and Gulf coasts come ashore with impacted stomachs after ingesting plastic bags and other debris.

A mass STRANDING can be defined as two or more cetaceans, excluding mother–calf pairs, that come ashore alive at the same time and place. Highly social species of odontocetes [e.g., sperm whales, pilot whales (*Globicephala* sp.), false killer whales (*Pseudorca crassidens*), and Atlantic white-sided dolphins (*Lagenorhynchus acutus*)] are the most probable victims. Many explanations have been proposed, but the only common link seems to be the strong social nature of these species. Once one or more animals strand, for whatever reason, the compulsion to stay together brings others ashore.

A stranded animal's chances of surviving diminish by the hour. Sea otters and pinnipeds risk hyperthermia, injury from terrestrial predators, and starvation. A cetacean has difficulty shedding heat even in cold weather, and a larger one may develop respiratory fatigue and distress as the chest cavity is compressed under its own weight. Within a few hours of stranding, some cetaceans begin to show evidence of shock or vascular collapse, which leads to poor circulation and impaired organ function. The onset of shock further impairs the whale's health and may prevent its recovery, even if it is returned to sea in what appears to be good condition.

L. Habitat Alteration and Disturbance

Marine mammals have adapted over millions of years to the often harsh conditions of the marine environment. In the past few decades, environmental change has proceeded at a rate far exceeding the slow pace of evolution. How well can marine mammals cope with urban and industrial wastes, coastal dredging, undersea construction, vessel traffic, and NOISE? As with other influences on health, the effects—if they can be determined with any degree of certainty—will vary depending on species, sex, age, individual tolerance and behavior, and a host of other factors.

1. Contaminants As long-lived predators at the top of the food chain, marine mammals accumulate contaminants in their tissues. The concentrations and distribution within tissues depend on the type of contaminant and the animal's age and sex. Because most compounds accumulate over time, older animals generally have more. Fat-soluble substances, such as the persistent DDT, PCBs, and related organochlorines, reside in fatty tissues like BLUBBER, liver, and brain; heavy metals are found in liver, but also distribute in muscle, kidney, and other organs. Pregnant and lactating females produce milk using stored fat and the chlorinated hydrocarbons that came with it. While the suckling offspring loads up with contaminated milk, the female depletes her stores and, over time, has proportionally less and less than a male of equivalent size and age. What concentrations are eventually harmful to the male, to the female as she loads and unloads the compounds with each reproductive cycle, or to the pup that may be even more sensitive? What happens to an animal of any age that becomes ill, stops eating, and uses stored fat, which releases these potentially toxic compounds into the bloodstream where, in increasingly higher concentrations, they are carried to other tissues?

As yet, no clear picture emerges, and broad differences in effects among species continue to invite speculation. In Baltic seals, organochlorine levels seem to be associated with low pregnancy rates and uterine pathology, as well as a disease complex characterized by metabolic disorders, hormonal imbalance, cranial bone lesions, and reduced immune function. The nature of marine mammals and the environment they live in pose serious challenges to conducting investigations that require tight controls and sophisticated technology. Meanwhile we rely on empirical observations and preliminary studies that offer clues. Experimental studies are, nevertheless, yielding data supporting the link between exposure to certain chlorinated hydrocarbons and impaired immune function in at least some species. A better understanding of the influence of contaminants on susceptibility to infectious disease will likely emerge from continued laboratory investigations.

2. Oil Spills Oil spills are visible and unsightly, and sea otters show us how quickly fatal one can be. The 1989 *Exxon Valdez* incident in Prince William Sound, Alaska, was dramatic and beyond the proportion of other spills that have affected marine mammals. Until that event, relatively few marine mammals were known to have been killed by oil.

The impact of spilled oil depends on its composition, environmental conditions, and the species involved. During the first few hours or days after a spill, low molecular weight fractions are the most acutely toxic. They irritate and harm tissues, especially the sensitive membranes of the eyes and mouth; they can be ingested during feeding or when a fouled animal is grooming; or their vapors can be inhaled and damage the lungs. Light fractions are absorbed into the blood where they can attack the liver, nervous system, and blood-forming tissues. Sea otters caught in the *Exxon Valdez* spill showed signs of lethargy, respiratory distress, and diarrhea, and evidence of liver damage, kidney failure, and endocrine imbalance. Between 3500 and 5500 otters were estimated to have died. Three hundred harbor seals also died; many had brain lesions, probably resulting from inhalation of vapors from fresh oil.

Evaporation of the low molecular weight fractions leaves heavy residues and thick, foamy emulsions called mousse. By sticking tenaciously to vital insulating hairs of sea otters, polar bears, and some species of pinnipeds (e.g., fur seals), these substances can destroy the animals' ability to maintain thermal balance. The sea otter is especially vulnerable because its entire existence depends on a well-groomed hair coat.

Except for the sea otter, there is no real evidence that marine mammals ingest much oil. They may be able to deal with small quantities of fresh oil or that premetabolized by their prey because they, like other mammals, have the liver enzymes required to metabolize and excrete such compounds.

3. Ingesting Debris Some marine mammals become entangled in fishing nets and debris. Others are as likely to ingest various types of discarded items and trash that enter the oceans—mostly from land sources—at a rate of over 6 million metric tons each year. Florida manatees, for example, face increasing risks of ingesting fishing line and hooks, wire, plastic bags, and other rubbish trapped in floating mats of vegetation. Some cetaceans, including pygmy sperm whales and some beaked whales, share a tendency to ingest plastics. Some items are small and inconsequential; others may block or perforate the gastrointestinal tract, leading to slow starvation or sudden death.

4. Other Disturbing Influences Habitat degradation can take many other forms: prey depletion, nutrient enrichment that leads to toxic algal blooms, underwater drilling noise, heavy vessel traffic, and disturbance of pupping or calving areas, to name a few. The potential range of effects is immense. A boat traveling through one of Florida's canals might collide with a manatee and kill it or raise the turbidity and inhibit the growth of water plants that are vital to its diet. Individuals might respond to food shortage or disturbance by moving to marginally suitable environments, e.g., northward to colder waters, where risks of cold stress are increased. A harp seal wandering far from its normal range following a collapse of prey stocks might introduce a pathogenic virus into a susceptible population. A sudden, unusual noise near a crowded pinniped rookery might cause animals to panic and stampede, trampling or abandoning their young.

Other reactions to disturbances may be more subtle. In terrestrial mammals, intense noise alone can cause disorders ranging from long-term hearing loss to physiological stress, hypertension, hormonal imbalance, and lowered resistance to disease. Such effects are nearly impossible to document in marine mammals. It can be assumed that animals are generally unlikely to become habituated physiologically to any disturbances that are associated with threatening situations.

III. The Future

We have a growing understanding of the range of pathogens in the sea and the mechanisms marine mammals have evolved to counter their effects. Except for the inevitable rise of new disease agents and the discovery of old ones, the elements of this endless tug-of-war are unlikely to change. Here, humans are only observers. However, the expression of illness, whether in an individual or a population, is governed by dynamic environmental conditions, and some of these are within our ability to control. Responsible stewardship of the oceans and coastal waters may, by that reckoning, be the key to marine mammal health in the future.

Hearing

J. G. M. Thewissen
Northeastern Ohio Universities College of Medicine, Rootstown

Vision and smell are senses that lose much of their usefulness in the watery medium where marine mammals live. As a result, hearing is generally more important in marine mammals than it is in land mammals. Hearing is a matter of life and death in odontocete cetaceans because they echolocate: they emit high-frequency sounds and determine the shape of their surroundings on the basis of the reflections of those sounds. Echolocation requires a sophisticated sound production organ (located in the nose) and sophisticated hearing. However, the physics of waterborne sound are very different than airborne sound (for a summary, see Denny, 1993). These two factors combined, the importance of well-developed hearing and the differences between sound in air and in water, have caused the organ of hearing to undergo a number of important changes. Some of these changes are well understood and occur across vertebrates that straddle the water–land boundary (Fay and Popper, 1985; Lombard and Hetherington, 1993), whereas others are the focus of intense investigations and controversies.

Sadly, sound is also important to marine mammals in another way. Dolphins may die if their middle ear is infected by nematodes because they are unable to detect prey. Loud sounds similarly may deprive whales and dolphins of their auditory abilities and may be a source of mortality.

I. Anatomy

The organ of hearing of all mammals consists of three parts: the external ear, the middle ear, and the inner ear (Fig. 1A). In land mammals, the external ear is basically an air-filled tube (the external auditory meatus) attached to a structure that funnels sound (the pinna). The tube ends medially at the tympanic membrane (eardrum), suspended by a bone called the ectotympanic. This tube fills with water when an animal enters the water. Medial to the tympanic membrane is the middle ear. It is an air-filled cavity, containing three small bones (ear ossicles) with two muscles attached to them. The bones are called malleus (hammer), incus (anvil), and stapes (stirrup) and form a chain contacting the tympanic membrane on one side (malleus) and the inner ear on the other (stapes). The middle ear cavity is air filled and is connected to the pharynx by means of the auditory tube (Eustachian tube), it does not fill with water when an animal is submerged. The inner ear is encased in a thick bone cover (the petrosal bone), it consists of a series of cavities in this bone that are filled with two kinds of fluids (perilymph and endolymph). For hearing, the most important of these cavities has the shape of a snail shell and is called the cochlea. It houses a long, hollow, rolled-up organ that mainly consists of three ducts that run the full extent of the cochlea. The scala vestibuli starts at the vestibule of the inner ear (where the oval window opens) and extends to the apex of the cochlea. There the scala vestibuli is connected to a second duct, the scala tympani, which extends from the apex to the base of the cochlea and ends at the round window. Both of these ducts are filled with perilymph. A third duct, the cochlear duct, is filled with endolymph and extends the length of the cochlea sandwiched between the two scalae. The floor of the cochlear duct is the basilar membrane in which a long row of neurons is implanted. The neurons of the organ of Corti are part of cranial nerve VIII (vestibulo-cochlear nerve) and pass auditory information to the brain.

Sea otters and polar bears have ears that are very similar to those of their land relatives. Pinnipeds and sirenians have ears that are, in gross features, similar to those of land mammals, although there are some important modifications (such as the absence of the pinna in phocids and sirenians). In cetaceans, the middle and inner ears still retain clearly recognizable anatomical features of land mammals, but the sound pathway through the external ear has been completely modified.

The cetacean external ear (Fig. 1B) retains an external auditory meatus supported by cartilages, but the duct is narrow to the point where it is not patent and there is no pinna. Instead, the cetacean mandible is involved in sound reception. The posterior part of the odontocete mandible, behind the teeth, has a thin lateral wall (sometimes called the pan bone). This part of the mandible is medially concave and houses a large fat pad. This fat pad extends anteriorly into the mandibular foramen, which is enormous, and continues into the area ventral to the teeth. Posteriorly, this fat pad touches the lateral bony wall of the ectotympanic. This wall is extremely thin, and the attachment area for the tympanic membrane in cetaceans is reduced greatly. The ectotympanic has a joint (syndesmosis) with the petrosal (also called periotic), but the two bones combined have very limited connections to the remainder of the skull, unlike most mammals. In delphinids, this connection is limited to one small piece of cartilage; in all other odontocetes, the tympano-periotic has a larger connection; and in mysticetes,

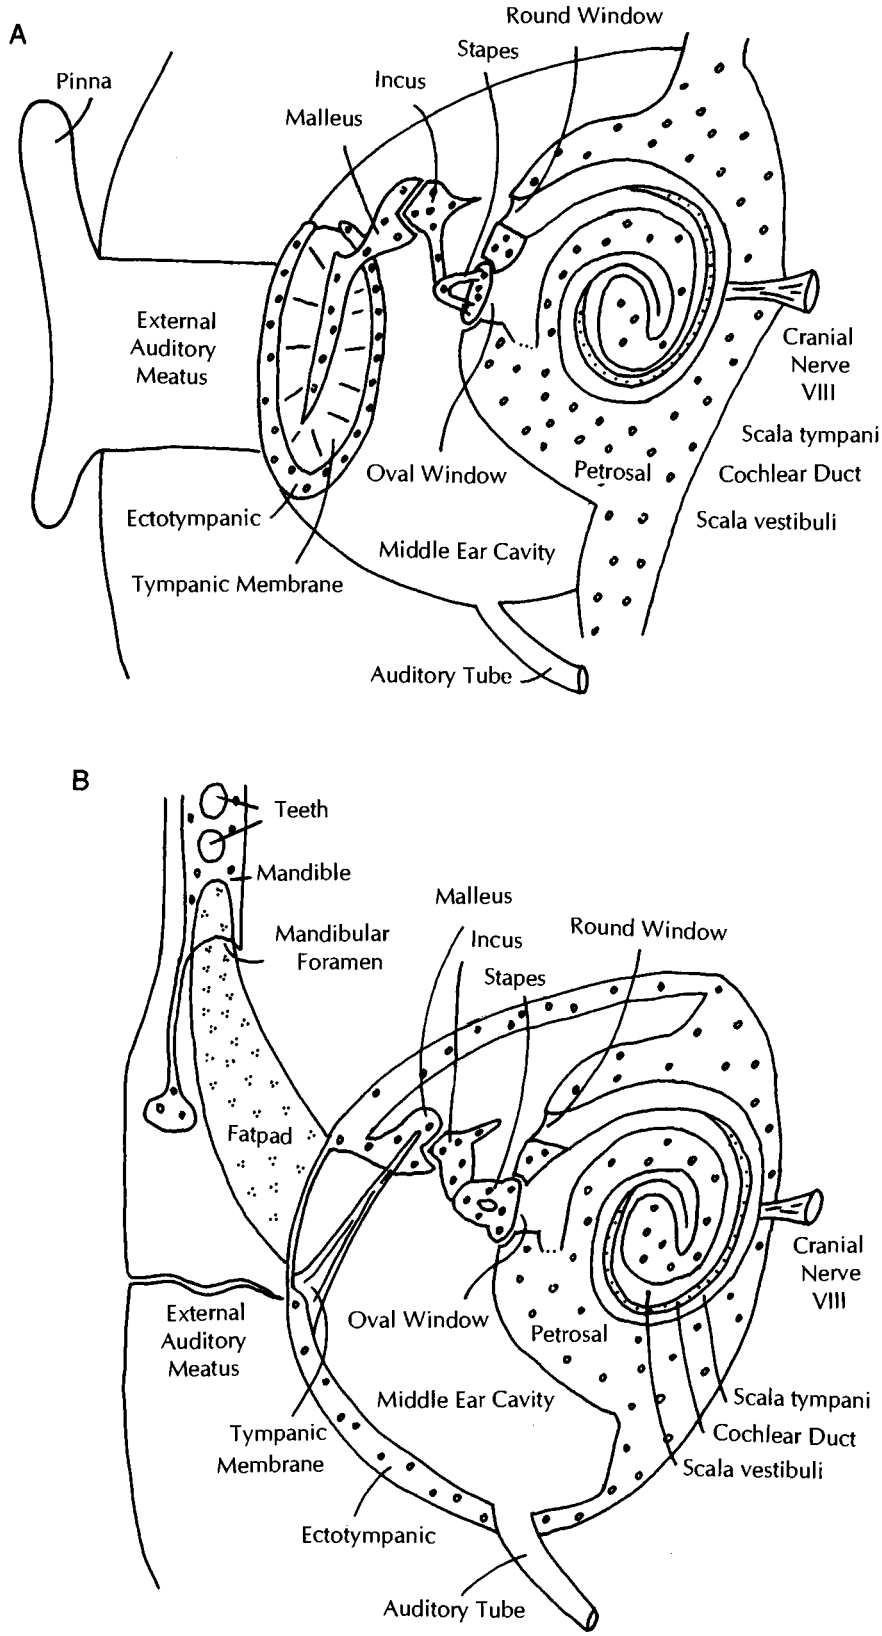

Figure 1 *Diagram of the ear in a generalized mammal (A) and a cetacean (B). Pinnipeds and sirenians have auditory systems similar to A.*

the complex is integrated into the skull similar to land mammals. The entire tympano-periotic of odontocetes is surrounded by spongy tissue that is filled with air spaces.

The tympanic membrane of odontocetes (often called tympanic ligament) is not the flat, more or less circular structure of land mammals. Instead, it is a strand of elastic tissue attaching to a small circular ectotympanic ring and then narrowing into an elastic tissue strap that attaches to the malleus (not unlike a folded-in umbrella). A similar structure occurs in mysticetes, but here an additional piece of the tympanic membrane forms a large, blunt protrusion into the external auditory meatus, often referred to as the glove finger. The ear ossicles of all cetaceans are highly pachyosteosclerotic and very different in shape from those of land mammals (Fig. 2). All cetaceans, except *Kogia* spp., have ossicles that are similar in overall form, and many of these morphological traits go back to the earliest Eocene cetaceans. In mysticetes, the stapes is much longer than in odontocetes. In *Kogia* spp., the malleus is fused to the ectotympanic in a unique shape. Sirenians and phocid pinnipeds (but not otariids and odobenids) also have pachyosteosclerotic ossicles, but they retain the shapes of the ossicles of their land relatives.

Middle ear muscles of cetaceans are reduced greatly. Suspended in the middle ear cavity is a plexus of veins and arteries collateral to the internal carotid artery. The internal ear of cetaceans is similar to that of land mammals, except that its proportions are different and that there are great differences among cetaceans (see Ketten, 1992).

The organ of balance in mammals consists mainly of three canals that run in the petrosal in a circular fashion. They are located immediately posterior to the cochlea and are also filled with perilymph and are innervated by cranial nerve VIII. Whereas the size of the cochlea scales closely to body size in mammals, the semicircular canals scale with body size in all mammals except cetaceans. In all modern cetaceans, the semicircular canals are much smaller than would be expected for their body size.

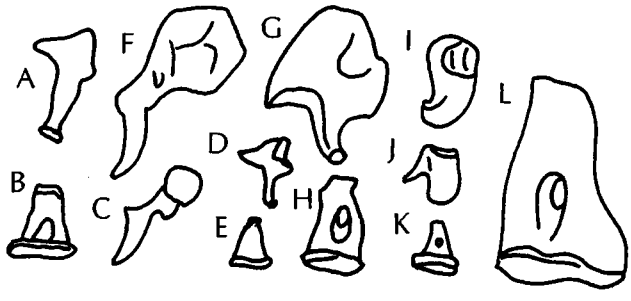

Figure 2 *Auditory ossicles of marine mammals; all are left ossicles in similar views and to scale. (A and B)* Ursus maritimus, *incus, and stapes. (C–E)* Eumetopias jubatus, *malleus, incus, and stapes. (F–H)* Lobodon carcinophaga, *malleus, incus, and stapes. (I–K)* Delphinus *sp., malleus, incus, and stapes. (L)* Dugong dugon, *stapes. A–E represent more or less primitive morphologies for mammals, whereas all others are modified to various degrees. Modified after Doran (1876).*

II. Functional Morphology

Sound consists of waves of vibrations of the molecules that constitute air or water (in the case of marine mammals). The ear amplifies the sounds and translates them into neural impulses. Left and right ears together also gather directional information.

The pathway of sound in pinnipeds and sirenians is not significantly different from that of land mammals (Fig. 1A). Sound is funneled to the tympanic membrane, which starts oscillations of this membrane. These vibrations are transmitted to the manubrium of the malleus, which leans against the tympanic membrane. The vibrations are then passed along the chain of ossicles, eventually causing the foot plate of the stapes to pump in and out of the oval window. Ossicles function as an amplifier in two ways. First, sound energy that arrives at the tympanic membrane is concentrated on the much smaller area of the foot plate of the stapes. Second, the amplitude of the vibrations is enlarged by a lever-arm system: small vibrations of the long in-lever (the manubrium of the malleus) are transmitted to a much shorter out-lever (the crus breve of the incus). These two mechanisms result in higher pressures at the stapedial foot plate then at the tympanic membrane. Higher pressures are necessary to start vibrations in the dense fluid of the inner ear (perilymph). As such, the middle ear matches the acoustic properties of the air in the external auditory meatus to those of the perilyph of the inner ear and is technically often described as an impedance matcher.

The vibrations that are caused by the stapes set up standing waves in the fluids of the scala vestibuli. The standing waves are transmitted to the endolymph in the cochlear duct and these stimulate the hair cells on the basilar membrane. The hair cells fire electric impulses that are carried to the brain. Different frequencies are perceived by the stimulation of different sections of the basilar membrane: specific hair cells are receptors for specific frequencies. Low frequencies are perceived near the apex of the cochlea, whereas high frequencies are perceived near the base of the cochlea.

The inner ear of cetaceans functions in the same way as that of land mammals, but the external and middle ears are very different. The area that is most sound sensitive on a dolphin's head is not the ear, but the skin over the lower jaw (Fig. 3). From here, sounds are transmitted through the bone of the mandible and through the fat pad to the bony wall of the middle ear. What happens here is controversial, but the best functional middle ear model for odontocetes has been proposed by Hemilä *et al.* (1999). A model in which the entire ectotympano-ossicle complex rotates around an axis through the malleus correlates well with experimental data for hearing at low frequencies. A model in which four bony units (malleo-incus, stapes, ectotympanic, and periotic) are connected by springs that mainly allow translations predicts higher frequency data well.

The cetacean middle ear (and that of some pinnipeds as well) also contains a plexus of arteries and veins. It is possible that this plexus represents an adaptation for deep diving and that it can be inflated to reduce the airspace in the middle ear cavity, thus increasing its pressure to match ambient pressure.

The inner ear of cetaceans is structurally and functionally similar to that of land mammals, but differs in the details. Ket-

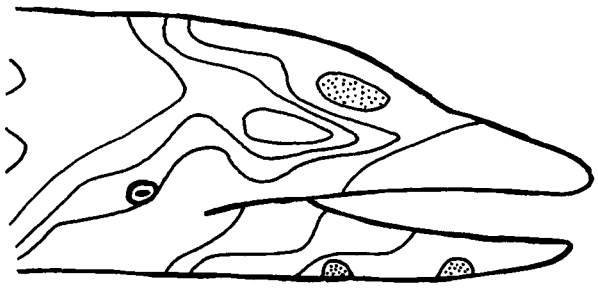

Figure 3 *One of the earliest determinations of sound sensitivity of the dolphin head. A hydrophone producing a sound of 65 kHz was pressed on different areas of this* Stenella attenuata, *resulting in this map of areas with similar sensitivities. The greatest sensitivity to sound (stippled areas) was on the lower jaw, with a lesser maximum on the forehead. The external auditory meatus (not shown, but located posterior to the eye) does not represent a maximum of sound sensitivity. Redrawn after Bullock et al. (1968). (See also Fig. 3, Echolocation).*

ten (1992) distinguished two types of odontocete cochleas mainly on the basis of the shape and size of the basilar membrane. The differences are related to specific frequency ranges. Mysticetes have a different cochlea that is adapted to low-frequency sound reception.

The middle ear of pinnipeds and sirenians contains the same elements as in land mammals, but the ossicles of phocids and sirenians are greatly enlarged. This pachyosteosclerosis does not occur in odobenids and otariids.

III. Measures of Hearing

Hearing can be described by a number of quantifiable variables. Components of hearing include localizing ability (directional hearing), spatial resolution, and frequency discrimination (for a review, see Wartzok and Ketten, 1999). One of the most useful measures of hearing is the minimum audible intensity, which varies as a function of the frequency of the sound. The resulting plot is called an audiogram (Fig. 4). Sound intensities in these plots are usually indicated in decibels (dB), a relative and nonlinear measure that requires a reference intensity. To make matters even more complicated, it is customary to use different reference pressures for in-air and underwater measurements. Frequency is measured in hertz (Hz). The organ of hearing operates over five orders of magnitude, and frequency is therefore usually plotted on a logarithmic scale. Although straightforward to understand and display, determining audiograms and other

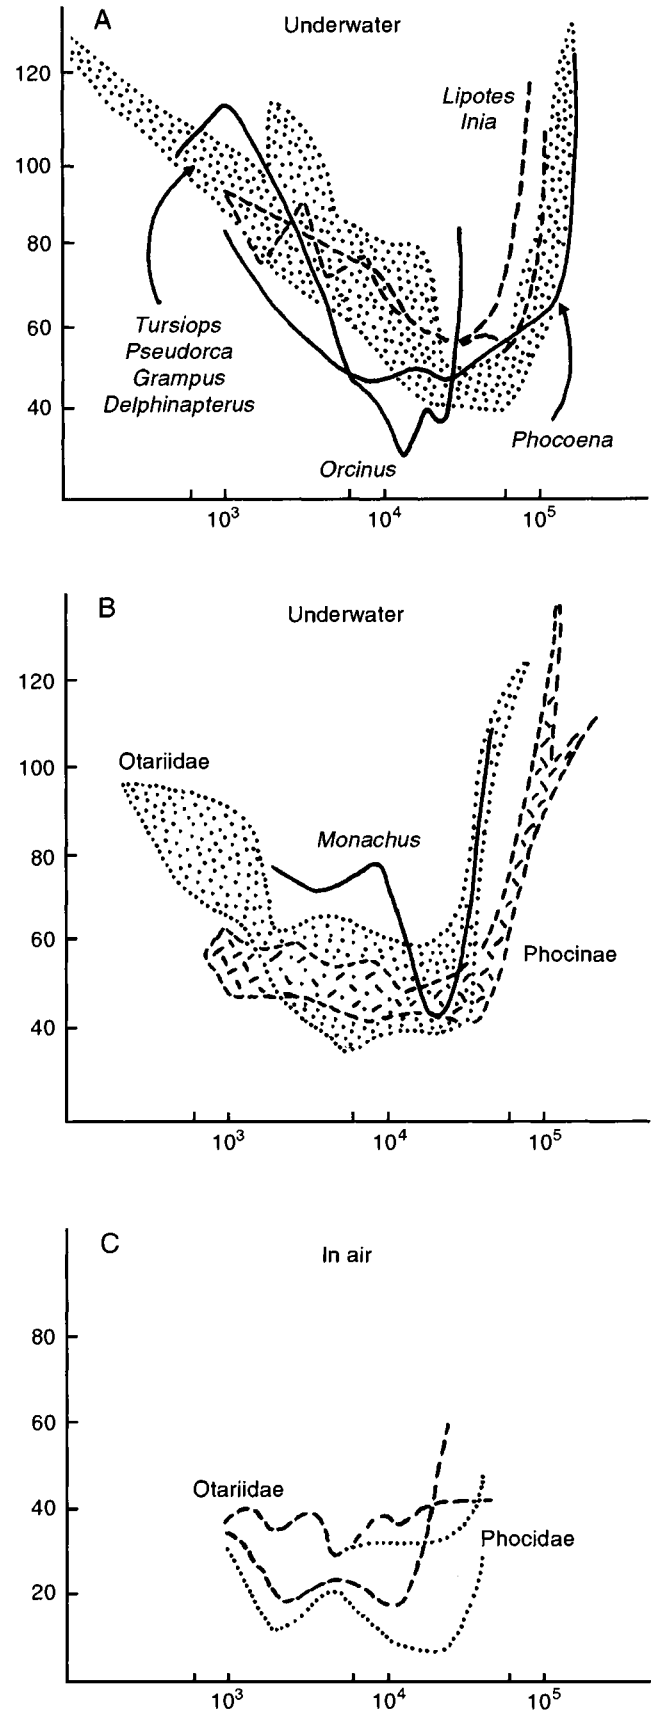

Figure 4 *Audiograms of cetaceans (A) and pinnipeds (B) for waterborne sound; (C) for airborne sound. The X axis is frequency on a logarithmic scale in Hz. The Y axis represents pressure level at minimum audible sound (in dB, with 1 A as a reference for waterborne sound, and SPL for airborne sound). Hatched areas represent envelopes containing data for multiple specimens. The source for A and B is Wartzok and Ketten (1999) and for C is Fay (1988).*

measures of hearing is usually technically very hard, and results are partly dependent on factors outside of the control of the investigator (such as the motivation of the investigated animal if the audiogram is based on behavioral responses). For cetaceans, audiograms are only available for five families of odontocetes, four of which are represented by a single individual. Sample sizes are thus small, although some generalizations can be made.

The delphinids *Tursiops* spp., *Pseudorca crassidens*, and *Grampus griseus* and the monodontid, *Delphinapterus leucas* show audiograms that have a fairly typical shape. For low frequencies (left side of Fig. 4A), minimum audible intensity decreases with increasing frequency. Auditory sensitivity peaks between 11,000 and 18,000 Hz (lowest part of the data envelope), and at higher frequencies, sensitivity is reduced. The peak in odontocete hearing is well above the frequency of best hearing in humans (2000 Hz, but variable with age) as a result of the use of high frequencies in echolocation. Optimal hearing in *Phocoena* spp. and *Orcinus orca* occurs at frequencies that are lower than for the delphinoids mentioned earlier. For *Phocoena*, the lower optimal frequency has been related to its particular cochlear shape (Ketten, 1992). *Orcinus* is a delphinid of large body size, and, in general, ears of animals with larger body sizes are tuned to lower frequencies, which is related to their longer cochlear duct (the size of the cochlea scales with body weight). The lower optimal frequency in *Orcinus* can also be understood in another way. The size of objects to be discerned poses limits on the echolocation frequencies that can be used in such a way that, to discern smaller objects, higher echolocation frequencies need to be used. *Orcinus* hunts larger prey than other delphinids and hence can use lower frequency signals. The freshwater dolphins *Inia geoffrensis* and *Lipotes vexillifer* have overall curves that are similar to those of the generalized delphinids but are less sensitive than in the generalized group. Several explanations are possible; one of them holds that these species hunt in small-scale river environments, where only prey close to the predator can be pursued. In open sea settings, prey that is further away can be pursued successfully. Echolocation signals and echos attenuate with distance, and hence a closer object can be discerned with a receiver that is less sensitive.

Underwater audiograms differ among different pinnipeds (Fig. 4B). Significantly, phocines (*Phoca* spp., *Pusa* spp., and *Pagophilus groenlandicus*) consistently show better high-frequency sensitivity than otariids. The only monachine (*Monachus* spp.) for which an audiogram is available lacks the high-frequency sensitivity of the other phocids and is similar to the otariids in this respect. The differences between phocines and otariines do not occur in in-air audiograms (Fig. 4C), suggesting that pinnipeds, means of sound transmission differ in air and in water. The curious bimodal sensitivity peak in two individuals also remains to be explained and may be the result of the compromise that the pinniped ear represents, a compromise between hearing in air and in water.

Hippopotamus

JOHN GATESY
University of Wyoming, Laramie

Hippopotamuses are stocky, large, semiaquatic, hoofed mammals that are classified as members of the family Hippopotamidae (order Artiodactyla). There are two extant species. The endangered pygmy hippopotamus, *Choeropsis liberiensis*, inhabits the dense forests of western Africa. The much larger common hippopotamus, *Hippopotamus amphibius* (see Fig. 1), has a broader geographic range that includes many of the water systems of sub-Saharan Africa.

I. Anatomy and Behavior

Due to its secretive nature, field observations of the pygmy hippopotamus are rare, so little is known of the ecology and natural history of this species. The animal is knockwurst-shaped, weighs approximately 150–250 kg, is basically hairless, and has a broad muzzle with prominent canine TEETH. *Choeropsis* is thought to be more solitary and less aquatic than *Hippopotamus*.

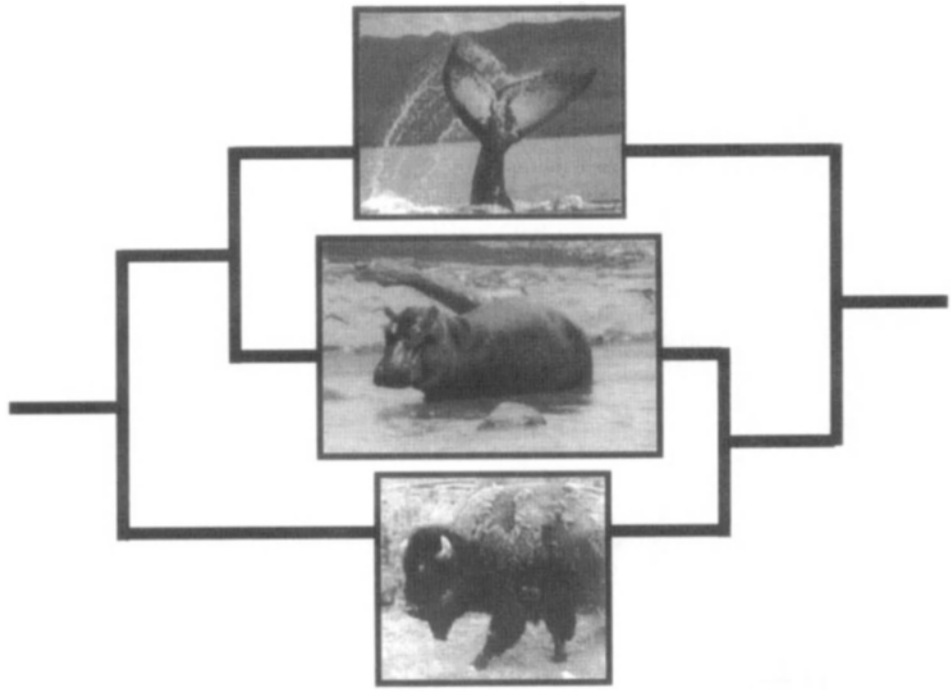

Figure 1 *Possible phylogenetic relationships among Cetacea (top) and artiodactyl ungulates—hippopotamuses (middle) and ruminants (bottom). Molecular data support the relationship on the left, and gross anatomical comparisons imply the relationship on the right. Molecular data suggest that cetaceans and hippopotamuses share aquatic specializations that may be further evidence of their close phylogenetic kinship. Whale photo is by Howard Rosenbaum (WCS), hippopotamus photo is by G. Amato (WCS), and bison photo is by C. Hayashi.*

The huge common hippopotamus ranges in size from approximately 1000 to 3500 kg. Like the pygmy hippopotamus, *Hippopotamus amphibius* is nearly hairless. The skin lacks sebaceous glands and is underlain by a thick layer of insulating fat. The limbs are short and stubby, and the skull is huge with the orbits and nostrils positioned dorsally. *Hippopotamus* individuals spend a large proportion of their lifetimes in rivers, lakes, or swamps. They are capable swimmers and are able to stay submerged for over 5 min. At dusk, the common hippopotamus advances to the land to graze on grasses and at dawn returns to the safety of the water to loll about, digest, and rest. *H. amphibius* is highly gregarious and, under some environmental conditions, this species concentrates into large herds of over 100 individuals. Groups of 10 to 20 animals are more typical. The males are territorial and battle viciously when competing for mates, but a variety of ritualized social behaviors limit intermale conflicts to some degree. Because of their enormous size and dangerous gape, adult common hippopotamuses have few natural enemies beside humans.

II. Fossil Record

The paleontological record of Hippopotamidae is quite rich in the Pleistocene and the Pliocene, the last five million years of geologic history. In fact, during some time intervals, five or more hippopotamid species were contemporaneous. The geographic distribution of hippopotamids was also more extensive in the not so distant past; hippopotamids ranged into Europe, Asia, North Africa, and Madagascar. In the Pleistocene, there were hippopotamuses in Great Britain! So the current complement of two extant species is a mere relic of past hippopotamid diversity.

Despite their relative abundance in the Plio-Pleistocene, definitive hippopotamids only extend back into the fossil record approximately 15 million years. The earliest described genus, *Kenyapotamus*, is found at several localities in East Africa (Pickford, 1983), but the evolutionary history of hippopotamids prior to 15 million years ago is obscure and may only be illuminated by further fossil discoveries.

III. Phylogeny of Hippopotamids

Semiaquatic hippopotamuses are not classified as marine mammals, the main focus of this encyclopedia. However, hippopotamuses recently have been implicated as close evolutionary relatives of cetaceans (whales, dolphins, and porpoises) and are thus relevant to this volume. The phylogenetic origins of Hippopotamidae are not clearly characterized, but among living species, mammalogists have traditionally aligned hippopotamuses closest to pigs and peccaries with ruminating ungulates (cattle, antelopes, deer, giraffes, chevrotains, and camels) considered their next closest evolutionary kin (Fig. 2a; Gentry and Hooker, 1988 and references therein). Based on morphological similarities, hippopotamuses and these other hoofed mammals

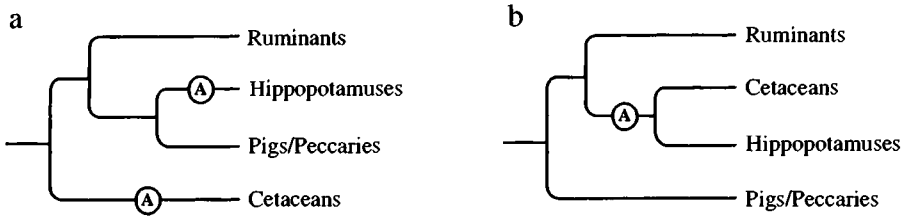

Figure 2 *Two phylogenetic hypotheses of hippopotamus origins that have different implications for the evolution of aquatic features. Acquisitions of aquatic traits shared by hippopotamuses and cetaceans are represented by open circles with "A" inside. (a) If hippopotamuses group within Artiodactyla, even-toed ungulates, and are only distantly related to Cetacea, aquatic specializations were derived independently in hippopotamuses and whales. (b) If cetaceans are the closest living relatives of hippopotamuses, shared aquatic specializations of these taxa may have been acquired only once in their common ancestors.*

are classified as members of the mammalian order Artiodactyla, even-toed ungulates. Hooves in which the axis of symmetry runs between the third and fourth digits, the so-called paraxonic condition, characterize all species in this group.

According to the majority of the gross anatomical evidence, cetaceans are only distantly related to hippopotamids (Fig. 2a). Therefore, the common aquatic specializations of cetaceans and hippopotamuses traditionally have been interpreted as convergences. In this case, independent adaptation to an aquatic environment was hypothesized to have driven the parallel evolution of grossly similar characteristics, such as near hairlessness, a thick layer of insulating fat, the lack of sebaceous glands, the lack of scrotal testes, and the ability to nurse offspring underwater. These features are common to all extant cetaceans and one or both extant species of hippopotamus.

Recently, a radically different interpretation of hippopotamid phylogeny has been presented. Examination of diverse genetic data suggests that cetaceans, not other artiodactyls, are the closest relatives of hippopotamids (Fig. 2b; Gatesy, 1998; Ursing and Árnason, 1998; Nikaido *et al.*, 1999). In this scheme, whales are simply highly derived members of "Artiodactyla." Therefore, at least some of the common aquatic specializations of hippopotamuses and whales could be interpreted as further evidence of a close evolutionary relationship between these mammals (Fig. 2b). The recent discovery of fossil whales with fully functional hindlimbs and paraxonic feet (Thewissen *et al.*, 1994) lends further credibility to close phylogenetic ties between whales and artiodactyls. If genetic data portray an accurate picture of hippopotamid origins, the seemingly ungainly hippopotamus may offer additional clues to the evolutionary derivation of the most graceful of marine mammals, the cetaceans (Fig. 2).

History of Marine Mammal Research

BERND WÜRSIG
Texas A & M University, Galveston

If research is the gathering of knowledge, then we can think of marine mammal research to have gone on as long as humans have gazed at whales spouting offshore and seals pupping on beaches. But early observations of nature were largely tied up with myths about animals and legends of their capabilities. A common theme appears to have been the changing of humans to dolphins and whales, and the reverse. This theme is recognized in remaining legends of Australian aborigine "dream time," baiji (*Lipotes vexillifer*) and boto (*Inia geoffrensis*) river dolphin folklore (Zhou and Zhang, 1991; Sangama de Beaver and Beaver, 1989, respectively), tales of the god-like

killer whales (*Orcinus orca*) of Pacific Northwest indigenous tribes (McIntyre, 1974), and many more.

Nevertheless, some early writings show remarkable insights in marine mammal biology. Well over 2000 years ago, scholars of China's Han Dynasty described baiji as related to marine dolphins, implying that those were known to intellectuals of the time. These descriptions, in the annotated dictionary "Er-Ya," survive to this day. Even earlier, the Greek philosopher/scientist Aristotle (384–322 B.C.) differentiated between baleen and toothed whales, and described both types in some detail. It is unfortunate but totally understandable in hindsight that he classified cetaceans as fishes, a practice still present in Britain's "Royal Fishes" as all whales and dolphins belonging by law to the Crown. The Roman writer/lawyer/admiral Pliny the Elder (23–79 A.D.) published a book on dolphins and whales 400 years after Aristotle's time as part of Pliny's 37-volume "Natural History."

Not much scientific inquiry or thought was conducted between Roman times and the western Renaissance, and knowledge, at least written knowledge, of marine mammals languished as well. The modern progression of marine mammal research can perhaps best be described as occurring in four general (and not mutually exclusive) phases: (1) morphological description from beach-cast specimens and fossils, (2) descriptions of behavior and anatomy as gathered during hunting and whaling activities, (3) studies of physiology and behavior in captivity, and (4) studies of ecology, behavior, and physiology in nature. These phases follow a rough chronology, with morphology and systematics the main topics pre-1900s, hunting-related morphological and behavioral research mainly from the 1850s to the 1970s, scientific captive animal descriptions beginning around 1950, and more ecologically oriented descriptions in nature beginning around the 1970s. All phases are ongoing, with electronic devices promising to elevate in-field research on marine mammal lives to a new level of sophistication. A very readable recent account of the history of marine mammal studies is found in Berta and Sumich (1999). This volume lists some of the major deceased marine mammal researchers of the past, with their annotated classic works in the field.

Pierre Bélon was probably the first "modern" marine mammal author since Pliny's time. He published accurate descriptions and woodcuts of whales, dolphins, and seals (Belloni, 1553), and these (and also, unfortunately, the less accurate ones) were much-copied by others in the next two centuries.

The real burst of marine mammal knowledge did not come until later, however. And then it came suddenly, in tune with 18th century awakening of scientific thought in the western world. While many authors could be mentioned, three early contemporaries did much to advance cetacean descriptions, taxonomy, and systematics. These were the French zoologist La Cépède (1804) and the Cuvier brothers. Georges Cuvier, who arguably founded modern evolutionary theory, wrote on many topics, including cetaceans; whereas his less-famed brother Frederic published two important works on cetaceans (F. Cuvier, 1829, 1836). These three were followed by the Belgian zoologist Van Beneden in the latter half of the 19th century, with work mainly consisting of compilations of information on fossil whales, and by a host of fine morphologists, taxonomists, systematists, and evolutionary historians in the 20th century (summaries are provided by Rice, 1998; Pabst *et al.*, 1999; Reynolds *et al.*, 1999; and Thewissen, 1998). While much of the earlier work centered on cetaceans, the British zoologist John Gray described both seals and whales in the British Museum (Gray, 1866), and the American zoologist Joel Allen wrote excellent monographs on whales, pinnipeds, and sirenians (Allen, 1880).

Yamase (1760) began the science of marine mammalogy in Japan at about the same time as serious studies began in the west. He presented accurate figures and descriptions of the external morphology of six toothed and seven baleen whale species and distinguished them from fishes. His work was brought to the west in a marine mammal section of "Fauna Japonica" by Siebold (1844). Otsuki began to describe the internal anatomy of cetaceans of Japan in 1808, but his manuscript remains unpublished.

A second major phase of information gathering, often linked intricately with that just described, involved descriptions of animals as related to HUNTING and WHALING. Morphological information was at the core of these descriptions, but behavior and the basic society structure of whales and pinnipeds—of course much of the time affected by the hunting activities themselves—were recorded as well. One of the earliest accurate accounts consisted of German-born and Russian-naturalized Georg Steller's descriptions of pinnipeds and the soon-after extinct Steller's sea cow (*Hydrodamalis gigas*), the largest and only cold-water sirenian known (originally published in Latin in 1751, but republished in English as Steller, 1899). Quite a few books related especially to whaling were produced, but perhaps the most enduring one from the 19th century was by the North American whaling captain Charles Scammon, who wrote with feeling and accuracy on behavior and life history habits of marine mammals of the North Pacific (Scammon, 1874). In the 20th century, one of the most famous works largely relying on whaling-accumulated data consists of Everhard Slijper's book "Whales and Dolphins" (published in English in 1976). A very readable account of whaling and the literature derived from whaling can be found in "Men and Whales" by Richard Ellis (1991).

While whaling, sealing, and other forms of direct hunting are much abated today as compared to in the 1960s, there are still powerful low-level, oft-indigenous hunts, especially in protein-poor areas of the world (Perrin, 1999). As a result, data are being accumulated and analyzed on morphology, GENETICS, taxonomy and SYSTEMATICS, life history, prey patterns, and so on. Excellent recent information has become available from results of hunting on (for example) pilot whales (*Globicephala* spp.), oceanic dolphins (especially of the genus *Stenella*), bowhead whales (*Balaena mysticetus*), sperm whales (*Physeter macrocephalus*), and several seal, fur seal, and sea lion species (summaries in Berta and Sumich, 1999; Reynolds and Rommel, 1999; and Twiss and Reeves, 1999).

A third major research avenue has come about as a result of keeping marine mammals in captivity. Attempts to do so in the early part of the last century usually resulted in the animals' untimely deaths—due to poor water, incorrect or tainted food, disease, and intraanimal aggression in confined spaces. Facilities that housed marine mammals simply replaced dead ones

by more captures from nature. However, especially since the 1970s, amazing strides in husbandry have been made for all marine mammals (except large whales), and the better aquaria now keep—and breed—animals very well. Unfortunately, there are still many "primitive" facilities, especially in less-developed parts of the world. At present, there are representatives of all major taxonomic groups in captivity, as show animals and for research: toothed whales and dolphins (only two baleen whales, each time young gray whales, *Eschrichtius robustus*, have been kept); pinnipeds of all types, but especially California sea lions (*Zalophus californianus*); sirenians (mainly the Caribbean manatee, *Trichechus manatus*, and the dugong, *Dugong dugon*,); and polar bears (*Ursus maritimus*) and sea otters (*Enhydra lutris*).

Only through holding animals in controlled situations have researchers learned that dolphins echolocate (Au, 1993); that all marine mammals exhibit reduced heart and general metabolic rates during dives (Ridgway, 1972; Pabst *et al.*, 1999); and that both dolphins and sea lions have remarkably advanced cognitive capabilities (Tyack, 1999). Furthermore, it is now fully appreciated that while pinnipeds and cetaceans are finely tuned underwater swimmers and divers with superbly evolved methods of breath holding, avoiding or reducing lactic acid depth during long submergences, and navigating in dark and cold waters, there is no secret "magic" to their energetic capabilities (Costa and Williams, 1999).

One major misstep from studies in captivity took place: the American John Lilly avowed in the 1960s that his research on bottlenose dolphins (*Tursiops truncatus*) proved that these popular show animals have an intelligence superior even to that of the brightest dogs and chimpanzees, and likely equal to that of humans (Lilly, 1967). Careful studies by others have shown that dolphins are undeniably "smart" (intelligence is very difficult to define and compare, but has something to do with well-developed flexibilities of behavior and of innovative learning), but that there is no reason to believe that dolphins fare better in this "intelligence/cognition" sphere than many other highly social mammals (Herman, 1980, 1986; Tyack, 1999; Wells *et al.*, 1999).

While the study of marine mammals as derived dead from nature and live from captivity continues and grows, a relatively new approach has become the major research avenue since the 1970s. This consists of researchers going out into nature to observe the animals in their own milieu; as the animals associate with conspecifics; eat and are being eaten; and mate, give birth, and raise their young. We are learning more about the lives of these generally social creatures as they face storms, heavy years of sea ice, seasons of poor food resources (e.g., caused by "El Niño" southern oscillation climatic events), giant parasite infestations, adoring but noisy boatloads of whale-watching tourists, crowded shipping lanes, and habitat degradation near shore and in mighty rivers. This information on ecology of marine mammals is vital if we are to help protect them and their natural ecosystems from the depredations of overfishing, habitat POLLUTION by chemicals, heavy metals, and noise; and the very real possibility of global climate change and whole-scale habitat destruction due to the effects of ozone depletion and global warming (Tynan and DeMaster, 1997).

Studies in nature often rely on visual or photographic recognition of individual whales, dolphins, and pinnipeds, often with the help of tags or color marks but also by natural markings (Hammond *et al.*, 1990). Researchers have described movement patterns by tracking animals with surveyor's transits from shore, and from shore and vessels by small radio tags placed on their bodies (Würsig *et al.*, 1991). Since the early 1990s, satellite tags that relay position information to earth-orbiting satellites have become smaller, less expensive, and ever more popular. As a result, we know that northern elephant seals (*Mirounga angustirostris*) swim and dive into deep oceanic waters for months at a time, humpback whales (*Megaptera novaeangliae*) take rapid zigzag courses between their mating and feeding grounds, North Atlantic right whales (*Eubataena glacialis*) undergo previously unsuspected jaunts between Greenland and New England during the feeding summer, and much more (Wells *et al.*, 1999). Tags are being fitted not only with depth-of-dive measuring and telemetering devices, but also with ways to ascertain swimming velocity, angles of dives, water and skin temperature, individual sound production, heart rate, and, in the future, other physiological measures. Recent advances in small and low-light capable video camera/record systems are even giving data on SWIMMING, socializing, and feeding behavior directly from the animals underwater (Davis *et al.*, 1999).

Physiological research, previously entirely within the realm of captivity, is more and more possible with innovative or sophisticated techniques in nature. Samples of stool, urine, blood, and even mother's milk are being collected from pinnipeds resting on land or ice. Trained dolphins have been released at sea, commanded to dive, and then told to exhale into a funnel to ascertain oxygen consumption values and to station themselves so that blood can be drawn. This interaction between animals in captivity and nature is especially fruitful for physiological research. Small darts have been developed that are fired from a cross bow or pneumatic pistol and that obtain skin and blubber samples for analyses of genetics (Dizon *et al.*, 1997), toxin loads, and blubber energy content for relative measurements of health within and between populations. Skin samples of breaching whales have been successfully (and in a totally benign fashion) collected from the water and genetically sampled for gender, social grouping, and population data. A technique has been developed to harmlessly "skin-swab" bow-riding dolphins, also for genetic analysis (Harlin *et al.*, 1999).

In response to an apparent increase in marine mammal strandings and the emergence of new marine mammal diseases in recent years, studies of wild marine mammal disease and ocean chemical contaminants are on the increase. While studies in nature have yielded data on the presence of deadly viruses and contaminant levels in tissues of beached and dying marine mammals (Aguilar and Borrell, 1997), they have provided little insight into immune defense against disease or the biochemical consequences of contaminants. For example, species-specific biomarkers have been developed to assess the dolphin immune system (Romano *et al.*, 1999). Because they are readily available for long-term studies requiring serial sampling of tissues and health and reproductive histories, captive marine mammals afford unique opportunities to provide basic insight

into the relationships among contaminants, the immune system, and animal health. Once they are developed and tested on animals in captivity, biomarkers can be used with wild marine mammal populations to assess contaminant exposures and their possible effects on immune systems and neurologic responses (Ridgway and Au, 1999), as well as on reproductive success (Ridgway and Reddy, 1995), growth, and development.

The sensitive hearing of marine mammals has led to concerns that intense sound or noise pollution generated by humans could impede COMMUNICATION, cause stress, or damage hearing. Marine mammal hearing studies currently underway should help to define mitigation criteria for the effects of human-generated sound in the ocean (Schlundt *et al.*, 2000), and ultimately allow us to find a balance between the ecological needs of marine mammals and the role the ocean plays in commerce, exploration, travel, and defense.

Ever-more sophisticated electronic and biochemical techniques are being developed to study the lives of marine mammals. However, the "tried and true" methods of looking at fossil bones, dissecting and describing pathologies of a net-entangled animal or one cast on shore after a storm, safely and carefully experimenting with animals in captivity, and the dogged gathering of behavioral information by binoculars and notebook are by no means passé. We are, in this new 21st century, in a vibrant phase of marine mammal research, and we see a very bright future for ever-more knowledge being gathered within our field.

Hooded Seal

Cystophora cristata

Kit M. Kovacs
Norwegian Polar Institute, Tromsø

I. Description and Distribution

The hooded seal is a large, northern phocid. It is silver-gray in color with irregular black spots covering most of the body (Fig. 1); the face is usually solid black. Adult males are about 2.5 m long and weigh an average of 300 kg, although some reach over 400 kg. Adult females are considerably smaller than males, measuring approximately 2.2 m long and weighing an average of 200 kg. Hooded seal pups are approximately 1 m long when they are born and weigh about 25 kg. They are blue-black on their backs and silver-gray on their bellies. The common name for hooded seal neonates "blue-back" comes from this distinctive coloration pattern. The most unique feature of the species is the prominent two-part nasal ornament of sexually mature males that gives the species its common name. When relaxed, this nasal appendage hangs as a loose, wrinkled sac over the front of males' noses. However, when they clamp their nostrils shut and inflate the sac it becomes a large, tight, bilobed "hood" that covers the front of the face and top of the head. Adult males also have a very elastic nasal septum that they can extrude through one of their nostrils as a big membranous pink balloon. These two rather bizarre structures are secondary sexual characters that males use to display to females and to other males during the breeding season.

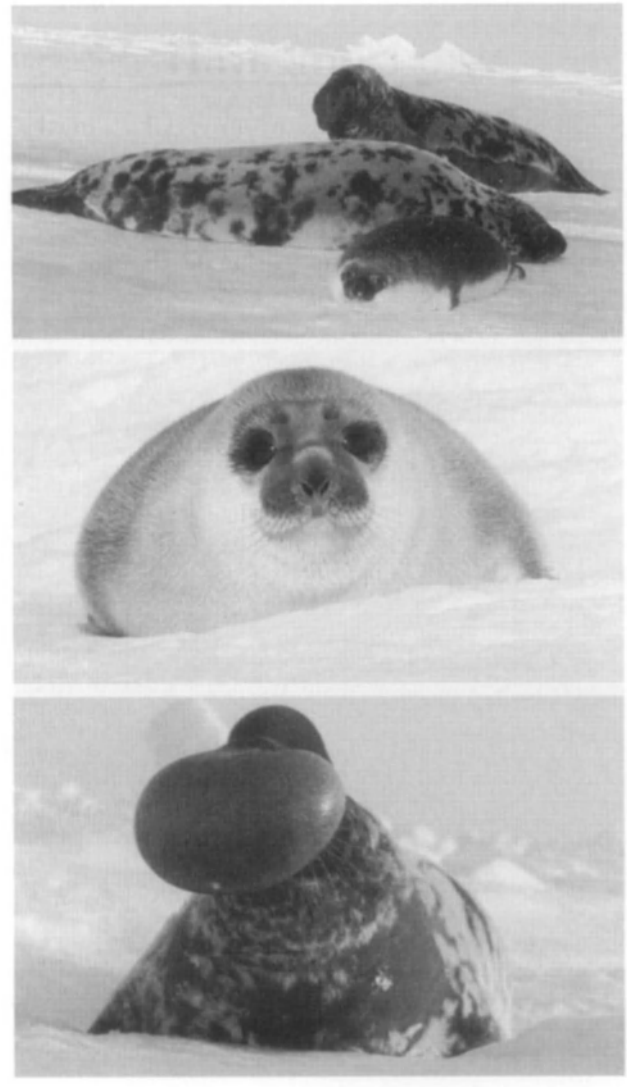

Figure 1 *Hooded seal mother–pup pair with an attending male in the background (top). Blue-back hooded seal newly weaned, 4 days old (middle). Hooded seal male with nasal septum extruded and hood somewhat inflated (bottom).*

Hooded seals are a migratory species with a range that encompasses a large sector of the North Atlantic (Fig. 2). They follow an annual movement cycle that keeps them in close association with drifting pack ice. During the spring the adults concentrate for breeding purposes in three locations: one group forms off the east coast of Canada, which is split into two whelping patches, one in the Gulf of St. Lawrence and the other north of Newfoundland—an area known as the Front; a second group congregates in the Davis Strait; and a third comes together on the West Ice, east of Greenland. Some weeks after breeding the animals move into traditional molting areas on the southeast coast of Greenland, near the Denmark Strait, or in a smaller patch that is found along the northeast coast of Greenland, north of Jan Mayen. After the annual molt, hooded seals disperse broadly for the summer and autumn months, preferring areas along the outer edges of pack ice.

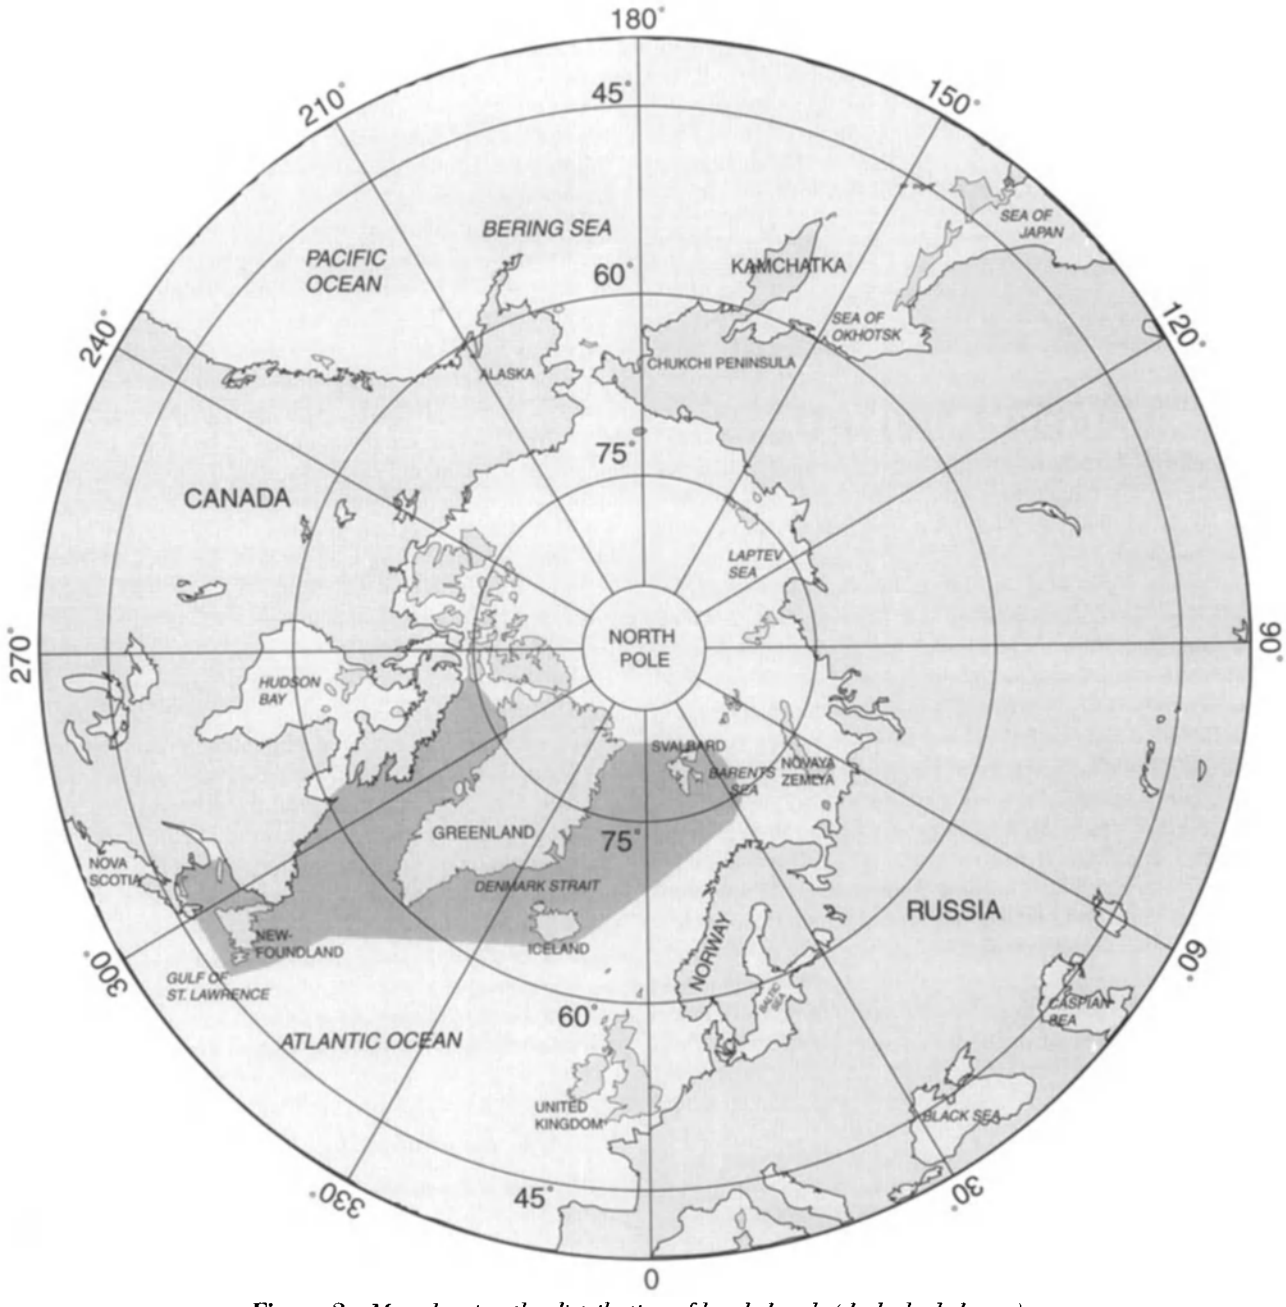

Figure 2 *Map showing the distribution of hooded seals (dark-shaded area).*

Records of hooded seals being found outside their normal range are not uncommon; young animals in particular are great wanderers. Juveniles have been found as far south as Portugal and Florida in the Atlantic Ocean and in California on the Pacific side.

II. Behavior and Ecology

Hooded seals are solitary animals outside the breeding and molting seasons. Even during these two annual phases when they do aggregate into loose herds, they are very aggressive with one another and do not tolerate close contact beyond the mother–offspring bond or a short male–female pairing period. Their vocal repertoire is quite simple, as would be expected for a species that is not highly social. The breeding season occurs in late March. It is short, lasting only 2–3 weeks in a given area. Females give birth in loose pack ice areas, preferring quite thick first-year ice floes for whelping. They space themselves out within the herd at intervals of 50 m or more when ice conditions permit, but the form of the herd and interfemale distances are highly variable, depending on the ice conditions. Mothers attend their pups continuously during the 4-day long period of lactation. Pups are born in a

very advanced developmental state, having already shed their grayish-white embryonic first coat of hair and having already accumulated a thin layer of subdermal BLUBBER. During the incredibly short nursing period, pups drink up to 10 l of milk per day that contains an average fat content of 60%. This energy-rich diet allows pups to more than double their birth mass during the few days that they are cared for by their mothers; they gain over 7 kg per day. Pups are weaned weighing 50–60 kg. During the time when mothers are with their pup, a male often attends the pair. Males compete with one another to maintain positions close to a female. The battles are often bloody. When a mother is ready to leave her offspring, the attending male accompanies her to the water where mating takes place. Hooded seals have delayed implantation of the embryo, for up to 4 months, similar to many other seal species. Males will return to the whelping area after mating with a female to resume mate searching. Individual males have been recorded with up to eight females in one breeding season.

The pups remain alone on the ice for some days or weeks before going to the water and learning to swim, dive, and forage. During their time on the ice they fast, using body reserves stored in their substantial blubber layer to fuel their energy needs. When they do start to eat, pups feed on krill and other invertebrates initially until they have sufficient aquatic skills to capture fish. Little is known about juvenile hooded seals. They are seen only infrequently among adult breeding or molting aggregations. It is assumed that they spend much of their time at sea and in isolated Arctic pack ice areas. When they reach sexual maturity, at an age of 3 for most females and 4 or more for males, they join the species-typical annual migratory cycle. Hooded seal live for 25–30 years.

Adult hooded seals can dive to depths of over 1000 m and can remain underwater for periods of up to almost an hour. They fed on a variety of deep-water fishes, including Greenland halibut (*Reinhardtius hippoglossoides*) and a variety of redfish species (*Sebastes* spp.), as well as squid. Herring (*Clupea harengus*), capelin (*Mallotus villosus*), and various gadoid fishes, including Atlantic cod (*Gadus morhua*) and Arctic cod (*Boreogadus saida*), have also been found in hooded seal stomachs.

Polar bears (*Ursus maritimus*) are natural predators of hooded seals, but human exploitation is likely the greatest source of mortality. Killer whales (*Orcinus orca*) are also a likely predator, although this has never been documented conclusively.

III. Exploitation and Conservation Status

Hooded seals have been commercially exploited for centuries, usually in conjunction with hunts whose primary target was the more abundant harp seal. Norway, Russia, Denmark–Greenland, Great Britain, and Canada have taken part in the commercial harvesting of hooded seals. Pre-World War II hunting was done for oil and leather, but improved techniques for handling furs meant that the blue-back pelt was the most financially lucrative product of the hooded seal harvest following the war. Adults continued to be taken for oil and leather production, but the numbers were reduced because the market demand for these products dropped. Because adult females remain on the ice to defend their pups against hunters, many adult females were killed. Regulations limiting the killing of mothers have become more restrictive in recent decades and relatively few females are now taken in the whelping patches. Annual catches of hooded seals have always varied dramatically, depending largely on ice conditions at the time of breeding. In years of high harvests, up to 150,000 animals have been taken in the North Atlantic. Seal management in international waters was put under the auspices of the International Commission for the Northwest Atlantic Fisheries (ICNAF), with Canada, Norway, and Denmark being voting members in the early 1960s. Documented population declines of hooded seals led to the introduction of quota management during the 1970s. A bilateral agreement for East-Atlantic harvesting between Norway and Russia was also formulated. Following Canada's declaration of a 200-mile economic zone in the late 1970s, Norway and Canada also created a bilateral agreement and ICNAF was transformed into the Northwest Atlantic Fisheries Organization (NAFO). Under this agreement, Canada and Norway cooperate extensively with information exchange regarding hooded seal abundance estimates and commercial hunting quota revisions. The small population of hooded seals breeding in the Gulf of St. Lawrence is currently protected from harvesting, as is the Denmark Strait molting concentration. The European economic community banned the importation of all seal products in 1985. This had a marked effect on the value and market place for hooded seal pelts. Subsistence harvesting of hooded seals takes place in Arctic Canada and in Greenland.

The global population size of hooded seals is very difficult to estimate because this species is difficult to survey. The total population size is almost certainly in excess of half a million animals.

Hourglass Dolphin

Lagenorhynchus cruciger

R. Natalie P. Goodall
Centro Austral de Investigaciones Científicas, Tierra del Fuego, Argentina

The hourglass dolphin, *Lagenorhynchus cruciger*, is the world's southernmost small dolphin. An oceanic species found in sub-Antarctic and Antarctic waters, it often bow rides ships and accompanies larger cetaceans but is one of the least studied cetaceans. Only three specimens were collected in the 136 years from the discovery of the species to 1960. Our knowledge of the biology of this species rests on 20 specimens (only 6 of them complete), 4 stranding observations and sightings at sea.

Figure 1 *Hourglass dolphins possess two lateral white areas along the flank that are united by a thin white line that resembles an hourglass. Schools of individuals can swell from the small group of 3 pictured, commonly around 6 or 7, and rarely up to 60 individuals. Photo by Robert Pitman.*

I. Taxonomy

The name *Delphinus cruciger* was based on a drawing from a sighting in the South Pacific in 1820. Synonyms include *D. albigena, D. bivittatus, Electra clancula, E. crucigera, D. superciliosus, Phocoena crucigera, P. d'Orbignyi, Lagenorhynchus wilsoni, L. latifrons*, and *L. Fitzroyi* (with *L. australis* and *L. obscurus*). The accepted combination, *L. cruciger*, was made by Van Beneden and Gervais in 1880. Common names have included the *crucigere*, the *albigena, grindhval*, sea skunks, and springers; the name in Spanish is *delfín cruzado*.

II. Diagnostic Characters

A. Pigmentation

The hourglass dolphin is mainly black or dark with two elongated lateral white areas, in some animals joined with a fine white line, which give it its common name (Fig. 1). The forward patch extends onto the face above the eye, which is within the black surface but outlined with a large dark eye spot with a point forward and a thin white line. The dark pigment of the lips is of varying shape; a gape to flipper stripe may be gray to tan, beige, or even rose. One animal had a white half-moon mark outlining the blowhole. On the side below the white flank patch, there is a lobe of white projecting forward, which may form a sharp point, a blunt, curved shape, or a hook. The flank patches on some animals almost meet on the upper tail stock. Part of the underside of the flippers is white. The ventral region is generally white, with some dark areas forward from the tail stock to the genital region. The pigmentation of juveniles has not been described.

B. Size and Shape

The hourglass is a rather stocky dolphin with a large, recurved dorsal fin that is variable in shape from erect to hooked. The tail stock is often keeled. Total lengths (n=9) range from 142 to 187 cm. Females (n=5) measure 142–183 cm, males (n=3) 163–187. This is probably not the total range of length for the species. Weights are known for only three specimens. Females of 163.5 and 183 cm weighted 73.5 and 88 kg. A 174-cm male weighed 94 kg.

III. Distribution

The hourglass dolphin is circumpolar in the Southern Ocean, in both Antarctic and sub-Antarctic waters, from about 45°S south to fairly near the ice pack (Fig. 2). Exceptional sightings were at 36°14′S in the South Atlantic and 33°40′S in the South Pacific off Valparaiso, Chile. The southernmost sighting was at 67°38′S in the South Pacific. Most specimens were found between 45 and 60°S, the northernmost from New Zealand and the southernmost from the South Shetland Islands. Sightings and specimens are plotted in Fig. 2.

IV. Ecology

A. Habitat

This dolphin is pelagic and circumpolar in the Southern Hemisphere on both sides of the Antarctic Convergence and northward in cool currents associated with the West Wind Drift. Recorded water temperatures range from −0.3 to 13.4°C. Although oceanic, sightings of this dolphin are often made near islands and banks. Sightings reflect observer effort, with most in the Drake Passage, reflecting ship traffic between South America and the Antarctic Peninsula.

B. Prey and Predators

The stomachs of five specimens from different oceans have been examined; one was empty. Prey items included unidentified small fish, the fish *Krefftichtys andersonii* (Mycophidae) of about 2.4 g and a length of 55 mm; small squid, including some from the families Onychoteuthidae and Enoploteuthidae; and crustaceans. They often feed in large aggregations of sea birds and in plankton slicks.

No predators are known, although killer whales and leopard seals are possibilities.

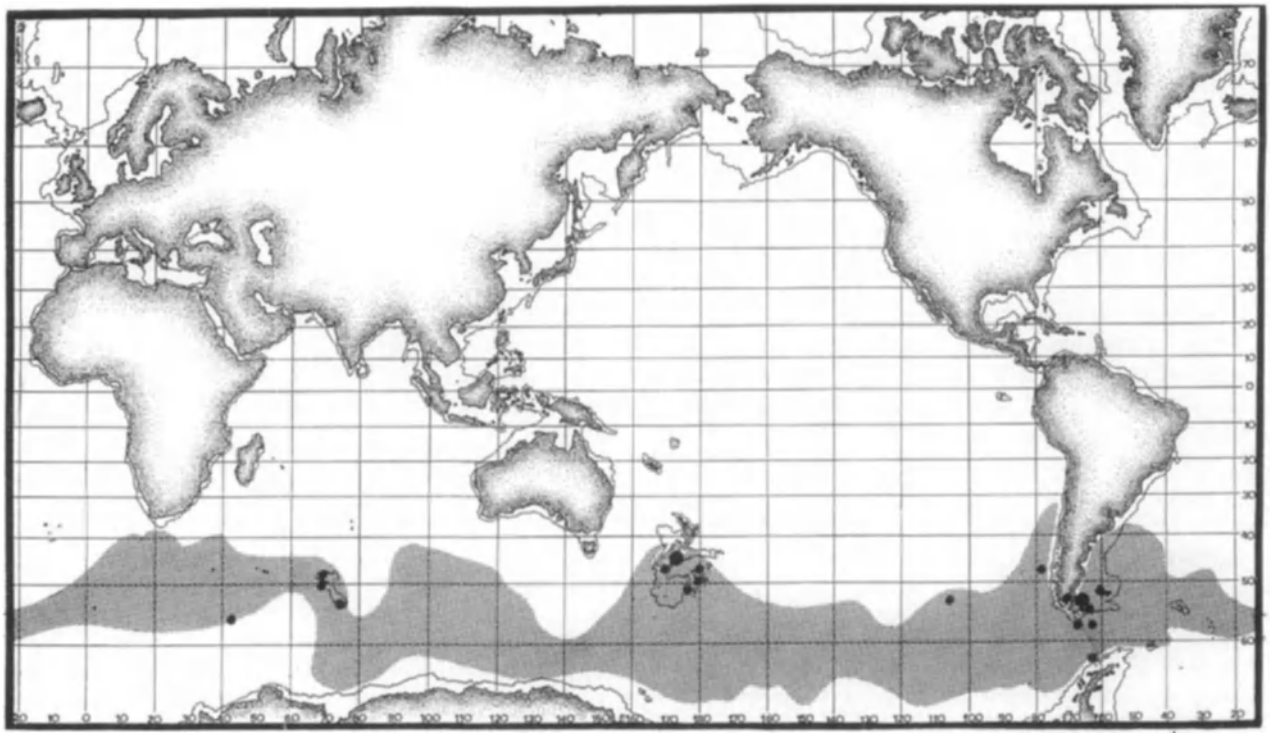

Figure 2 *Distribution of the hourglass dolphin compiled from incidental and dedicated sightting surveys and the location of specimens from 1824 to 1997. Small circles indicate single specimens, and large circles represent three specimens off New Zealand and four at Tierra del Fuego.*

V. Behavior

Nothing is known of the migratory movements of this species. Hourglass dolphins are rapid swimmers with a forward, plunging movement. They commonly bow-ride ships, especially in rough weather. These dolphins were found so often with fin whales (*Balaenoptera physalus*), that whalers used them as "spotters" in finding whales. They have also been seen with sei and minke whales (*B. borealis* and *B. bonaerensis*), large bottlenose whales (*Hyperoodon* and *Berardius*), pilot whales (*Globicephala melas*), and southern right whale dolphins (*Lissodelphis peronii*).

During the Southern Hemisphere minke whale assessment cruises conducted by the INTERNATIONAL WHALING COMMISSION, school sizes ranged from 1 to 60 animals (mean 7). Other studies reported mean sizes of 4 and 5.7 animals.

The sounds of this species have not been recorded.

VI. Internal Anatomy

The condylobasal lengths of 11 skulls ranged from 316 to 370 mm. Visible teeth numbered 26–34 upper and 27–35 lower in each jaw. Vertebral count is CV7, Th12–13, L18–22, and Ca 29–33 for a total of 69–72 (n=7). The first two cervicals are fused (n=4). The vertebrae of *L. cruciger* are smaller than those of *L. australis*, but slightly larger than those of *L. obscurus* and are similar to the latter in shape. There are 12–13 ribs (n=7). One specimen had seven pairs of sternal ribs, another eight. The phalangeal formula (n=5) is I=2–3, II=8–11, III=6–8, IV=2–4, and V=0–2.

The internal organs were examined for one specimen and organ weights are known for another. The intestine length of one specimen was 18 m.

VII. Life History

A. Growth and Reproduction

Very little is known of growth and reproduction in this species. A 163.5-cm female was sexually immature and one of 183 cm was pubescent. Males of 174 and 187 cm were sexually mature. Based on fusion of the vertebral epiphyses, the 163.5-cm female was physically immature. The 183-cm female was subadult. In males, an animal of 163 cm was subadult, one of 187 cm was nearly mature, and one of 174 cm was physically mature. Nothing is known of the young, times of birth, and reproduction rates; only three calves, seen in January and February, have been reported. No studies on aging have been published.

B. Parasites and Disease

Nematodes (*Anisakis* sp.) were reported in the stomachs and intestines of two animals. The largest animal known, a male, had long-standing gastric trauma with extensive peritonitis. No other diseases have been reported.

VIII. Interactions with Humans

Several hourglass dolphins have been taken for scientific study. No other directed catches are known. The only INCIDENTAL

CATCHES reported were three females from New Zealand and a drift net catch in the southern Pacific Ocean. No animals have been kept in CAPTIVITY.

Humpback Dolphins

Sousa chinensis, *S. plumbea*, and *S. teuszii*

GRAHAM J. B. ROSS

Australian Biological Resources Study, Canberra

The names given to the humpback dolphins, genus *Sousa*, reflect both their distribution (Fig. 1) and their distinctive humped appearance when they surface (Figs. 2 and 3). These coastal animals occur in small groups from northwestern Africa to northern China and Australia and are subject locally to incidental mortality in nets. Their biology is poorly known and their classification is open to discussion, not least because study material across the range is limited.

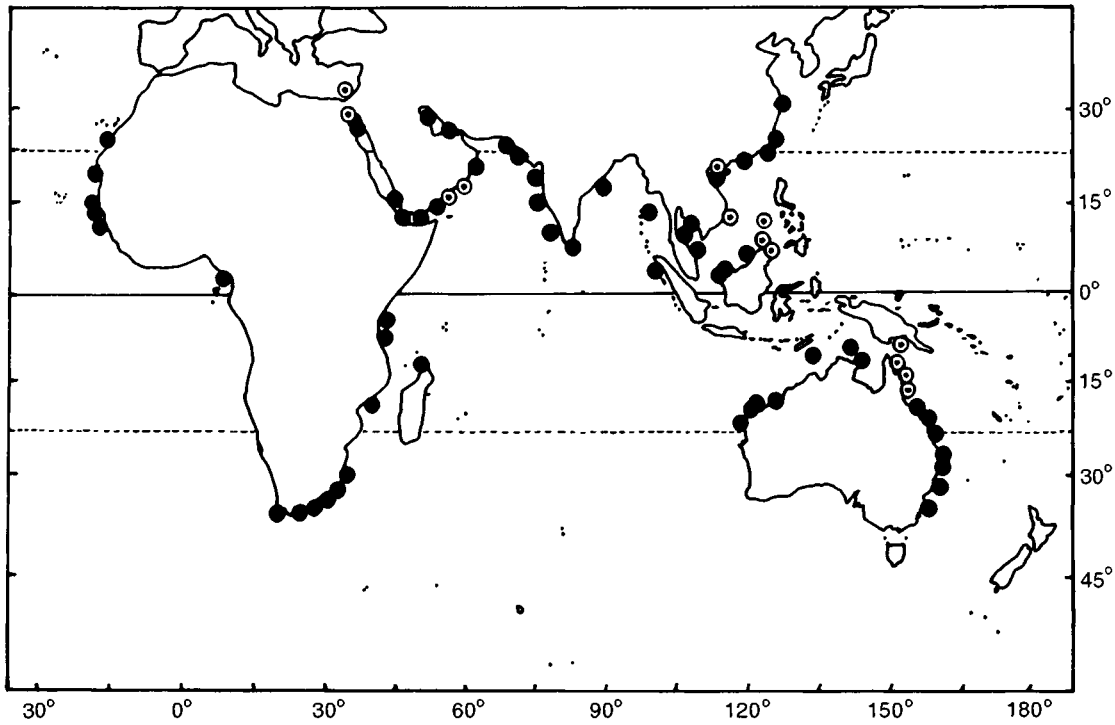

Figure 1 *Distribution of* Sousa *worldwide. Closed and open circles represent specimens and sightings, respectively. After Kerem and Goffman (2000), Ross* et al. *(1994, 1995), and Smith* et al. *(1997).*

Figure 2 *Subadult* Sousa *in Richards Bay, southern Africa, showing the humped back and ridged dorsal fin base typical of animals westward of Sri Lanka.*

I. Description

Humpback dolphins are medium sized and robust in form. The melon, moderate in size, is slightly depressed and, in profile, slopes gradually to an indistinct junction with the long, narrow snout. Neonates have vibrissae. The gape is straight. The broad flippers are rounded at the tip, and the flukes are broad and full, with a deep median caudal notch. Dorsal and ventral ridges on the caudal peduncle are well developed in African and Indian Ocean populations. The distinctive dorsal fin comprises a thickened base supporting a thinner, fin-shaped upper component; its overall form varies geographically (Figs. 2 and 3). Its length varies in relation to body length. Total length reaches a maximum of 2.5–2.8 m in different parts of the distribution. South African males and females are sexually dimorphic; mean lengths and weights for fully grown males are 2.70 m and 260 kg compared to 2.40 m and 170 kg in females. The few available data suggest that Arabian Gulf animals may also be dimorphic in length. The biology of any population is poorly known. These dolphins live close to shore in depths of 25 m or less. Characteristic features of the skull include a long, narrow rostrum, strengthened by raised premaxillary bones and increasingly compressed toward the tip (Fig. 4), large temporal fossae on which the jaw muscles insert, and pterygoid bones that are separated in the midline by up to 11 mm. A broad gap exists between the posterior margin of the maxillary bones and the supraoccipital crest of the skull. The mandibular symphysis is long, and each jaw bears 27 to 38 teeth, wedge-shaped at their base.

II. Distribution

Atlantic humpback dolphins occur widely along the West African coast, between southern Morocco (23°54′N) and Cameroon. Indo-pacific humpback dolphins are distributed continuously along the coast from False Bay, South Africa to the South China Sea, including the Red Sea, Arabian Gulf, the Indian subcontinent, Gulf of Thailand, Malacca Straits and northern Borneo, and the coast of China to the Yangtze River (31°50′N). At least one animal reached the Mediterranean via the Suez Canal (Fig. 1). Australian animals reach 25°S on the west coast, extending to 34°S facilitated by the warm eastern boundary current; similarly, those resident in southern South Africa live at 34°S in water temperatures of 15–22°C.

III. Taxonomy

The taxonomy of the genus is not well established, partly because sample sizes for morphological and genetic comparisons are small for most populations. Three species were recognized by Rice (1998): *Sousa chinensis* (Osbeck, 1765), *S. plumbea* (G. Cuvier, 1829), and *S. teuszii* (Kukenthal, 1892). Other nominal species include *S. lentiginosa* (Owen, 1866) and *S. borneensis* (Lydekker, 1901). However, recent morphological studies, supported somewhat equivocally by genetic analyses, indicate that there is a single, variable species for which the name *S. chinensis* has priority.

IV. Regional Differences

Regional differences occur in external proportions, especially in body length, snout length, and the length of the dorsal fin base, although data on the mean or maximum body length exist for few populations. Animals in northeastern Australia and Hong Kong waters attain 2.3–2.5 m in length; Indian dolphins are generally shorter than 2.6 m; however, four animals exceeded 3.0 m in length. Beak length varies from about 6% of total length in West African animals to about 10% in northeast Africa. Dorsal fin height varies only in relation to total length, rather than regionally. In dolphins from Sri Lanka westward, the base of the dorsal fin forms a distinct elongate mid-dorsal ridge with a small, falcate upper component (Fig. 2). The basal part includes vascular structures similar to those in the dorsal fin of other delphinids, perhaps assisting in THERMOREGULATION, and may attain 39% of body length in southern African animals. Eastward of Sri Lanka, the fin base comprises a broad, thickened pad that rises slightly above its surroundings surface and supports a larger, almost triangular upper component with a rounded tip (Fig. 3). The few specimens known from the east

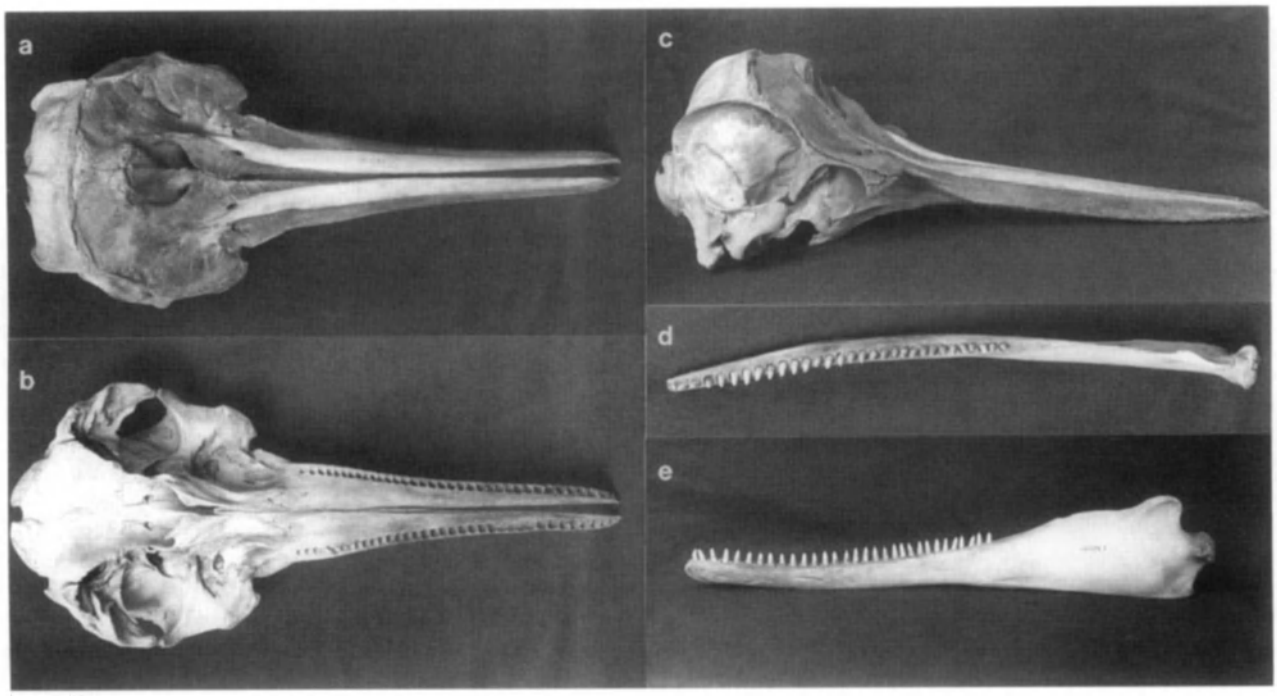

Figure 4 *Dorsal (a), ventral (b), and lateral (c) views of the skull, and dorsal (d) and lateral (e) views of the mandible of an adult male* Sousa *from South Africa. Photo by G. Ross, after Ross* et al. *(1994).*

coast of India suggest that the transition from one form of fin to the other occurs in this region.

Color varies greatly, with age and location, in both the timing and extent of the loss of the gray background color to become white (pink when flushed) and the development of spotting on the flanks and back. Born with a typical neonatal dark-grayish pigmentation above and paler gray below, animals lose gray pigmentation at different rates. Thus populations on the coast of China pale earlier than any other, turning white or pink within a few years of birth, a process that takes considerably longer in Australian and other populations to the west. Dolphins from eastern India to the Arabian Gulf coastline become spotted with white as mature adults, and there is no such pigment loss in any African population other than a pale fin mark in some southern African adults. Black spotting over the head and body develops in adults of all populations from the Arabian Gulf eastward.

Skull morphology is similar in all populations, apart from lower tooth counts, a shorter mandibular symphysis, and a broader cranium in West African animals. However, such low tooth counts may reflect small sample size, as the well-sampled southern African population varies greatly (30–38 teeth). The median number of TEETH per jaw increases eastward from 28 or 29 in West African animals to 36 or 37 teeth in north Indian Ocean populations and declines to 32 or 33 teeth in Southeast Asian and Australian animals. Regional differences occur in the ear bones of different populations. The range of vertebral formulae in South African animals was C7 T11–12 L9–12 Cd 20–24 = 49–52. Vertebral counts in humpback dolphins further east are similar to those of the South African sample (49–53), and West African humpback dolphins have 52–53 vertebrae.

V. Habitat

Humpback dolphins rarely occur in waters more than 25 m deep throughout their range. Saline, often turbid, waters in mangrove channels, embayments, and tropical river deltas or over shallow banks form important habitats. Occasionally they occur offshore, such as in the Great Barrier Reef, usually associated with islands or reefs, or in reef lagoons, such as Ningaloo Reef, Western Australia. Along the high-energy southern African coast, where sandbars limit access to rivers, humpback dolphins generally occur less than 1 km offshore, often close to the surf zone; conversely, in southern China, dolphins may swim up rivers for tens of kilometers.

VI. Behavior

Humpback dolphins swim slowly at about 5 km/hr, surfacing briefly at intervals of up to a minute. Longer dives may last up to 5 min. Typically they avoid boats and rarely bow ride. When approached, they generally dive, split up into small groups or single animals, and often change course underwater, reappearing unexpectedly some distance away. When a dolphin surfaces, the beak or occasionally the whole head is typically raised clear of the water and the body is arched, humping the back and perhaps exposing the flukes, before sounding. In one study, movement, feeding, social activities, and resting accounted for 49, 27, 15, and 8% of observation time, respectively. Single animals or pairs are generally adult; immatures tend to associate with groups containing more than one adult. Calves form about 10% of the population. Group size is generally 4 to 7 (range 2 to about 25). Body contact, displays during SWIMMING, leaping and

chasing, or activities focused on inanimate or animate objects form part of the behavioral repertoire.

VII. Biology

These dolphins feed primarily on fish and cephalopods in shallow reef, littoral, or estuarine-associated habitats. Senegalese dolphins follow the rising tide into mangrove channels to feed, returning with the ebb tide, and South African dolphins spend more time feeding on the rising tide. Temporary beaching by dolphins to retrieve bonefish deliberately washed onto exposed sandbanks has been reported. Fishes in the families Haemulidae, Sciaenidae, Sparidae, Mugilidae, and Clupeidae and cuttlefishes (Sepiidae) are the most important prey across the range of *Sousa*. Notably, the first three of these families produce underwater sounds, which may assist dolphins to detect their prey.

Clear evidence of migration in humpback dolphins has not been found, although Senegalese animals may shift northward in summer. Humpback dolphins on the southern Cape coast of South Africa appear to be resident, and those in southern China are present throughout the year.

The effects of predation on humpback dolphins are uncertain. Off Natal, some 35% of these dolphins captured in nets bear healed shark bites, suggesting that shark attack is a significant cause of mortality, as this sample merely represents the survivors of such attacks. The few records of PARASITES include the whalelouse *Syncyamus aequus* and the nematode *Halocercus* (?) *pingi*.

Sound production and reception are vital to humpback dolphins in the often murky habitat they occupy. They produce clicks comprising highly directional single pulses repeated in series at variable rates between 10 and 500 Hz, apparently used for echolocation. Whistles and screams are frequency-modulated sounds: the former are produced singly or in series and are of variable length (milliseconds to seconds), whereas screams have a harmonic structure and occur in series. These may be important in communication, as their high-frequency components exceed the frequency range of sounds produced by fish and crustaceans and ambient environmental NOISE. The cochlear nerve in *Sousa* is specialized with large nerve fibers, permitting rapid transfer of information to the brain; the largest of some 77,000 fibers in this nerve are 50 μm in diameter, the greatest observed in any vertebrate.

Reproductive and other life history data are minimal for all populations. Calves are about 1 m long at birth. Off South Africa, births occur throughout the year, two-thirds of which are in summer; females mature at about 10 years old and males about 3 years later, assuming one growth layer group in teeth per year. The length at maturity is unknown. Data from other populations are minimal. The fat content of humpback dolphin milk is about 10%, similar to that of bottlenose dolphins but lower than that of common dolphins. Copulation occurs with one dolphin inverted below its partner, lasting 20–30 sec. Observations of dolphins rising vertically belly to belly in a vertical position in the Arabian Gulf and the Indus delta have been ascribed to mating behavior.

VIII. Relationships

The relationships of *Sousa* with other delphinoid genera are equivocal. Air sinus structure suggests that *Sousa* and *Steno* are closely related, whereas earbone structure places *Cephalorhynchus* with these two genera as a closely related group comprising the subfamily Sotaliinae. More recent genetic studies indicate that *Sousa* is a member of the Delphininae. No fossils of *Sousa* are known.

IX. Human Influence

Humpback dolphins from South African, Australian, and Thai populations have survived in captivity for periods from 3 months to over 30 years. In southern Queensland, up to seven free-ranging humpback dolphins visit Tin Can Bay regularly, where they are fed fish by visitors. Humpback dolphins are particularly susceptible to the effects of human activities in the coastal zone, especially fishing. Incidental catches in nets are reported for West Africa, northeastern Africa, the Arabian Gulf, Indus delta, and southwestern India. Off Natal, shark nets set to protect bathing beaches caught at least 67 humpback dolphins between 1980 and 1989, from a population of unknown size, although clearly small. Catch data for humpback dolphins in Australian protective nets are unknown. Changes in the Indus delta and other tropical regions through construction, drainage, and destruction of mangroves strongly affect the prime habitat of humpback dolphins.

Organochlorine residues are evident in several populations. In three southern Indian animals, total DDTs and PCBs in blubber reached 11,000–14,000 ppm and 920–1800 ppm, respectively. Off Natal, total DDT levels in blubber ranged from 59 to 243 ppm and PCBs 1000 to 130,000 ppm, the highest residue level for any marine mammal of that region. Mercury pollution levels of up to 0.9 ppm in Hong Kong *Sousa* present a potential threat to this population.

The conservation status of almost all populations of humpback dolphins throughout their range is uncertain, primarily because the monitoring of mortality rates is minimal in most regions and determining population size is difficult, even locally, although all appear to be small. Simple population estimates for the Indus delta and the Saloum delta, Senegal, are 500 and 100 animals, respectively. Density in Moreton Bay, southeast Queensland, is estimated at 0.1 dolphin/km^2.

Humpback Whale

Megaptera novaeangliae

PHILLIP J. CLAPHAM
Northeast Fisheries Science Center, Woods Hole, Massachusetts

The humpback whale (Fig. 1) is one of the best known and easily recognizable of the large whales. It is known for its frequent acrobatic behavior and its occasional tendency to approach vessels. In recent years, thousands of humpback whales have been identified individually from natural markings (notably the pattern on the ventral surface of the tail flukes), and as a result, much has been learned about the biology and behavior of this species.

I. Characters and Taxonomic Relationships

At close range, humpback whales are easily distinguished from any other large whale by their remarkably long flippers, which are approximately one-third the length of the body. The flippers are ventrally white and can be either white or black dorsally depending on the population and the individual; flippers of North Atlantic humpbacks tend to be white, whereas those in the North Pacific are usually black (Fig. 1). The body color is black dorsally, with variable pigmentation on the underside (black, white, or mottled). The head and jaws have numerous knobs called tubercles, which are also diagnostic of the species. The dorsal fin is small but highly variable in shape, ranging from low (almost absent) to high and falcate. Like all rorquals, humpbacks have a series of ventral pleats running back from the tip of the lower jaw, in this species to the umbilicus. The tail is usually raised during a dive; the underside exhibits a pattern that is unique to each individual, which ranges from all white to all black. The presence of white on the ventral surface, and the prominent serration of the trailing edge, distinguishes humpbacks from other whales that "fluke" while DIVING, such as right, bowhead, blue, gray, and sperm whales.

Adult female humpback whales are typically 1 to 1.5 m longer than males. Maximum reliably recorded adult lengths are in the 16- to 17-m range, although 14–15 m is more typical (Clapham and Mead, 1999). Calves are 3.96 to 4.57 m at birth and approximately 8–10 m at independence (Clapham *et al.* 1999), which occurs at the end of the calf's natal year. There are no easily observable differences between male and female humpbacks. Females possess a grapefruit-sized lobe at the rear of the genital slit; this lobe is absent in males (Glockner-Ferrari and Ferrari, 1990). In addition, the spacing between the genital slit and the anus is considerably greater in males.

The SKULL of the humpback whale is easily distinguished from that of other baleen whales by the narrowness of the rostrum relative to the zygomatic width. The humpback has between 270 and 400 baleen plates on each side of the mouth. The plates are usually black, although those close to the tip of the jaw are sometimes white or partly white.

The genus *Megaptera* is monotypic and is one of two genera in the family Balaenopteridae (the "rorquals"). No subspecies are recognized. The binomial *Megaptera novaeangliae* derives from the Greek for "big wing" (*mega* + *pteron*) and the Latin for "New England," which was the origin of the specimen used by Borowski in his description of the species in 1781.

II. Distribution and Ecology

Humpback whales are found in all oceans of the world (Fig. 2). They are a highly migratory species, spending spring through fall on feeding grounds in mid- or high-latitude waters, and wintering on calving grounds in the tropics, where they do not

Figure 1 *The long flippers of humpback whales are white, whereas the dorsum of the body is usually black. The display of the flipper is a small part of a spectacular behavioral repertoire that includes tail slashing, breaching, and other behaviors. Pieter A. Folkens/Higher Porpoise DG.*

eat (Dawbin, 1966). Humpback whales are typically found in coastal or shelf waters in summer and close to islands or reef systems in winter. Some documented MIGRATORY MOVEMENTS of this species represent the longest known migration of any mammal, being almost 5000 miles one way (Palsbøll *et al.*, 1997). Not all humpbacks migrate every year, although the sex/age class of nonmigratory animals remains unclear. Remarkably, the purpose of migration remains unknown; it may reflect a need to maximize energetic gain by exploiting pulses of productivity in high latitudes in summer and then gaining thermodynamic advantages by overwintering in warm water in winter. The only nonmigratory population is that residing in the Arabian Sea, where monsoon-driven productivity in summer permits the whales to remain in tropical waters year-round (Mikhalev, 1997).

In the North Atlantic, humpbacks return each spring to specific feeding grounds in the Gulf of Maine, Gulf of St. Lawrence, Newfoundland, Labrador, Greenland, Iceland, and Norway. Fidelity to these areas is strong and is determined by where a calf was taken by its mother in the former's natal year. Recent genetic analysis has indicated that this fidelity is maintained on an evolutionary time scale in at least Iceland and Norway (Palsbøll *et al.*, 1995; Larsen *et al.*, 1996). Despite this fidelity, whales from all feeding grounds migrate to the a common breeding area in the West Indies, where they mate and calve (Katona and Beard, 1990). Historically important breeding areas in the Cape Verde Islands and the southeastern Caribbean appear to be utilized by relatively few whales today.

In the North Pacific, there are at least four separate breeding grounds in Hawaii, coastal Mexico, offshore Mexico (Revil-

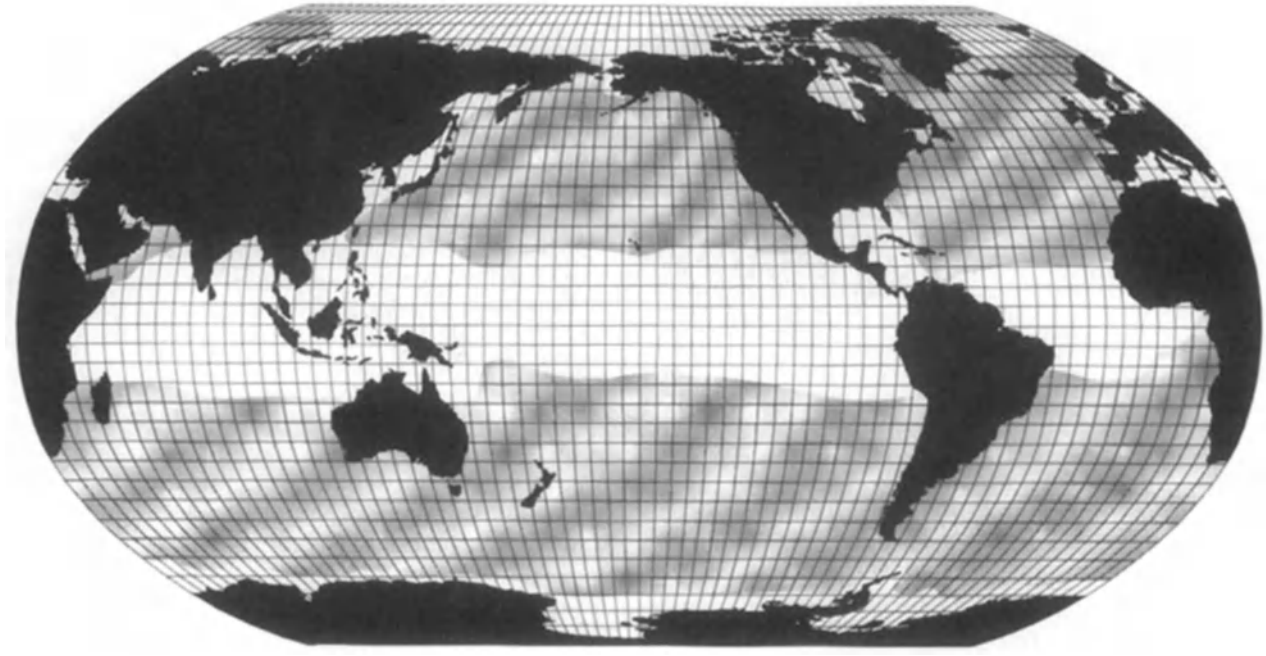

Figure 2 *The distribution of the humpback whale* (Megaptera novaeangliae) *illustrates a common pattern that, for the most part, excludes tropical warm waters in summer (Arabian humpbacks are an exception). The humpback is especially well known as a migratory species, tending to feed and mate at higher latitudes but calving at lower latitudes. From Perry* et al. *(1999); adapted from Johnson and Wolman (1984).*

lagigedos Islands), and Japan (Calambokidis *et al.*, 1997). Whales from these wintering areas migrate primarily to Alaska, California, possibly the Bering Sea, and the western North Pacific, respectively. However, crossover is not unknown and some transoceanic movements have been recorded (e.g., British Columbia to Japan and back).

In the Southern Hemisphere, humpbacks feed in circumpolar waters around the Antarctic and migrate to relatively discrete breeding grounds in tropical waters to the north. Six populations or "management areas" are recognized by the International Whaling Commission in the Southern Hemisphere, but some movement between these areas is very likely.

The humpback whale has a generalist diet, feeding on euphausiids and various species of small schooling fish. The latter include herring (*Clupea* spp.), capelin (*Mallotus villosus*), sand lance (*Ammodytes* spp.), and mackerel (*Scomber scombrus*). Humpbacks appear to be unique among large whales in their use of bubbles to corral or trap schooling fish. Whales blow nets, clouds, or curtains of bubbles around or below schools of fish and then lunge with mouths open into the center of the bubble structure (Jurasz and Jurasz, 1979; Hain *et al.*, 1982). As with other balaenopterids, the ventral pleats expand when a humpback is feeding, allowing the animal to increase the capacity of its mouth greatly.

Rake-mark scars from TEETH attest to the fact that humpbacks are commonly attacked by killer whales (*Orcinus orca*). However, it seems likely that fatal attacks are largely confined to very young calves, and predation does not appear to be a significant effector in the social organization of the humpback (Clapham, 1996).

III. Life History and Behavior

Breeding in humpback whales is strongly seasonal. Females come into estrus in winter, at which time testosterone production and spermatogenesis also peak in males (Chittleborough, 1965). The gestation period is about 11 months, with the great majority of calves born in midwinter. Calves probably begin to feed independently at about 6 months of age, but nursing likely continues in many animals until shortly before independence at about a year of age. Sexual maturity is reached in both sexes on average at 5 years. Interbirth intervals in females are most commonly 2 years, although annual calving is not unknown (Clapham and Mayo, 1990; Glockner-Ferrari and Ferrari, 1990). Although multiple fetuses have been recorded in dead pregnant females, living twins or multiplets are unknown.

The social organization of the humpback is characterized by small unstable groups, and individuals typically associate with many companions on both feeding and breeding grounds (Clapham, 1996). Longer-term associations (those lasting days or weeks) are occasionally recorded, but their basis is unclear. There appears to be no territoriality in this species.

In winter, male humpback whales sing long, complex songs, the primary function of which is presumably to attract females. All whales in a given population sing essentially the same song, and although the form and content of all songs change over time, the whales somehow coordinate these changes. Males also compete very aggressively for access to females (Tyack and Whitehead, 1983), and the resulting "competitive groups" can last for hours and involve tail slashing, ramming, or head butting. Males may also form coalitions, but further research is required to assess the significance and composition of such alliances.

In part because of the prominent male display aspect (i.e., singing behavior), the mating system has been compared to a lek (Mobley and Herman, 1985), although it does not possess the rigid territoriality common to such systems. Males almost certainly remain in breeding areas longer than females and attempt to obtain repeated matings, whereas newly pregnant females return quickly to higher latitudes (Dawbin, 1966) where they will feed for many months in order to prepare for the considerable energetic cost of lactation.

Humpbacks are well known for their often spectacular aerial behaviors. These include breaching, LOBTAILING, and flippering. Such behaviors occur at all times of year and in a variety of contexts, and it is clear that they perform a range of functions. These may include play, COMMUNICATION, parasite removal, and expression of excitement or annoyance.

IV. Conservation Status

The humpback whale was heavily exploited by the whaling industry for several centuries. Because of its coastal distribution, it was often the first species to be hunted in a newly discovered area. This century, some 200,000 humpbacks were slaughtered in the Southern Hemisphere alone; of these, more than 48,000 were taken illegally by the Soviet Union (Yablokov *et al.*, 1998). It is quite likely that more than 90% of the animals in some populations were killed during the most intensive periods of exploitation. As a result, the humpback is considered an endangered species. Despite this, most studied populations appear to be making a strong recovery. The North Atlantic population has been estimated at 10,400 animals (Smith *et al.*, 1999) and the North Pacific at 6000–8000 (Calambokidis *et al.*, 1997). Strong population growth rates have been reported for many areas, ranging from 6.5% in the Gulf of Maine to more than 10% in some Southern Hemisphere populations (IWC, 1999). Commercial whaling for humpbacks officially ended worldwide in 1966, although the Soviets continued to hunt this species for some years afterward. Small aboriginal hunts for humpbacks still occur in a couple of locations, and many more whales die from entanglement in fishing gear or collisions with ships. However, none of these impacts appears to be significant at the population level, and the outlook for this once overexploited species appears good in most areas.

Hunting of Marine Mammals

RANDALL R. REEVES
Okapi Wildlife Associates, Hudson, Quebec, Canada

Ancient middens testify to the importance of marine mammals in the lives of early maritime people around the world. Many of the bones and bone fragments found in such sites probably came from animals that were scavenged from beaches. However, ingenious methods of capturing pinnipeds, sirenians, and cetaceans eventually were developed, and the archaeological refuse came to signify past hunting. The rewards were tempting—large amounts of nutritious meat and fat, hides, ivory, sinews for sewing, and bones for making household implements or weapons. These products eventually came to have high commercial value, fueling global whaling and sealing industries in modern times.

Among the marine mammals, no taxonomic group has been entirely spared from hunting pressure. However, some species have been hunted more intensively than others. The great whales (the sperm whale *Physeter macrocephalus* and the baleen whales) have been sought for their oil, meat, and baleen; pinnipeds for their oil or pelts; sea otters (*Enhydra lutris*) for their furs; and sirenians mainly for their flesh and skins. In contrast, some dolphin populations have hardly been hunted at all, and they remained secure until the advent and proliferation of unselective fishing methods, which result in the incidental killing of nontarget organisms. Marine mammals have also been hunted with the intention of reducing their predation on valued resources such as fish, crustaceans, or mollusks (Northridge and Hofman, 1999). This culling, often implemented through government-sponsored bounty programs, is similar to that directed at wolves, mountain lions, and other predators in parts of North America, with the outspoken support of ranchers and sport hunters.

I. Hunting of Whales, Dolphins, and Porpoises

People in the Arctic were hunting bowhead whales (*Balaena mysticetus*) as long ago as the middle of the first millennium, and western Europeans were taking right whales (*Eubalaena glacialis*) by the beginning of the second (Ellis, 1991; McCartney, 1995). While the technology and culture of subsistence whaling spread within the Arctic and sub-Arctic from the Bering Strait region, the Basques were responsible for the development and spread of commercial WHALING (see Section V). From its beginnings in the Bay of Biscay, this whaling eventually reached all of the world's oceans and involved people of many nationalities. Modern whaling, characterized by engine-driven catcher boats and deck-mounted harpoon cannons firing explosive grenades, began in Norway in the 1860s (Tønnessen and Johnsen, 1982). A key feature of modern whaling was that it made possible the routine capture of any species, including the blue whale (*Balaenoptera musculus*), fin whale

(*B. physalus*), and other fast-SWIMMING balaenopterines. In the first three-quarters of the 20th century, factory ships from several nations (e.g., Norway, the United Kingdom, Germany, Japan, the United States, and the Soviet Union) operated in the Antarctic, the richest whaling ground on the planet. At its pre-War peak in 1937–1938, the industry's 356 catcher boats, associated with 35 shore stations and as many floating factories, killed nearly 55,000 whales, 84% of them in the Antarctic.

Commercial whaling declined in the 1970s as a result of conservationist pressure and depletion of whale stocks. The last whaling stations in the United States and Canada were closed in 1972, and the last station in Australia ceased operations following the 1978 season. By the end of the 1970s, only Japan, the Soviet Union, Norway, and Iceland were still engaged in commercial whaling. With the decision by the INTERNATIONAL WHALING COMMISSION (IWC) in 1982 to implement a global moratorium on commercial whaling, Japan and the Soviet Union made their final large-scale factory-ship expeditions to the Antarctic in 1986/1987, and Japan stopped its coastal hunt for sperm whales (*Physeter macrocephalus*) and Bryde's whales (*Balaenoptera edeni*) in 1988. Iceland closed its whaling station in 1990 and shortly thereafter withdrew its membership in the IWC. Contrary to the widespread belief that commercial whaling had ended, however, Norway and Japan continued their hunting of minke whales through the 1990s. By formally objecting to the moratorium decision, Norway reserved its right to carry on whaling. Thus, Norwegian whalers continued to kill more than 500 northern minke whales per year in the North Atlantic. Using a provision in the whaling treaty that allows member states to issue permits to hunt protected species for scientific research, Japan continued taking more than 400 southern minke whales in the Antarctic and 100 northern minke whales in the western North Pacific each year. In 1999, the Icelandic parliament approved the resumption of a shore-based commercial hunt. Because the main incentive for commercial whaling in the 1990s was Japanese demand for whale meat, Norway and Iceland were eager to reopen the international trade in whale products. Norway continued to stockpile meat and blubber in anticipation that the trade ban under the Convention on International Trade in Endangered Species of Wild Fauna and Flora would be lifted.

The hunting of smaller cetaceans has generally been confined to coastal waters and conducted on a smaller, or at least localized, scale. There are, however, some examples of large, well-organized hunts (Mitchell, 1975). Fishermen in the Faroe Islands have continued to kill hundreds, and in some years well over a thousand, long-finned pilot whales (*Globicephala melas*) and Atlantic white-sided dolphins (*Lagenorhynchus acutus*) in a drive fishery that is centuries old. The driving method involves a number of small boats that herd the animals into shallow water where they can be killed with lances, long knives, or firearms. There has also been a long-standing drive fishery in Japan, taking a variety of delphinid species, most notably striped dolphins (*Stenella coeruleoalba*). The Japanese hunt for small cetaceans involves other methods as well, including the hand-harpooning of dolphins and Dall's porpoises (*Phocoenoides dalli*) and the use of harpoon guns to take short-finned pilot whales (*G. macrorhynchus*) and other medium-sized cetaceans. A large commercial hunt for dolphins (*Delphinus delphis* and *Tursiops truncatus*) and harbor porpoises (*Phocoena phocoena*) was conducted in the Black Sea from the 19th century through the mid-1960s (the Soviet Union banned dolphin hunting in 1966), and this hunting with rifles and purse seines continued in the Turkish sector until at least 1983.

Aboriginal hunters in Russia, the United States (Alaska), Canada, and Greenland kill several tens of bowhead whales, 100–200 gray whales (*Eschrichtius robustus*), and many hundreds of white whales (*Delphinapterus leucas*), narwhals (*Monodon monoceros*), and harbor porpoises (Greenland only) each year (Fig. 1). This hunting is primarily for food, and the products are generally consumed locally or sold within proscribed markets (see Section V). In recent years, aboriginal whalers in Washington State (USA), British Columbia (Canada), and Tonga (a South Pacific island nation) have expressed interest in reestablishing their own hunts for large cetaceans. In fact, in the spring of 1999, the Makah tribe in Washington took their first gray whale in more than 50 years.

Figure 1 *Adult white whales (belugas) killed by Eskimos in Kasegaluk Lagoon near Point Lay on the Chukchi Sea coast of Alaska in July 1993. Canoes powered by outboard motors are used to drive the whales toward shore before killing them with rifles (top). The flukes, flippers, and skin with adhering blubber (locally called maktak) are saved as a delicacy (bottom). Courtesy of Greg O'Corry-Crowe.*

II. Pinnipeds

Sealing began in the Stone Age when people attacked hauled-out animals with clubs (Bonner, 1982). Later methods included the use of harpoons thrown from skin boats and gaff-like instruments for killing pups on ice or beaches. Traps and nets were used as well. The introduction of firearms transformed the hunting of pinnipeds and caused an alarming increase in the proportion of animals that were killed but not retrieved, especially in those hunts where the animals were shot in deep water before first being harpooned. This problem of "sinking loss" also applies to many cetacean hunts.

In addition to their meat and fat, the pelts of some seals, especially the fur seals and phocids, are of value in the garment industry. Markets for oil and sealskins fueled commercial hunting on a massive scale from the late 18th century through the early 20th century (Busch, 1985). The ivory tusks and tough, flexible hides of walruses (*Odobenus rosmarus*) made these animals exceptionally valuable to both subsistence and commercial hunters. At least 10,000 walruses are killed every year, most of them by the native people of northeastern Russia, Alaska, and northeastern Canada. The killing is accomplished mainly by shooting. The meat, BLUBBER, and skin are eaten by people or fed to dogs, while the tusks are either used for carving or sold as curios. Native hunters in the circumpolar north also kill more than a hundred thousand seals each year, mainly ringed seals (*Pusa hispida*) but also bearded (*Erignathus barbatus*), ribbon (*Histriophoca fasciata*), harp (*Pagophilus groenlandicus*), hooded (*Cystophora cristata*), and spotted seals (*Phoca largha*) (Fig. 2). Seal meat and fat remain important in the diet of many northern communities, and the skins are still used locally to make clothing, dog traces, and hunting lines. There is also a limited commercial export market for high-quality sealskins and a strong demand in Oriental communities for pinniped penises and bacula. The sale of these items, along with walrus and narwhal ivory, white whale and narwhal skin (maktak), and polar bear (*Ursus maritimus*) hides and gall bladders, has helped offset the economic losses in some local hunting communities caused by the decline in international sealskin markets.

Figure 2 *Greenlanders butchering a bearded seal in Wolstenholme Fjord in June 1988. Bearded seals are especially prized by native people of the circumpolar north because of their tasty meat and tough, flexible hide. The hide is used to make leather lines, boat and tent covers, boot soles, and various other items. Courtesy of Steve Leatherwood.*

The scale of commercial sealing, like that of commercial whaling, has declined considerably since the 1960s. It continues, however, in several parts of the North and South Atlantic. After a period of drastically reduced killing in the 1980s, the Canadian commercial hunt for harp and hooded seals has been reinvigorated, at least in part as a result of governmental subsidies. An estimated 350,000 harp seals were taken by hunters in eastern Canada and West Greenland in 1998 (Lavigne, 1999). A few tens of thousands of molting pups are clubbed to death on the sea ice, but the vast majority of the killing is accomplished by shooting.

Norwegian and Russian ships continue to visit the harp and hooded seal grounds in the Greenland Sea ("West Ice") and Barents Sea ("East Ice"), taking several tens of thousands of seals annually. Also, thousands of South African fur seals (*Arctocephalus pusillus pusillus*) and South American fur seals (*A. australis*) have been taken annually in southwestern Africa and Uruguay, respectively. These hunts are centuries old, having been driven initially by commercial markets for skins and oil and, more recently, by the Oriental demand for seal penises and bacula. Also, especially in Africa, the hunt has been justified as a response to concerns about competition between seals and fisheries.

III. Sirenians

Sirenians have been hunted mainly for their delectable meat and blubber and their strong hides. The Steller's sea cow (*Hydrodamalis gigas*) was hunted to extinction within about 25 years of its discovery by European sea otter and fur seal hunters. Much like tortoises on tropical islands, the sea cows were easy to catch and provided local sustenance to ship crews, enabling the men to carry on their pursuit of fur, oil, and other valuable resources. Local people in West Africa and Central and South America used manatee hides to make shields, whips, glue, and plasters for dressing wounds. Large-scale commercial killing of Amazonian manatees (*Trichechus inunguis*) to supply mixira (fried manatee meat preserved in its own fat) took place in Brazil from the 1780s to the late 1950s, and manatee hides were in great demand for making heavy-duty leather products and glue between 1935 and 1954 (Domning, 1982). Dugongs (*Dugong dugon*), like manatees, have long been a prized food source for seafaring people throughout their extensive Indo-Pacific range (Nietschmann, 1984). It is impossible to make a reasonable guess of how many manatees are killed by villagers each year in West Africa and South America, but the total (three species, combined) is probably in the thousands. Hunting of dugongs continues in much of their range, including areas where the species is almost extinct.

Sirenians have been captured using many different methods, apart from simply stalking and lancing or harpooning them from boats, or setting nets to enmesh them. People in West Africa and South America developed ingenious fence traps and drop traps to catch manatees. These could be baited to attract the animals or just placed strategically to take advantage of

their natural movements through constricted channels. Dugong hunters in some areas used underwater explosives to kill their prey. In Torres Strait between Australia and New Guinea, portable platforms were set up on seagrass beds, and the hunter waited there overnight for opportunities to spear unsuspecting dugongs as they grazed.

IV. Sea Otters and Polar Bears

Sea otters have been cursed by the luxuriance of their pelts, which are among the most desirable of all mammalian furs. They were hunted remorselessly to supply the Oriental market from the 1780s onward—until very few were left and protection came in 1911. As otters were depleted in a region, hunting efforts there would be redirected at fur seals. Although anchored nets were sometimes used to catch sea otters (Kenyon, 1969), most of the hunting was conducted by men in boats, using lances initially and rifles later on. In California, otters were sometimes shot by men standing on shore, and in Washington, shooting towers were erected at the surf line and Indians were employed to swim out and retrieve the carcasses (Busch, 1985). Aboriginal people in Alaska are still allowed to hunt sea otters as long as the furs are used locally to make clothing or authentic handicraft items. The reported annual kill during the mid- to late-1990s was in the range of 600–1200.

Polar bears have always been prime targets of Eskimo hunters, and non-Eskimo sport hunters have taken large numbers of bears as trophies (Stirling, 1988). At least several hundred polar bears are still killed each year, most of them by Eskimos for meat and the cash value of their hides. In Canada, the hunting permits allocated to native communities are often sold to sport hunters, on condition that a local guide accompany the hunter and that only the head and hide be exported. These expeditions generally involve dogsled travel, thus reinvigorating a traditional mode of winter transportation while at the same time creating a need for more hunting—to obtain fish and marine mammal meat to feed to the dogs. Today, polar bears are killed almost exclusively by shooting them with high-powered rifles, but in the past they were also hunted with baited set-gun traps in Svalbard. A small number of polar bears are killed each year in self-defense.

V. Market (Commercial) vs Subsistence (Household-Use) Hunting

An important, although often problematical, distinction has been made between hunting for profit and hunting as a means of survival. This distinction is more than academic. The nature and degree of regulation have often depended on how a given hunter's enterprise was classified. The dichotomy between "commercial" and "subsistence" exploitation has had particular meaning in the context of the worldwide regulation of whaling. The IWC recognizes "aboriginal subsistence" whaling as a special category and has traditionally exempted certain groups of whalers from regulation. Similarly, many national and multilateral restrictions on sealing have applied only or primarily to industrial operations and not to "aboriginal" hunters hunting for "subsistence" (e.g., the U.S. Marine Mammal Protection Act and the North Pacific Fur Seal Convention).

Initially, the reasoning behind such special treatment was that these hunters used less destructive or wasteful gear and methods, and served only local, relatively small markets. However, those criteria are now called into question as aboriginal hunters have adopted modern weaponry and mechanized transport, and have increasingly chosen to sell their produce for cash. Some products, notably sealskins and the ivory obtained from walruses and narwhals, enter a global marketplace.

Anthropologists argue that the term "subsistence" should be broadly defined and not exclude cash-based exchanges when these occur within a context that emphasizes local production and consumption. They point to the fact that modern Eskimos, for example, are simply adapting to a changing world by hunting marine mammals with rifles, outboard motors, and snowmobiles. Only by selling skins, tusks, and, in the case of polar bears, their own services as hunting guides are these traditional hunters able to obtain the cash needed to live comfortably while continuing to be engaged in a domestic mode of production, providing highly esteemed and nutritious food for their home communities. Indeed, the IWC still considers Greenland whaling for minke and fin whales to be "aboriginal subsistence" whaling even though most of the whales are killed with deck-mounted harpoon guns firing explosive grenades and the meat and other products enter a country-wide, cash-based exchange network (Caulfield, 1997). At the same time, the IWC has resisted Japan's efforts to have "small-type coastal" whaling, which also serves a domestic but cash-based market, reclassified as something other than commercial whaling.

The difficulty of distinguishing commercial from subsistence hunting is not unique to situations involving marine mammals. Similar issues have arisen in relation to the trade in "bush meat" in Africa, Asia, and the Neotropics. Unregulated hunting is incompatible with the concept of sustainability. Considering the enormous increases in killing power afforded by firearms and mechanized transport, together with rapid human population growth and the attendant rise in resource consumption, we are long past a time when racial or cultural entitlement can be allowed to preclude a vigorously enforced management regime based on conservation principles.

VI. Future Hunting

For two reasons, the hunting of marine mammals in the foreseeable future is unlikely to approach the scale at which it was pursued throughout the 19th and much of the 20th century. First, the populations of many species remain far below earlier levels. Even if some recovery is achieved, the environmental carrying capacity has almost certainly declined in many instances. Considering the low productivity of these relatively large, long-lived animals, it is unrealistic to expect their aggregate biomass to return to "pristine" levels in a world so thoroughly transformed by human endeavor. Second, attitudes toward marine mammals have changed considerably, and any initiative to expand the scope or scale of hunting is subject to public scrutiny as never before. Many people, particularly in the United States, Europe, and Australasia, are morally opposed to the killing of cetaceans, if not all marine mammals. While this certainly does not mean that hunting will stop

altogether, it does make it more likely that hunters will need to prove that their enterprise is both sustainable (within the productive capacity of the affected animal population) and humane.

Hybridism

MARTINE BÉRUBÉ
University of California, Berkeley

Speciation is assumed to be a function of genetic divergence caused by reproductive barriers between gene pools (i.e., different populations). Traditionally, species are either *allopatric* or *sympatric*. In the case of sympatric species mechanisms such as temporal segregation, behavioral differences, and gametic incompatibilities ensure reproductive isolation. Hybridization denotes the successful mating between two individuals from different and reproductively isolated gene pools accepted as species. Hybridization is observed frequently among higher plants, but only rarely among vertebrates. Within mammals, hybrids have been recorded in a number of marine as well as terrestrial species. The evolutionary consequences of such hybrids vary depending on the frequency, the degree of genetic differences between the parental species, mating system, and the ecological circumstances.

The examination of hybrids has always attracted much attention, as such incidences and their frequency might provide clues to reproductive behavior, dispersal capabilities, and phylogenetic relationship of species. As might be expected, hybrids are more common within genera where the different species have similar life histories and habitat requirements. When the frequency of hybridization is low, the fitness of the hybrids is generally low as well and hybrids usually are nonviable or sterile and thus do not represent a threat to the genetic constitution of the parental species. However, as the frequency of hybridization increases, so may the number of viable and reproductive hybrids, which in turn might cause the breakdown of previous reproductive barriers between the two species. One evolutionary consequence of such a scenario is introgression. A recent well-documented example of this is the high incidence of coyote genes in what morphologically seem to be gray wolves observed in North America (Lehman *et al.*, 1991). The ultimate evolutionary consequence of introgression is the extinction of the species whose genome is being replaced by the other.

With regard to marine mammals, a total of some 61 cases of alleged hybridization have been described; 40 within Cetacea and 21 within the pinniped Carnivora. Putative hybrids have been observed in captivity as well as in the wild. Most of the marine mammal hybrids reported so far have only been described morphologically. However, molecular techniques have been applied in some cases in order to confirm the identity of hybrids and identify the parental species.

I. Evidence of Mating between Species

Although the theoretical expectation is that male and female genital morphology evolves continuously and thus makes interspecific mating difficult or impossible, attempts of interspecific mating have been observed between pinniped species where no hybrids have yet been reported. Such mating appears to be aggressive, and usually the heterospecific male is much larger than the female. Often the female does not survive such a mating (Miller *et al.*, 1996).

This kind of aggressive interspecific mating was first observed between a male gray seal (*Halichoerus grypus*) and a female harbor seal (*Phoca vitulina*) (Wilson, 1975). Later reports of such aggressive behaviors include mating between (i) a male New Zealand sea lion (*Phocarctos hookeri*) and a dead female New Zealand fur seal (*Arctocephalus forsteri*) (King, 1983), (ii) a south American sea lion (*Otaria flavescens*) and a South American fur seal (*A. australis*) (Miller *et al.*, 1996), (iii) a female California sea lion (*Zalophus californianus*) and a male Steller sea lion (*Eumetopias jubatus*) (Miller *et al.*, 1996), (iv)

and finally between southern elephant seals (*Mirounga leonina*) and Australian fur seals (*A. pusillus*) (Miller *et al.*, 1996).

The aggressive mating by sea lions with heterospecific females has been interpreted as "excess of violent sexual selection" (Miller *et al.*, 1996). This aggressive behavior seems to be widespread in the family Otariidae (eared seals), and possibly the number of hybrids is much higher than reported to date.

II. Reported Occurrences of Hybridization in Captivity

Among captive cetaceans, 25 hybrids have been identified, all within the suborder Odontoceti (toothed whales). All hybridizations occurred between seven species of the Delphinoidea superfamily, where the bottlenose dolphin, *Tursiops truncatus*, was one of the parental species in all cases (see Table I, Fig. 1). The majority of these hybrids have not survived. However, a first-generation hybrid between a bottlenose dolphin (*T. truncatus*) and a false killer whale (*Pseudorca crassidens*) has given birth twice after mating with a bottlenose dolphin (Duffield, 1998). When these occurrences were reported in 1998, one of the two calves from this second generation was still alive. Finally, within the pinnipeds, hybridization in captivity has been observed within the two families Phocidae (earless seals) and Otariidae (eared seals) (see Table I).

III. Reported Occurrences of Hybridization in the Wild

Probably the most impressive occurrences of hybridization among marine mammals are those identified within the suborder Mysticeti (baleen whales). A total of 11 hybrids among baleen whale species have been reported so far; all of these were captured during commercial whaling operations. In all incidences the parental species involved were a blue (*Balaenoptera musculus*) and a fin whale (*B. physalus*). The first report of such anomalous baleen whales was in 1887 by A. H. Cocks (1887), who recorded 6 hybrids, or "Bastards," along the Lapland coast. However, this number is likely to be an underestimate as the author mentioned that sometimes hybrids were entered in their records as a fin whale instead of "Bastard." Later, Doroshenko (1970) reported a hybrid between a blue and fin whale, taken in 1965 off Kodiak Island (in the Gulf of Alaska), identified from its exceptional but intermediate morphological traits.

More recently, three anomalous baleen whales, one female and two males, caught during the Icelandic whaling operations between 1983 and 1989 were described morphologically as fin/blue whale hybrids. The parental species of these specimens were later confirmed by molecular analyses of the maternally inherited mitochondrial genome as well as Mendelian-transmitted nuclear genes (Árnason *et al.*, 1991; Spilliaert *et al.*, 1991). Interestingly, the female Icelandic fin/blue whale hybrid was in her second pregnancy. Molecular analyses of the fetus found that it was the result of a mating between the hybrid mother and a male blue whale. Finally, a fin/blue whale hybrid caught off northwest Spain in 1984 was identified morphologically, and subsequent molecular analyses found the maternal species to be a blue whale and the paternal species a fin whale (Bérubé and Aguilar, 1998).

Within the Odontoceti, the first three hybrids described were from a stranding on the West Coast of Ireland in

Blacksod Bay (Fraser, 1940). Morphological analysis concluded that the three stranded specimens were hybrids from matings between bottlenose and Risso's dolphins (*Grampus griseus*). The occurrence of as many as three hybrid individuals in the same stranding, each a cross of the same parental species, is highly unusual given the overall low rate of hybridization among cetaceans per se. For the same reason, Fraser himself first thought the hybrids to be a novel species rather than hybrids. Since the stranding in Blacksod Bay, only a single incidence of hybridization in the wild has been reported within the family Delphinidae. This specimen was caught by fishermen off the Peruvian coast and determined to be a hybrid between common (*Delphinus capensis* or *delphis*) and dusky dolphin (*Lagenorhynchus obscurus*) based on its morphology (Reyes, 1996).

In 1990, an anomalous whale skull was collected in Disko Bay at west Greenland. The morphological characteristics of this skull were intermediate between those of adult narwhal (*Monodon monoceros*) and beluga (*Delphinapterus leucas*), and the authors hypothesized that the specimen was likely a narwhal–beluga hybrid (Heide-Jøgensen and Reeves, 1993).

The most recent case of hybridization reported within Odontoceti is a female fetus recovered from a dead Dall's porpoise (*Phocoenoides dalli*). Morphological and molecular analyses determined the fetus as a cross between a Dall's and a harbor porpoise (*Phocoena phocoena*) (Baird *et al.*, 1998).

The most common occurrence of hybridization in pinnipeds is between the sub-antarctic (*Arctocephalus tropicalis*) and the Antarctic fur seal (*A. gazella*) (Table II). Based upon the population estimates for each of the two species and the frequency of hybrids, the magnitude of hybridization has been estimated to represent 9.3 and 0.1% of the *A. gazella* and *A. tropicalis* populations, respectively (Kerley, 1983).

IV. Evolutionary Implications of Hybridization

The evolutionary significance of hybridization is not known, but hybridization does provide an opportunity for gene flow between otherwise isolated gene pools, e.g., exchange of adaptive traits. Among marine mammals, hybridization has been shown to occur between a variety of species (Tables I and II). However, the overall rate of hybridization appears to be quite limited, and no cases of introgression have yet been identified. The apparent scarcity of hybrids may not be a true reflection of the actual rate, i.e., it is possible that hybrids simply are overlooked or not reported (during commercial or subsistence whaling) in order to avoid sanctions for killing protected species (e.g., blue whales). Furthermore, the identification of hybrids so far has relied primarily on morphological characters, which usually require that the specimen be killed. However, the introduction of nonlethal methods (Lambertsen, 1987) to obtain the necessary tissue for molecular methods as skin biopsies from free-ranging cetaceans makes it a simple task to identify hybrids today.

Marine mammals are genetically relatively similar. In comparison, the level of genetic divergence between the fin and the blue whale is similar to that observed among human (*Homo sapiens*), chimpanzee (*Pan troglodytes, P. paniscus*), and gorilla (*Gorilla gorilla*) (Árnason and Gullberg, 1993). Even within all cetaceans, where mysticetes and odontocetes probably diverged some 40 million years ago, nearly all species have the same num-

Figure 1 *Hybridization can occur in both natural and captive settings. Instances are more common between closely related taxa, but the ability to hybridize is not always indicative of close phylogenetic affinity. Pictured here is a hybrid between* Tursiops *and* Steno. *Photo by S. Leatherwood.*

ber of chromosomes ($2n=44$; a few have $2n=42$) and similar karyotypes. Among the pinnipeds, more variation in chromosome number has been detected; the number of diploid chromosomes can be from 32 to 36 (Árnason, 1990). The relatively similar genetic background and often sympatric existence (in feeding or breeding range) among closely related marine mammals would seem to favor hybridization. However, as mentioned earlier, hybridization is rare, and between species where several hybrids have been observed (such as the fin and the blue whale), the genetic integrity of the parental species appears intact.

It has been argued that hybrids of the heterogametic sex (males in mammals with a single X and Y chromosome) were most likely to be sterile or nonviable (Haldane, 1922). Since then, evolutionary geneticists have been looking to test this "Haldane's" rule. Among cetaceans, specifically the family Mysticeti, the only two male blue/fin whale hybrids examined to date were both sexually immature despite their relatively high age (Árnason *et al.*, 1991). Although consistent with Haldane's rule, which has been supported in a number of terrestrial mammals, the small sample size makes it impossible to assess with certainty if the rule applies to marine mammals as well.

The incidence of anomalous marine mammals reported so far has shown that hybridization does occur in captivity as well as in natural settings. Some of these hybrids (mainly in captive animals) have been carried to term and survived. However, only a single case has produced viable calves (unfortunately, the time of birth was not mentioned), of which only one was reported still alive in 1998 (Duffield, 1998). In the case of captive animals, it is difficult to assess if the seemingly low viability of the offspring is related to their hybrid origin or to the general low rate of survival in observed captive-born cetaceans (Van Gelder, 1977). Nonetheless, the observed occurrences of viable and fertile hybrids in captivity suggest that such could happen in the wild. However, to date no offspring of a hybrid has been observed alive in the wild. Whether this is due to our limited ability to detect such hybrids or if indeed (as the lack of introgression indicates) that such viable offspring from hybrids are rare is still an open question.

Identification Methods

RANDALL S. WELLS
Chicago Zoological Society, Illinois

Individual identification is an important tool for studies of animal behavior, ecology, and population biology. Much can be learned from recognition of individuals within a population or social unit, or from tracking individuals through time. Repeated observations of a recognizable individual can help to define its ranging patterns or site fidelity or to quantify habitat use. Behavioral studies benefit greatly from the ability to recognize individuals. Individual identification is essential to understanding group compositions, and this understanding is enhanced when the individual's gender, age, genetic relationships, and reproductive condition are known. Similarly, interpretation of social interactions requires the ability to distinguish between the players. Behavioral descriptions often involve measurements of rates of occurrence of behaviors. These rates are measured most accurately when a selected individual is followed through time or when the individual's behaviors are recorded at predetermined intervals, a process referred to as focal animal behavioral observations (Altmann, 1974).

Descriptions of life history patterns and empirical measures of population dynamics can be facilitated by individual identification (Hammond *et al.*, 1990). By following individuals through time it is sometimes possible to determine age at sexual maturity, calving intervals, calf survivorship, and life span, providing measures of reproductive success. Combined, such individual measures can provide population level vital rates, including birth rates, mortality rates, and recruitment (e.g., Wells and Scott, 1990). Mark-recapture techniques use individual identification to arrive at abundance estimates. Individual identification provides one of the best tools for documenting exchanges of individuals between populations, allowing estimation of rates of immigration and emigration.

Selection of specific identification techniques depends on the research questions being addressed and the species under study. Frequent monitoring of individuals may require the ability to readily identify animals from a distance at each encounter, whereas other studies may only need to recognize an animal when it is handled subsequently, alive or at the end of its life. Some species exhibit individually specific natural markings that facilitate identification in the field. Other species lack such distinctive markings and require the attachment of artificial marks, or tags, if individual identifications are desired. Some species are visible on land at times, whereas others are entirely aquatic. Morphological, behavioral, and ecological features must be considered in order to determine what kind of tag or attachment is most appropriate in terms of safety to the animal and effectiveness for the research. It is now also possible to collect small samples of tissues that allow the identification of individuals genetically. Individual identification techniques have been summarized recently for cetaceans, pinnipeds, and sirenians (Hammond *et al.*, 1990; Scott *et al.*, 1990; Würsig and Jefferson, 1990; Erickson *et al.*, 1993; Wells *et al.*, 1999).

I. Cetaceans

A. Natural Markings

Cetaceans exhibit a variety of individually distinctive natural features. In most cases, features appearing above the surface of the water during the respiratory cycle are most useful. In particular, heads, backs, dorsal fins, and flukes are used most frequently for individual identification, with variations occurring in color patterns, skin patches, body scarring, and nicks and notches along fin edges (Hammond *et al.*, 1990). Some individuals of most cetacean species acquire distinctive scars from previous wounds or injuries, which are often used for identifications. Perhaps the most unique features used to identify individual cetaceans are the callosities of the right whales, *Eubalaena* spp. (Payne *et al.*, 1983). These individually distinctive raised patches of roughened skin are present on the rostrum anterior to the blowholes in a pattern referred to as the bonnet, on the chin, lower lips, above the eyes, and near the blowholes. WHALE LICE, cyamid crustaceans that frequently live on the callosities, often give them a white, orange, yellow, or pink appearance. Callosities have allowed for the reliable recognition of individuals over periods of decades.

Color variations, where they exist among cetacean species, have been used with much success for individual identification,

especially among the mysticetes (Hammond *et al.*, 1990). Reminiscent of "Moby Dick," a few anomalously white individuals have been noted for several species of large and small cetaceans, offering unusual opportunities for individual identification. Blue whales (*Balaenoptera musculus*) and gray whales (*Eschrichtius robustus*) exhibit individually distinctive mottling on their backs (Fig. 1). The dorsal fin and dorsal ridge, respectively, are used as reference points for locating mottling patterns on these species. Bowhead whales (*Balaena mysticetus*) often have a distinctive pattern of white pigmentation on the chin and/or caudal peduncle. These patterns are readily seen from aircraft, the most commonly used observation platform for this arctic species. Fin whales (*Balaenoptera physalus*) exhibit strongly asymmetrical body pigmentation, with the lower and upper lips and first third of the baleen on the right side of the head appearing white or pale gray, while the left side lips and baleen are dark. A light-colored "blaze" sweeps back on the right side, and a V-shaped light-colored "chevron" occurs on both sides behind the blowhole. Minke whales (*B. acutorostrata* and *B. bonaerensis*) exhibit a pattern of pale lateral pigmentation on the body, often divided into three distinct swaths, with the relative brightness of the three swaths apparently varying consistently between northern and southern hemispheres. The distinctive dark and white patterns of the flippers and ventral surface of the flukes are familiar identification features for humpback whales, *Megaptera novaeangliae* (Katona *et al.*, 1979).

Some of the smaller cetaceans also exhibit useful color variations, from the perspective of the researcher. Most notable are the light colored saddled patches behind the dorsal fin of the killer whale (*Orcinus orca*), which differ in size and shape. Similar features are used for short-finned pilot whales (*Globicephala macrorhynchus*), though the saddle marks are less distinct. Dorsal fin and/or back pigmentation variation has proven useful in studies of Dall's porpoises (*Phocoenoides dalli*), Pacific white-sided dolphins (*Lagenorhynchus obliquidens*), Risso's dolphins (*Grampus griseus*), and Hector's dolphins (*Cephalorhynchus hectori*), and facial color patterns have been used to identify baiji (*Lipotes vexillifer*). Extensive speckling develops with age in spotted dolphins (*Stenella attenuata* and *S. frontalis*). Such speckling has provided much opportunity for individual identification from both above and below the water's surface in behavioral studies of Atlantic spotted dolphins (*S. frontalis*).

A variation of the color pattern is scarring that results in pigment variations. For example, Risso's dolphins acquire distinctive long-term white scars on their otherwise brown or gray bodies, and belugas (*Delphinapterus leucas*) acquire dark scars on their otherwise white bodies. Bottlenose dolphin (*Tursiops* spp.) scars on the dorsal fin often are white, in contrast to their general gray coloration. Cookie-cutter shark (*Isistius* spp.) bite wounds leave permanent small-diameter oval-shaped scars that are often depressed and pigmented differently from the rest of many pelagic cetaceans' bodies.

Dorsal fins typically are prominent features that are visible to researchers during most cetacean surfacings. In many cetacean species, dorsal fins develop distinctive shapes or acquire nicks and notches, often through intraspecific or interspecific interactions, that allow for individual identification. Among the larger whales, fin, sei (*Balaenoptera borealis*), Bryde's, minke, humpback, and sperm whale (*Physeter macrocephalus*) dorsal fins serve as useful identification features. Building on the pioneering work of Bigg (1982) with killer whales and Würsig and Würsig (1977) with bottlenose dolphins, studies based on dorsal fin identifications of various delphinids and other small cetaceans have blossomed in the last quarter century (Hammond *et al.*, 1990; Scott *et al.*, 1990; Würsig and Jefferson, 1990; Wells *et al.*, 1999). Species that have received the most attention include killer whales, bottlenose dolphins, pilot whales (*Globicephala* spp.), humpbacked dolphins (*Sousa* spp.), white-sided dolphins (*Lagenorhynchus acutus* and *L. obliquidens*), dusky dolphins (*L. obscurus*), Risso's dolphins, spinner dolphins (*Stenella longirostris*), Atlantic spotted dolphins, Heaviside's dolphins (*Cephalorhynchus heavisidii*), Hector's dolphins, harbor porpoises (*Phocoena phocoena*), Amazon River dolphins (*Inia geoffrensis*), tucuxi (*Sotalia fluvatilis*), and baiji (Fig. 2). The frequency of occurrence

Figure 1 *Distinctive color patterns of a blue whale. Photo by R. S. Wells.*

Figure 2 *Killer whale dorsal fins and saddle patches provide reliable identification cues. Photo by R. S. Wells.*

of distinctive fin features varies from species to species, and in some cases from population to population. Along the central west coast of Florida, approximately 60–80% of bottlenose dolphins are considered to be distinctive based on dorsal fin features. Unlike color patterns that vary from one side of the animal to the other, dorsal fin features are often equally visible from both sides and are distinctive under a broad range of lighting conditions, facilitating data collection in the field.

Some cetacean species regularly lift their flukes from the water prior to a dive, providing predictable opportunities for researchers to note the occurrence of nicks, notches, and other features on the trailing edge of the flukes. Humpback whales offer both distinctive color patterns as well as trailing edge features for identification (Fig. 3). Humpback whale flukes were among the first natural markings on cetaceans to be recognized for their individual specificity, and the technique has achieved extensive application worldwide in studies of population size and structure (Smith *et al.*, 1999). Sperm whales also demonstrate much individual-specific variability in fluke edge features.

Figure 3 *Distinctive dark and light patterns on the ventral surface of a humpback whale's fluke. Photo by R. S. Wells.*

Many of the cetacean features used by researchers for individual identification are visible above the surface of the water only briefly during respiratory cycles or are too subtle to be of use for accurate identification in real time. Most cetacean individual identification research involves the collection of permanent records of the distinctive features for subsequent detailed analysis through a process generally referred to as photoidentification. As the name indicates, the process frequently involves 35-mm photography of cetaceans. Advances in digital imaging through still cameras and video are expanding the capabilities and possibilities for individual identification and facilitating image processing, storage, and sharing.

At its most basic level, photoidentification involves trying to obtain high-quality, high-resolution, full-frame images of identifying features (Würsig and Jefferson, 1990). Although photoidentification can sometimes be accomplished from shore, typically scientists in research vessels, whale-watching boats, or aircraft attempt to place themselves in position to be able to obtain an image of the features that is parallel to the photographic plane (lens oriented perpendicular to the feature of interest). Telephoto lenses aid the researcher in enlarging the features to fill the photographic frame. Motor drives or video allow multiple images to be taken in quick succession to optimize capturing fins, backs, or flukes at their greatest perpendicularity and height above the water's surface, for example. Data backs that print the time and date on the image provide additional assurance that images and data records can be matched correctly during subsequent analyses. Film selection varies with species, lighting conditions, and researcher preference. The film must have sufficiently fine grain to be able to resolve distinctive features, while allowing a shutter speed setting sufficiently fast to "freeze" the animal but slow enough to optimize depth of field for focus. Some researchers use black and white film, especially if expense or ease of manual processing is a concern. Color film is often used when documentation of wounds or the freshness of fin features is desired, for example. The use of high-resolution digital cameras is rapidly gaining acceptance and will eventually make conventional filming a thing of the past.

Techniques for image storage, retrieval, and analysis vary greatly across research situations. Often, images in the form of slides, prints, or negatives are labeled and stored chronologically in archival plastic sheets in binders and then examined under magnification through a hand-held loupe or dissecting microscope. In recent years, computer scanning of images into files suitable for electronic storage or transmission over the Internet has become increasingly popular. Such scanning also facilitates computer-assisted automated analysis. Previously, photographic matches were made through the laborious process of individual comparison by eye of the image of interest to all possible matches in a catalog of distinctive individuals. Computer software has been developed that can search thousands of images of such animals as sperm whales, humpback whales, or bottlenose dolphins in a very short time to produce a limited set of potential matches. The researcher can then make the final match

using the exceptional resolving capabilities of the human eye. Additional rigor is often incorporated into the process through the use of multiple judges for difficult final identifications. Computer-assisted matching is becoming increasingly important as catalogs are now incorporating many thousands of individuals, and as contributions to centralized catalogs are being made by numerous researchers in widely dispersed locations.

Other kinds of "natural markings" that are being used increasingly are genetic markers from skin biopsy samples. Molecular analyses of small samples allow determination of gender and individual identification from genotypes provided by microsatellite loci. This technique was developed for large-scale use during an ocean basin-wide study of humpback whales in which photographs were used to identify 2998 individual whales and microsatellite loci were used to identify 2015 whales (Smith *et al.*, 1999). Based on the results of these initial studies, molecular techniques hold a great deal of promise for studies of a variety of cetaceans.

B. Temporary Markings

Natural temporary markings include skin lesions on parts of the body visible to researchers (Wilson *et al.*, 1999) and soft-bodied barnacles that attach to dorsal fins, for example. Such markings can be useful for distinguishing between otherwise unmarked animals within a group, but their changeable nature make them less reliable for accurate identifications over long periods. Skin lesions may take weeks to months to fully heal and disappear, but their characteristics change during the healing process. Soft-bodied barnacles favor dorsal fin tips for attachment, leading to low variability in positioning, thus minimizing their value for identification.

Anthropogenic temporary markings have been found to be of limited utility with cetaceans (as reviewed by Scott *et al.*, 1990). Remotely applied paint and tattoos have been tested with small cetaceans, and in all cases the animals were either not reidentified or the markings disappeared within 24 hr due to skin sloughing. In some cases, zinc oxide-based, brightly colored sun protection ointments have been applied to dolphins' dorsal fins prior to release. These have allowed for the short-term identification of animals otherwise lacking in distinctive marks, and transfer of colors between animals can indicate social interactions.

C. Scarring and Branding

Dorsal fin notching has been attempted in a few cases with killer whales, bottlenose dolphins, pantropical spotted dolphins (*Stenella attenuata*), and spinner dolphins (Scott *et al.*, 1990). Notching provides the same kinds of features used in the photographic identification of natural marks. Such notching requires capturing the animals, which also provide opportunities to learn the sex and age of the marked dolphin, as well as other biological information. One report indicated minor but persistent bleeding as a result of notching, but this has not been reported by others.

Freeze branding, using metal numerals 5–8 cm high applied to the animals' body or dorsal fin for 10–20 sec, has been used safely and successfully with a variety of small cetaceans, including bottlenose dolphins, spinner dolphins, short-beaked common dolphins (*Delphinus delphis*), Pacific white-sided dolphins, short-finned pilot whales, false killer whales (*Pseudorca crassidens*), Amazon River dolphins, and rough-toothed dolphins (*Steno bredanensis*) (Irvine *et al.*, 1982; Scott *et al.*, 1990). Freeze-brand application typically results in little or no reaction by dolphins, but minor skin lesions may occur if brands are applied for too long. Readable white marks usually appear within a few days (Fig. 4). Freeze brands fade over time, but the marks can often still be identified for many years in good-quality photographs even if they are not readily visible in the field. Fading appears to be age related, with brands disappearing more rapidly and more completely on younger animals but remaining readable on adults for as long as 11 years or more (Irvine *et al.*, 1982; Scott *et al.*, 1990).

D. Attachment Tags

The use of attachment tags for identification purposes (rather than telemetry, covered elsewhere in this volume), including

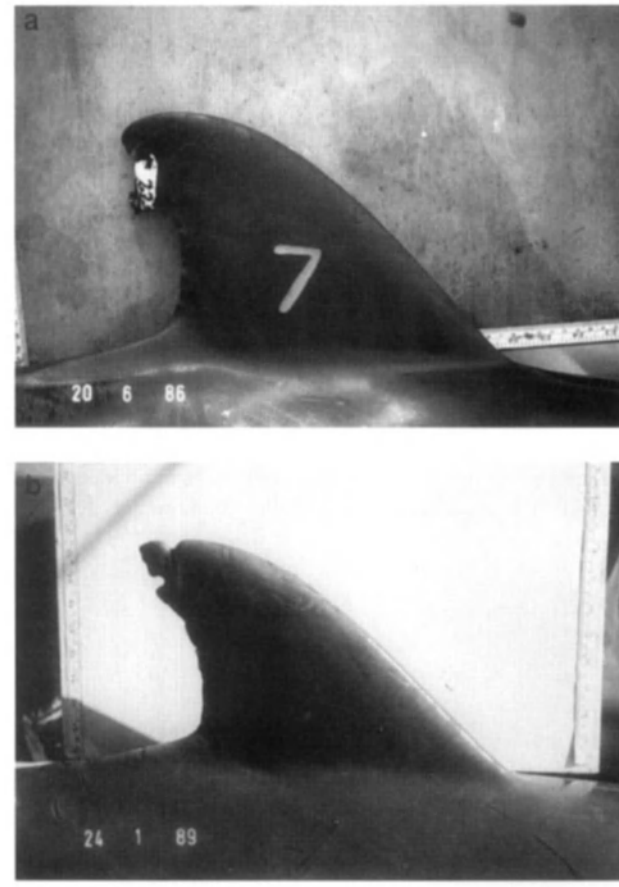

Figure 4 *(Top) Dorsal fin of a 2-year-old female bottlenose dolphin showing a fresh freeze brand ("7") above a year-old freeze brand and a 1-year-old roto tag. (Bottom) Dorsal fin of the same bottlenose dolphin at 5 years of age showing 3- and 4-year-old freeze brands, a naturally acquired notch at the top of the leading edge of the fin, and a notch formed from loss of a roto tag on the trailing edge of the fin. Photographs by Sarasota Dolphin Research Program.*

Discovery tags, spaghetti tags, button tags, and roto tags, has been reviewed by Scott *et al.* (1990). Discovery tags are numbered metal cylinders shot into the BLUBBER from whaling ships or research vessels. The tags have been used primarily with baleen and sperm whales and are recovered when the whales are captured and rendered, providing information on two points within the animals' range. Tagging was initiated in 1932 and continued until the whaling moratorium in 1985. More than 20,000 Discovery tags have been used, but return rates have been low, typically below 15%. Smaller versions of these tags have been used with small whales without notable success, and use with cetaceans less than 4.6 m long has been discouraged because of risk of serious injury.

Streamer or spaghetti tags, originally developed for fish tagging, are colored vinyl-covered strands of wire cable of variable length with steel or metal dart tips that are applied with either a crossbow or a jab stick, with the intent of anchoring the tip between blubber and muscle. Thousands of these tags have been applied to dolphins, porpoises, and belugas, especially in association with the tuna seine net fishery in the eastern tropical Pacific Ocean. Because of poor retention and high risk of injury to the animal, use of spaghetti tags with small cetaceans has been discouraged for many years (Irvine *et al.*, 1982).

Dorsal fins or ridges are commonly used for tag attachment because of their structure, prominence, and regularity of appearance above the water's surface. Button tags, typically numbered and colored fiberglass or plastic disks or rectangular plates designed after the Peterson disk fish tags, have been applied to several species of small cetaceans, including bottlenose dolphins, pantropical spotted dolphins, spinner dolphins, common dolphins, Pacific white-sided dolphins, belugas, and harbor porpoises (Evans *et al.*, 1972; Scott *et al.*, 1990). Usually, button tags are attached through the dorsal fin by means of one or more plastic (especially delrin) or stainless-steel bolts or pins that connect the tag halves on each side of the fin. Although some button tags have lasted for several years on pelagic dolphins, inshore animals often lose the tags within weeks or months, often by breaking them through rubbing on the shallow sea floor. Use of button tags has been largely discontinued due to poor tag retention and the potential for injury to the animals (Irvine *et al.*, 1982).

Small plastic cattle ear tags, or rototags, clipped through the trailing edges of dorsal fins have proved successful for identifying small cetaceans in the field, including bottlenose dolphins, pantropical spotted dolphins, spinner dolphins, common dolphins, rough-toothed dolphins, Pacific white-sided dolphins, short-finned pilot whales, and harbor porpoises (Fig. 4a; Norris and Pryor, 1970; Scott *et al.*, 1990). Typically, a small hole is made in the thin tissue of the trailing edge using a sterile technique, and the tag is clipped through the fin with special pliers. Although the written markings are too small to be read at a distance, the number of tags, color, and position on the fin provide a useful degree of variation. Rototags have remained in position of periods of years, although often they are lost within months. Rototag halves may separate, leaving a healed hole in the fin, or they migrate through the trailing edge of the fin, leaving a small healed notch; both pose minimal risks to the animals but offer continuing identification features. Barnacle and algae fouling and pressure necrosis are infrequent problems. As a modification of this technique, small VHF radio transmitters have been attached to rototags for short-term tracking (up to 30 days), with a modification involving the use of a corrosible nut system to release that tag at that time.

Other attachment techniques, such as the use of tethers or plastic-coated wires or polypropylene or soft rubber tubing, have proved to be ineffective and injurious to the animals when attached to the caudal peduncle. Tag loss rates have been high, and abrasions were frequently noted.

II. Pinnipeds

A. Natural Markings

Natural body markings have been used in only a few studies of pinnipeds such as gray seals (*Halichoerus grypus*), northern elephant seals (*Miromga angustirostris*), Steller sea lions (*Eumetopias jubatus*), Hawaiian monk seals (*Monachus schauinslandi*), harbor seals (*Phoca vitulina*), and California sea lions (*Zalophus californianus*). Yochem *et al.* (1990) examined pelage patterns of harbor and larga (*Phoca largha*) seals to distinguish between populations and individuals. Using black and white photographs they scored the presence or absence of spots, clarity of spots, relative density of spots, complexity of spots, presence of rings, and spacing of rings in selected body areas (especially sides of the head, neck, and chest). Hiby and Lovell (1990) described a computer-aided matching system for screening a library of digitized natural mark photographs of gray seals. Their system created a three-dimensional model to locate features on the seal's body, especially using the side of the neck. For most pinniped species, studies using natural markings are hampered by a lack of distinctive markings and the large numbers of individuals or pack ice distributions of many species (Erickson *et al.*, 1993). Most pinniped researchers have resorted to the use of artificial markings and tags for individual identification.

B. Temporary Markings

Techniques for temporary markings of pinnipeds include paints, dyes, bleaches, and pelage clippings (Erickson *et al.*, 1993). These techniques offer the advantages of often being able to be applied without having to restrain the animals and permitting remote identification without disturbance. However, these marks are typically lost upon moulting, precluding the continuity of identification beyond a single season. A variety of paints (marine, highway, rubber-based, quick-drying cellulose, aerosol sprays, and house paint) have been used to mark seals and sea lions. Paints have been applied from brushes or rollers on poles and from plastic bags thrown at the animals. Quick-drying paint has proved relatively effective, with a useful lifespan of about 1 month on average. Northern fur seals (*Callorhinus ursinus*) have been marked successfully for 2–12 months with a fluorescent plastic resin, naptha-based paint. This technique apparently results in the matting of guard hairs, which then break off, leaving an outline of the mark. High-gloss marine enamel applied from aerosol cans to mark Hooker's sea lions (*Phocarctas hookeri*) has resulted in markings lasting 3 months, even after the animals have been at sea. Carbon

dioxide-powered paint guns firing small capsules have proved less effective for marking elephant seals due to reliability problems and the small size of the marks.

Dyes have been used with several species of pinnipeds, especially light-colored species (Erickson *et al.*, 1993). Successful dying usually occurs when permanent dyes are used and when the animals are dry and remain out of the water for a period of time following application. Colored dyes and black Nyanzol D have lasted 3–4 months on gray seals, harbor seals, and California sea lions. The addition of alcohol to Nyanzol D leaves a more distinct marker because it dissolves fur oils and also prevents the dye solution from freezing. Yellow picric acid in a saturated alcohol solution has been used with gray seals, with results that last through pup molting, appearing on the adults as well. This solution can be applied from a backpack tree sprayer to wet or dry seals. Fluorescent dye mixed with small quantities of epoxy resin has also been used with success. In some cases, such as southern elephant seals (*Mirounga leonina*), dyes have been less successful.

Bleach offers a very effective and sometimes longer-lasting alternative to paints and dyes (Erickson *et al.*, 1993). Many of the bleach solutions can be applied to sleeping animals via a squeeze bottle, thus minimizing risk, effort, and disturbance. Commercially available products such as Lady Clairol Ultra Blue dye in combination with various chemicals have been used most often, resulting in a white or cream-colored mark that is most visible on dark pelages. Combinations resulting in thicker consistency allow for distinct lines. Bleach marks on elephant seals last until moult, sometimes for 6 months, and have lasted for two seasons on fur seals. Combinations of bleaches and dyes have also been used in some cases, such as northern elephant seals (Fig. 5).

Hair clipping is somewhat more difficult than the previous techniques, but effective when the underfur is a different color from the guard hairs (Erickson *et al.*, 1993). This technique involves clipping or singeing the pelage to create a distinctive mark. It has been used with success with northern fur seals, Steller sea lions, and Antarctic fur seals (*Arctocephalus gazella*).

C. Scarring and Branding

Punch marks and amputations have been used extensively with fur seals, with poor success and concerns about injury to the animals (Erickson *et al.*, 1993). Initial efforts to mark northern fur seals and Antarctic fur seals by punching holes in flippers in unique combinations of numbers and positions found this technique to be unreliable due to healing and occlusion. Hair on the flippers of phocids seals precludes utility with these species. Flipper notching was also found to be unreliable due to tissue regrowth. Although ear notching was used successfully for cohort marking in northern fur seals, it is no longer used because of concerns regarding interference with diving abilities.

Both hot branding and freeze branding have been used with great effect with pinnipeds (Erickson *et al.*, 1993). Hot brands have been used since 1912 with thousands of northern fur seals, Cape fur seals (*A. pusillus*), southern elephant seals, Weddell seals (*Leptonychotes weddellii*), grey seals, and leopard seals (*Hydrurga leptonyx*). Some marks have remained readable for up to 20 years. The technique seems best suited to colonial seals due to the bulky nature of the branding tools and heat source. Typically, brands are heated to red hot and are applied with firm, even pressure for 2–7 sec, depending on whether the hair has been clipped. Brands are applied to the upper saddle, middle back, or upper shoulder to optimize sightability.

Freeze branding differs from hot branding in that it involves the selective killing of pigment-producing cells through contact with a super-cooled metal numeral or symbol (typically 5 cm high) (Erickson *et al.*, 1993). Brands are cooled with liquid nitrogen or a dry ice and alcohol mixture and applied for about 20 sec to an area where hair has been removed. Correct freeze brand application results in a nonpigmented pelage mark, ranging from dark (elephant seals, California sea lions) to pink (California sea lions; walrus, *Odobenus rosmarus*). Freeze branding has had mixed success. Many freeze brands on pinnipeds have been found to repigment within 1–2 years, perhaps as a result of excessive branding. Readable brands have been obtained for elephant seals (up to a year, discernible for 3 years), California sea lions (readable for 1.5 years, discernible for up to 4 years), walrus (readable for many years), and Australian sea lions, *Neophoca cinerea* (legible on flippers for 7 years, on flanks for 4 years).

D. Attachment Tags

Plastic or metal attachment tags are used more widely than any other kind of individual identification system with pinnipeds (Erickson *et al.*, 1993). Monel or stainless-steel tags such as those used to mark livestock are the most common metal tags. These metal strap tags are self-piercing and are attached by means of special pliers to the trailing edge of the fore flippers of otariids and to the interdigital web of the hind flippers of phocids. Typically, the tags are stamped with an organization address and serial number. Thousands of metal tags have been attached to phocids. Retention rates on phocid seals are low, with postattachment tears and cuts sometimes becoming infected. Hundreds of thousands of metal tags have been attached to otariids, with similar poor results.

The use of plastic tags is now much more common than metal tags for identifying pinnipeds (Fig. 6). Two kinds of plastic bags are used commonly: rototags and Allflex tags. Both consist of

Figure 6 *Flipper tag on a northern elephant seal. Photo by B. J. LeBoeuf.*

self-piercing male and female elements that are applied with special pliers, as with metal tags. Plastic tags are available in a variety of colors, leading to more than 300 unique color combination possibilities. The visibility of both metal and plastic attachment tags can be enhanced through the use of streamer markers, such as nylon cloth strips reinforced with vinyl, which may last for a year or more.

Tagging success with both metal and plastic tags is less than desired. Loss rates of the two kinds of plastic tags are variable, but tend to be lower than for metal tags, about 10% annually. However, the long-term durability of metal tags is better than plastic. Wounds from metal tags are more common than for plastic.

III. Sirenians

A. Natural Markings

The process of developing new techniques and applying existing technology to studies of sirenians has been reviewed by G. Rathbun in Wells *et al.* (1999). Natural marks, including deformities and scars, have been used to identify individual manatees since the 1950s. Among the marks that have proven most useful for individual identification are the scars from collisions with boats, especially propeller scars. Most manatees (*Trichechus manatus*) in Florida waters bear scars from boat collisions, often from more than one event. Boat scars occur over all parts of the manatee's body, but especially the dorsal surface and paddle, where notches may be cut by propellers (Fig. 7). Individual identification progressed from sketches of marks to surface and underwater 35-mm photography. Photography allowed for the tracking of changes in identifying characteristics through time and for distinguishing between manatees with similar markings. Technological advances have resulted in photographic images of scar patterns being saved, cataloged, and searched with the assistance of computers.

B. Temporary Markings

No widely accepted techniques currently exist for temporarily marking sirenians. Paint, flipper bands, and harnesses have been tested, but have been found to be ineffective (Irvine and Scott, 1984). "Paintstiks," oil-based crayon-like markers, have remained visible for 3–7 days during field tests, although rubbing eventually smears or removes them. Aerosol paint was short-lived and application startled the animals and polluted the water.

C. Scarring and Branding

Although not intentional, the most widely used features for identifying individual manatees are propeller scars. In recent years, scientists have begun cutting small notches in the paddles of manatees. The positions of the notches around the paddle are coded to provide information on cohorts. Freeze branding is also used with manatees that have been captured or rehabilitated on occasion, with some success (Irvine and Scott, 1984). Although most brands fade with time, some have remained readable at distances of 15 m for as long as 4 years. Success may vary with whether the manatees are shedding, as well as season, water temperature, and salinity.

D. Attachment Tags

Lacking dorsal fins, sirenians provide few opportunities for tag attachment. As described for cetaceans, spaghetti tags have been tested with manatees (Irvine and Scott, 1984). These 20-cm-long plastic streamer tags attached to a metal dart have been applied with either a lance or a crossbow, attempting to anchor the tag about 2 cm below the skin. Spaghetti tags demonstrated poor retention and caused abscesses on some manatees.

The most effective technique for tag attachment involves a break-away "belt" looped around the animal's peduncle. This belt is designed to minimize chafing, break away if it should become snagged on an obstacle in the environment, and carry a floating VHF or satellite-linked radio transmitter at the end of a tether. Each transmitter float is color coded to allow for individual identification visually. The tethers can be replaced by swimmers as necessary.

Passive integrated transponders, or PIT tags, have been implanted in nearly every Florida manatee that has been handled in recent years (Wright *et al.*, 1998). These glass-encapsulated microchips are about the size of a rice grain. They are implanted

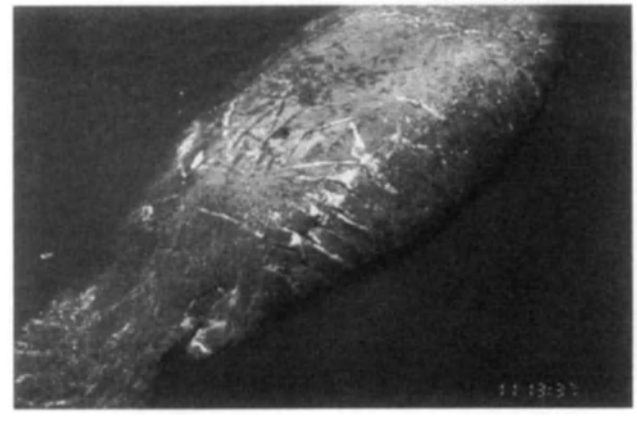

Figure 7 *Identifying scars from boat collisions on a Florida manatee. Photo by J. K. Koelsch.*

subcutaneously at a depth of about 3.5 cm, dorsal and caudal to the ear, and medial to the scapula. A small incision is made, and the tag is inserted via a 12-gauge needle. Each is programmed with a unique identification code that is activated by a hand-held scanner when it passes nearby. PIT tags are relatively easy to implant, last a long time, are reusable, rarely infect the animals, have an unlimited number of potential codes, and allow for easy data recording and transfer, but they suffer from the fact that they must be scanned from no more than 15 cm away and that the receivers are not waterproof.

Illegal and Pirate Whaling

Robert L. Brownell, Jr.
Southwest Fisheries Science Center, La Jolla, California

A. V. Yablokov
Center for Russian Environmental Policy, Moscow

Illegal whaling occurs in contravention of national laws or internationally agreed quotas, seasons, area restrictions, and other limitations, whereas "pirate whaling" refers to unregulated whaling conducted outside the aegis of the International Whaling Commission, usually under a flag of convenience. Such activities can lead directly to depletion of whale stocks through overexploitation. Furthermore, the lack of catch

data, or the reporting of falsified data, can lead to serious error in assessment of the size and status of stocks and erroneous management advice ultimately contributing to their collapse.

I. Illegal Whaling

Known instances of illegal whaling were conducted by several nations. Because the offenses of the USSR were the most egregious, most of this discussion will focus on what is now known of Soviet activities. The Soviet Union conducted massive illegal whaling and falsification of data over a period of decades, with catastrophic consequences for whale CONSERVATION and development of the science of whale MANAGEMENT. The USSR commenced pelagic whaling in the North Pacific with the *Aleut* in June 1933 (Tønnessen and Johnsen, 1982). This floating factory operation continued through the 1967 season. After this date, four additional Soviet factory ships conducted pelagic whaling operations in the North Pacific. For more than a decade following the end of World War II, the USSR operated a single whaling factory ship (*Slava*) in the Antarctic. Beginning in 1959, the Soviets began expanding their whaling operations, adding one new factory ship in each of the next three Antarctic seasons (*Sovietskaya Ukraina* in 1959/1960, *Yuri Dolgorukiy* in 1960/1961, and *Sovietskaya Rossiya* in 1961/1962). This expansion occurred at a time when there was extensive discussion at the IWC about declining stocks and other countries were decreasing their whaling operations. The USSR voted against the drastic reductions in catch quotas required to meet scientific recommendations and against implementation of an International Observer Scheme (IOS), both of which were eventually put in place. After the breakup of the Soviet Union, a number of Russian and Ukrainian biologists who had served as scientists aboard Soviet factory ships and knew of the existence of accurate but unreported catch statistics decided to collect them and make them available to the world scientific community. This section summarizes information on Soviet illegal activities during the two major phases of its whaling in the Southern Hemisphere and North Pacific and briefly notes recent information on illegal whaling activities by other nations.

A. Southern Hemisphere

A summary of the disparity between USSR catch data reported to the IWC and actual takes is given in Table I (modified from Yablokov *et al.*, 1998). These data concern catches made by Soviet fleets working in, or en route to or from Antarctic waters. The period concerned is from the beginning of postwar Soviet whaling in 1947 until the introduction of international observers in the 1972/1973 whaling season, when most illegal activities ceased. During this period, unreported catches totaled 102,335 whales, almost half (44%) of which were humpbacks (*Megaptera novaeangliae*). However, 11,397 animals (primarily fin whales, *Balaenoptera physalus*, which were then an unprotected species) were actually overreported; this was done to conceal the massive illegal catches of pygmy blue (*B. musculus brevicauda*), sei (*B. borealis*), humpback, and southern right whales (*Eubalaena australis*).

Massive falsification of geographic catch data began in 1959 and was practiced by all four Soviet Antarctic whaling fleets. The primary areas for illegal catches were numerous sections of the South Atlantic, the Indian Ocean (including as far north as the Arabian Sea), and the southwestern Pacific (Yablokov, 1994; Zemsky *et al.*, 1995a,b). IWC regulations prohibited the taking of baleen whales (mysticetes) north of latitude 40°S, although the killing of sperm whales (*Physeter macrocephalus*), killer whales (*Orcinus orca*), and bottlenose whales (*Hyperoodon planifrons*) in this region was permissible. Therefore, the Soviets used the pretext of hunting toothed whales to exploit mysticete populations in the prohibited area. Soviet whaling fleets bound for the Antarctic began search and catcher operations immediately after leaving the Suez Canal or after passing either Gilbraltar or Portuguese waters.

TABLE I
Comparison of Southern Hemisphere USSR Catch Data (1947–1972)[a]

Species	*Reported*	*Actual*	*Disparity*
Blue whale	3,887	3.681	206
Pygmy blue whale	10	9,215	−9,205
Sei whale	29,751	53.366	−23,615
Fin whale	52,860	42,889	9,971
Bryde's whale	10	1,457	−1,447
Minke whale	1,246	384	862
Humpback whale	2,820	45,831	−43,011
Southern right whale	4	3,368	−3,364
Sperm whale	50,715	72,372	−21,657
Killer whale	482	124	358
Southern bottlenose whale	10	17	−7
"Others"	0	29	−29
Total	141,795	232.733	−90,938

[a]Reported to the IWC with numbers actually taken. Modified from Yablokov *et al.* (1998) and Tormosov *et al.* (1998).

Virtually all biological data reported to the IWC were "corrected" to disguise the extensive illegal catches. Because of a prohibition on killing mothers and calves, all such cases were either unreported or were concealed with false data. Thus, a fin whale mother and calf might be reported as "two sei whales," whereas a catch of four female sperm whales would be reported as "two males." It has been estimated that at least 80% of all officially reported Soviet data on length, weight, sex ratio, reproduction, and maturational state are false.

The scale of the Soviet catches partly explains the apparent failure to recover that has been evident in some mysticete populations despite their supposedly protected status. The Soviets killed 12,896 blue whales in the Southern Hemisphere, of which more than 9200 were unreported pygmy blues killed after the IWC accorded protected status to both subspecies in the 1965/1966 season. Catches were made over a wide area, including the Indian Ocean north of the equator. Thus, these populations were reduced to much lower levels than the 800–1600 (blue) and 10,000 (pygmy blue) that were estimated at the time. Although recent estimates of 500 and 5000 for current Antarctic populations of blue and pygmy blue whales,

respectively, are not statistically robust, it is apparent that the population sizes are smaller than would be expected following three decades of protection.

Humpback whales were even more seriously impacted by illegal catches. In addition to the huge number (45,831) of unreported catches made by the Soviets, it is known that additional illegal takes were made in Antarctic waters by the *Olympic Challenger*, a pirate factory ship owned by Aristotle Onassis (Tønnessen and Johnsen, 1982), discussed later. The Australian biologist Graeme Chittleborough (1965) asserted that large discrepancies in calculated mortality coefficients for humpbacks could be explained only by the occurrence of extensive illegal catches, a view that is now validated by the Soviet catch data reported here. Many of the Soviet catches were made from the management division known as Antarctic Area V (Dawbin, 1966), which explains the collapse of shore whaling station operations in eastern Australia and New Zealand in the 1960s. There is now evidence of strong population growth in some Southern Hemisphere humpback populations (Bannister, 1994; Paterson *et al.*, 1994; Findlay and Best, 1996), but the status of other stocks remains unclear.

Additional illegal Soviet pelagic whaling occurred in the Arabian Sea on humpback (Mikhalev, 1997a), blue, Bryde's (*Balaenoptera edeni*), and sperm whales during the 1960s (Mikhalev, 1996, 1997b; personal communication). This whaling occurred while the whaling fleets were en route to the Antarctic whaling grounds. Biological data from humpback catches made in November 1966 off Oman and India have resolved a long-standing issue regarding the identity of this population, which is unique among humpbacks in that it resides in tropical waters year-round (Mikhalev, 1997a). However, the status of this tropical population of humpbacks remains uncertain.

Southern right whales have always been protected under IWC regulations; this status dates from a League of Nations agreement in 1935. Recovery (increasing populations) is today apparent in only 4 of the 13 putative populations of this species (Best, 1993), although five of the remaining nine stocks are considered impossible to monitor on a regular basis. True data show that the Soviets made large (3368) unreported catches of this species between 1950 and 1971 (Tormosov *et al.*, 1998). Many of these takes were made around remote islands or in midoceanic areas such as Campbell Island, Crozet, Kerguelen, Tristan da Cunha, and the central Indian Ocean.

B. North Pacific

A single Soviet whaling factory operated in the North Pacific between 1933 and 1967, a small vessel named the *Aleut*. Four additional Soviet factory ships later operated in the North Pacific. A new ship, the *Sovetskaya Rossiya* (build as the sister ship to the *Sovetskaya Ukraina*), operated for four seasons (1962–1965) and then again for three more seasons in 1973, 1978, and 1979. The *Slava*, after working many years in the Southern Hemisphere, worked in the North Pacific for four seasons (1966–1969). Two sister whaling factory ships were built specifically for the North Pacific (*Vladivostok* and the *Dalniy Vostok*); both started operations in 1963. The *Vladivostok* operated through 1978 and the *Dalniy Vostok* through 1979. The main areas of operations for these two fleets were the Bering Sea, Gulf of Alaska, and other more southern parts of the North Pacific.

The whales in the North Pacific did not fare any better than those in the Southern Hemisphere. However, the available records are not as good. Doroshenko (2000a) and others reported numerous illegal catches of North Pacific right whales (*Eubalaena japonica*) in both the western and eastern North Pacific. Brownell and colleagues (2000) provided some data on massive illegal catches of sperm whales in the North Pacific. Soviet pelagic whaling operations in the North Pacific also illegally took blue, humpback, and gray whales (*Eschrichtius robustus*) (Doroshenko, 2000a). A summary of the inconsistencies between data reported by the USSR to the IWC and actual catches is in Table II.

It is known that illegal whaling on a similarly large scale was also conducted by the USSR throughout the Northern Hemisphere, although relevant catch data have yet to be analyzed. In light of these revelations in both the Southern Hemisphere and the Northern Hemisphere, it is clear that current views regarding the status and recovery potential of virtually all affected whale populations worldwide need revision. This is a long-term project that will continue for the next decade or longer.

At the 50th IWC meeting in Oman in 1998, the IWC took action on the Scientific Committee's (SC) concern about the falsified Soviet whaling data, mainly for sperm whales, by adopting the SC recommendation to remove official USSR Southern Hemisphere whale catches from the IWC database.

The USSR was not alone in the illegal harvest of whales. Recent evidence on the falsification of catch statistics has been reported in various North Pacific coastal-based operations conducted by the Japanese (Kasuya, 1999; Kasuya and Brownell, 1999, 2001; Kondo, 2001). Suspicions about illegal reporting in Japanese operations are not new and have been presented in the past (Kasuya and Miyazaki, 1997). The scale of these activities, however, was much smaller and the consequences less severe than in the case of the Soviet illegal whaling. Sperm whales catches between 1954 and 1964 were 1.4 to 3 times greater than the numbers Japan reported to the IWC. The total true catches of Bryde's whales taken during the final years of commercial land-based whaling (1981–1987) off the Bonin Islands were 1.6 times

TABLE II
Comparison of North Pacific Commercial USSR Catch Data (1961–1972)[a]

Species	*Reported*	*Actual*	*Disparity*
Blue whale	517	1,205	−688
Fin whale	10,613	8,621	+1,992
Sei whale	9,048	4,177	+4,871
Bryde's whale	775	714	+61
Humpback whale	3,043	6,793	−3,750
Gray whale	0	138	−138
Right whale	0	508	−508
Bowhead whale	0	133	−133
Total	23,996	22,289	+1,707

[a]Reported to the IWC, with numbers actually taken.

the numbers Japan reported to the IWC. Fin whales were reported taken illegally by the Republic of Korea in the 1980s.

During the 1990s and the following decade, numerous reports appeared regarding the sale of "illegal whale products" from protected whales collected in the Japanese market (Baker *et al.*, 2000). It is argued that Japan's scientific whaling program (since 1989) has acted as a cover for undocumented or illegal products from various protected species (fin, sei, humpback, and gray). While this is possible, there are no available data to support the occurrence of any large-scale illegal whaling during the 1990s. The most parsimonious explanation for the whale products from protected species is that they are from (1) whales killed before the 1986 IWC moratorium on commercial whaling, (2) past scientific hunts by Iceland or Norway, (3) bycatches from Japanese fisheries, and (4) STRANDINGS in Japan.

II. Pirate Whaling

As noted earlier, unregulated whaling conducted under the flags of non-IWC member nations has contributed to the depletion of some whale stocks. The most famous of these operations was that conducted by interests in Norway and Japan from 1968 to 1979 in the North and South Atlantic under the flags of Somalia, Cyprus, Curaçao, and Panama. Meat from the whales was shipped to Japan for human consumption. The *Run* operated mainly in the South Atlantic from January 1968 to February 1972. It was renamed the *Sierra* in 1972 and expanded major operations to the North Atlantic in 1975, where it continued taking whales until it was rammed and sunk by the *Sea Shepherd* (a privately operated vessel dedicated to interference with commercial whaling) in 1979 off Portugal (Watson, 1979). The *Tonna* joined the *Sierra* in December 1977 and operated until July 1978, when it foundered during processing of a large whale on deck. The *Cape Fisher*, later renamed the *Astra*, operated briefly as a processing vessel for the *Sierra* in 1979.

The Sierra Fishing Agency submitted its catch statistics to the Bureau of International Whaling Statistics in Norway until 1976, when the practice was discontinued because of a perceived lack of credibility of data. Data for the remaining years of operation were destroyed, but some information was salvaged through interviews with former crew members (Best, 1992). The catches included blue, fin, sei, Bryde's, humpback, and minke (*Balaenoptera acutorostrata* and/or *B. bonaerensis*). Large catches of fin whales totaling hundreds were made off the coasts of Spain and Portugal (the IWC's "Spain–Portugal–British Isle Management Area") after 1976.

Another notorious episode of pirate whaling occurred in the Southern Hemisphere from 1951 to 1956 by the factory ship *Olympic Challenger* and its fleet of 12 catcher boats (Tønnessen and Johnson, 1982). The Olympic Whaling Company, an affiliate of the Pacific Tankers Co. of New York, was financed by the Greek-born Argentine citizen Aristotle Onassis. The ownership of the vessel, a converted tanker, was later transferred to the Olympic Whaling Company S.A. in Montevideo, Uruguay. The captain was German and the expedition manager Norwegian. The factory ship and some of the catcher vessels flew the Panamanian flag and the remainder of the catchers the Honduran flag. Neither Panama nor Honduras were members of the IWC at the time, so the whaling operations were completely unregulated. The expedition took thousands of whales in the Antarctic South Pacific sector and off Chile, Peru, and Ecuador, including blue, humpback, sei, right, and sperm. Catch data were reported to the International Bureau of Whaling Statistics, but these have been shown to incorporate extensive falsification of numbers, species, and sizes of whales caught (Barthelmess *et al.*, 1997). As noted earlier, these unregulated catches in combination with later illegal catches by Soviet fleets contributed in a major way to the catastrophic decline of whales in the Southern Ocean, particularly the humpback.

Incidental Catches

SIMON NORTHRIDGE
University of St. Andrews, Scotland, United Kingdom

Marine mammals sometimes get caught up and killed in fishing operations. In many cases these deaths are entirely unintended by the fishermen concerned and are incidental to the main fishing operation. They are therefore referred to as incidental catches. Sometimes they are also referred to as "bycatches," although this term is also used to described the capture of some species that, while not the main target of a fishery, still have some value and may therefore be landed. Incidental catches are generally unwanted and discarded.

Incidental catches of marine mammals have probably occurred for as long as people have been putting nets and lines into the water. Most species of marine mammal that occur in places that are heavily fished have been recorded caught in at least one type of fishing gear. Most types of fishing gear have been reported to ensnare marine mammals at one time or another. Some captures seem to defy reason. Large whales, for example, may become caught in a single lobster pot line, whereas porpoises get caught in simple fish traps that they are able to find their way into, but not out of. Others catches are easier to comprehend, as when trawls with openings of several hundred meters in circumferences scoop whole schools of dolphins from the sea.

In the past, and indeed in many parts of the world today, unintentional captures of marine mammals might be treated as a bycatch and landed for consumption. During the latter half of the 20th century, however, fishing technology has changed faster and more completely than ever before, which has led to a reappraisal of the issues surrounding bycatch and incidental catch. Nets have become larger and stronger, numerous new fishing techniques have been devised, and fishing intensity throughout the world has increased dramatically, nearly trebling marine fishery landings over a period of just 40 years.

Such developments have had unintended negative impacts on nontarget species, including marine mammals, so that incidental catches have now become a critical issue for some marine mammal populations. Marine mammals generally reproduce slowly, and their populations are not able to withstand much additional nonnatural mortality. The removal of just 1% of the population per year may be more than a marine mammal population can sustain in the longer term. For this reason, many nations now legislate to protect marine mammal populations from deliberate or accidental exploitation, and there are several international agreements with the same aim.

Legislation to protect marine mammals from excessive mortality has resulted from a variety of case studies that have uncovered unsustainable levels of incidental capture. Several of these case have become widely publicized and have generated considerable public attention and debate.

I. Examples

A. Eastern Tropical Pacific Tuna Purse Seine Fishery

The first interaction to be recognized as a serious concern for the conservation of marine mammals was the large-scale capture of pelagic dephinids (mainly *Stenella* and *Delphinus* species) in the U.S. tuna purse seine fishery of the eastern tropical Pacific Ocean (ETP). Tuna boat skippers learned that they could catch large tuna by herding dolphin schools with speedboats and then surrounding them with long, deep, purse seine nets. Fishermen were exploiting the curious fact that in the ETP (and some other places), large yellowfin tuna (*Thunnus albacares*) will school under and follow dolphin schools. Once the dolphins and associated tuna are surrounded, the nets can be "pursed," whereby the bottom end of the net is closed off, thereby catching the tuna. At this point the dolphins can still surface to breathe within the encircled net and could escape by jumping over the floats. Pelagic delphinids, however, seem to find it difficult to escape from such an enclosed situation, and many became trapped and died under folds of the surrounding purse seine or simply fainted and died.

This fishing technique was begun in the 1950s, but was not recognized as a potential conservation problem until the early 1970s, when a monitoring program was established. During much of the 1960s and up to 1972, annual mortalities are thought to have ranged between 200,000 and 500,000. Thereafter a variety of efforts were made to reduce the kill, but tens of thousands of dolphins were still being killed annually throughout most of the 1980s. Pantropical spotted dolphins (*Stenella attenuata*) were the most frequently killed species, and numbers of this species in the ETP were more than halved over the 1960s and 1970s. Populations of other species were also severely impacted.

Largely as a result of public pressure, and the introduction of "dolphin safe" tuna retailing, this practice has now been greatly reduced. New techniques have been devised by the skippers to ensure that a very high proportion of the dolphins used in this way to catch tuna are encouraged to escape from the nets before the fish are removed. Under a training and monitoring scheme run by the Inter-American Tropical Tuna Commission, dolphin mortalities had been reduced to between 2000 and 4000 animals per year by the mid-1990s. Efforts continue to reduce these figures further still.

Throughout the world, since the discovery of the effect of the ETP tuna fishery on dolphin populations, it has become clear that there are numerous other fisheries in which marine mammals are being killed in large numbers. In some cases, populations or species have been threatened with extinction. Two of the most severe cases are those concerning the baiji (*Lipotes vexillifer*) and the vaquita (*Phocoena sinus*).

B. The Baiji

The baiji, otherwise known as the Chinese river dolphin, inhabits the middle and lower parts of the Yangtse River system in China. The total population size is not known, but is thought to be a few hundred at most and is declining. The major source of mortality for this species appears to be snagging in "rolling hook" fishing lines. These are lines equipped with many closely set, sharp, unbaited hooks designed to snag fish foraging on the river bed in the same areas as the Baiji. In one study, 45% of all known Baiji deaths were attributed to snagging in rolling hooks.

C. The Vaquita

The vaquita is a species of porpoise restricted to the upper part of the Gulf of California in Mexico. Population studies suggest that only around 600 animals remain, that numbers are declining, and that the species is in critical danger of extinction. Again, the major source of mortality is incidental catches in fishing operations, in this case gill net for sharks and other large fishes. Gill nets are simple long panels of netting that are set to stand vertically in the water with floats along their top and a weighted rope on their bottom. Depending on the amount of weight added, they either sit on the seabed floating upward or they float at the surface hanging down. They are left to ensnare fish that happen to swim into them, but also catch marine mammals by entangling them. Annual vaquita mortalities in gill net fisheries are estimated at around 40–80 per year, which is clearly an unsustainable level of mortality given the size of the population.

D. New Zealand Sea Lion

Another species that has been threatened in a similar way, but by an entirely different sort of fishery, is the New Zealand sea lion (*Phocarctos hookeri*). These sea lions are restricted to New Zealand's sub-Antarctic islands, mainly the Auckland Islands. The population is thought to have been much reduced by commercial sealing activities in the 19th century. The total population size was estimated at around 13,000 animals in the mid-1990s, although it has been further reduced by a mass die-off in 1998. A trawl fishery for squid was started around the Auckland Islands in 1979, which subsequently resulted in significant numbers of sea lions being drowned in the large trawl nets, raising concern that the population might be reduced further or even threatened with extinction. The New Zealand government implemented an observer scheme in the late 1980s to monitor the numbers being killed and it now sets incidental catch limits every year in order to prevent unsustainable levels of mortality. Once the annual limit is reached the fishery must stop fishing.

II. Causes for Concern

Although the just-described examples are perhaps the most extreme cases, there are numerous others around the world where significant numbers of marine mammals are killed incidentally in fishing operations. It is usually the smaller species and those that occur in continental shelf waters where most fishing occurs that are impacted most heavily.

Incidental catches do not always impact on entire species. In many instances, marine mammal species may be widespread and in little danger of overall extinction. Nevertheless, incidental catches may be frequent enough to reduce or eliminate a local population (Fig. 1). This is the case for the harbor porpoise (*Phocoena phocoena*). While they are in no imminent danger of extinction as a species, in several areas, including the Gulf of Maine off the U.S. northeast coast, incidental catch rates are or have been high enough to push local populations into decline.

In other parts of its range, including the English Channel and the Baltic Sea, harbor porpoises have all but disappeared. While the causes of these disappearances are not known, fishing is intense in both areas and incidental catch rates in adjacent areas are known to be high enough to be unsustainable.

Throughout the world, small inshore species such as the harbor porpoise are known to be victims of incidental catches in fishing operations, but the level of such catches and the likely impact remain unknown. Monitoring incidental catch rates and estimating population sizes are both very expensive. A significant issue in this regard is that there does not need to be a very large number of incidental kills for the total effect to be significant. When a marine mammal population numbers in the hundreds or even the tens of thousands, a few individuals to a few hundred individuals taken per year may be enough to generate a population decline. Furthermore, even when the marine mammal population is much larger, if the fishery is also large, significant catches can occur while still remaining unknown. Generally speaking, incidental catches are rare events. Typically, a capture event only occurs in one or two out of every hundred fishing operations. Such low levels may remain unnoticed, although the aggregate effect over a large number of vessels and operations may be significant. Such low levels of capture also make monitoring more difficult.

Although most attention worldwide has focused on the potential conservation issues that incidental catches of marine

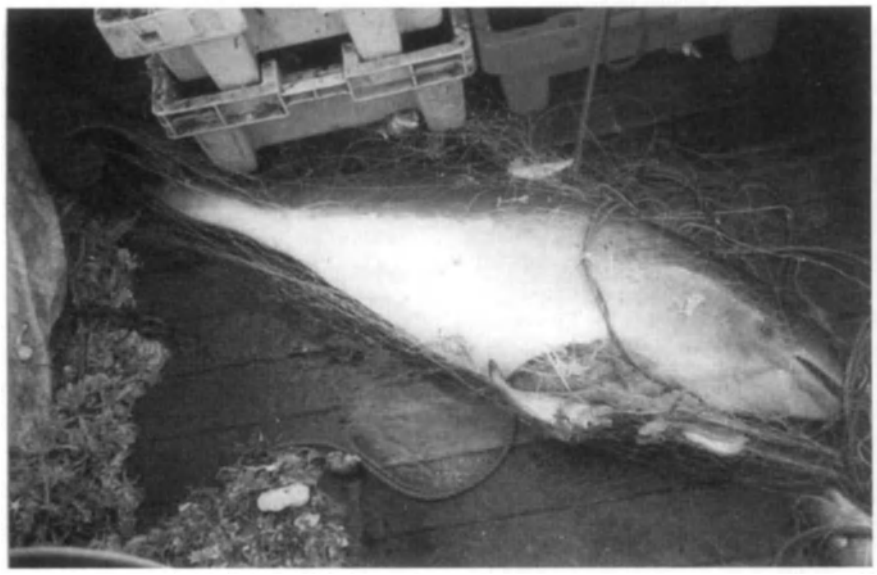

Figure 1 *A harbor porpoise entangled in a cod gillnet in the North Sea, one of several thousand dying this way every year in European gillnet fisheries. Photo by Nigel Godden/Sea Mammal Research Unit.*

mammals raise, animal welfare considerations are also a concern. Whereas some incidental capture of marine mammals in fishing operations is an inevitable consequence of fishing, in some nations at least, any large-scale fatalities of marine mammals are publicly unacceptable regardless of whether they are sustainable at a population level.

III. Attempts to Resolve the Problem

Most of the numerically significant incidental catches of marine mammals tend to be in static fishing gear, mainly gill nets. Despite the attention focused on this subject in recent years, it is still not known how or why marine mammals actually become caught in such nets. It is not known, for example, whether mammals are attracted to nets by curiosity or by the presence of trapped fish, whether they do not notice the netting, or whether they simply do not understand the potential consequence of swimming into it. Despite our ignorance, some progress has been made toward resolving the problem.

One potential solution to the problem of marine mammal capture in gill nets has been developed in North America. Pingers, or acoustic beacons, exploit the sensitive hearing of marine mammals by emitting an intermittent, short, high-pitched noise that most fish cannot hear but that appears to repel or warn off marine mammals. Attached at regular intervals along the length of a gill net, these 16-cm-long cylindrical devices have been shown to reduce the numbers of marine mammals (mainly harbor porpoises, but also dolphins and sea lions) caught by up to 90% (Kraus *et al.*, 1997). Pingers were first developed in Canada, and their use is now mandatory in several U.S. fisheries.

Pingers certainly appear to be useful but there are still some concerns about their use. As they are a recent technological innovation, marine mammals may become habituated to their noises and start to ignore them. If, as seems to be the case, pingers displace animals from an area, and if they are used to the very large numbers that would seem to be necessary, then it is also possible that marine mammals may become excluded from parts of their foraging habitats. Pingers rely on batteries, and they rely on people replacing those batteries to ensure that they continue to work. This can be an expensive and time-consuming operation that many people might eventually prefer to forget about. Finally, the pingers themselves are expensive, so that the cost of equipping a net with pingers may exceed the cost of the net. In many less-developed countries, it is unlikely that they will ever become widely used for this reason alone.

Issues with mobile fishing gear are somewhat different. There are or have been several initiatives worldwide that aim to keep marine mammals out of towed fishing gear. In the ETP tuna fishery referred to earlier, special techniques and nets have been developed to help dolphins to escape from the purse seine net once the net has fully encircled the school of tuna. During the "backdown procedure" the skipper reverses the vessel and is able to sink a part of the net floatline under the water, enabling the dolphins to escape. This part of the net is also made up with a smaller meshed panel (the Medina panel), reducing the chances of dolphins becoming entangled as they escape. Similarly, in New Zealand, special marine mammal escape devices have been designed and used in squid trawls. A large grid is placed near the rear of the net, set at a 45° angle to the vertical plane. Fish can pass through the grid, but larger animals such as sea lions are forced upward and out the net through an escape hatch.

In general, the incidental capture of marine mammals is caused by a combination of fishing technique or gear design and the behavior of the marine mammal. Resolving problematic interactions therefore involves some combination of change to fishing gear use or design and the manipulation of marine

mammal BEHAVIOR. Very little is known about the behavior of marine mammals in relation to fishing gear, especially in the context of incidental capture. In part this is because of the difficulties of studying marine mammals underwater, but it is also because of the rarity of such events, which makes observing their occurrence very difficult. Finding solutions to the problem is therefore a slow and arduous process.

Most fishing practices and gear designs have been adopted by fishing communities because they are effective in catching fish, and making changes may therefore reduce the profitability of a fishery. Effective mitigation measures therefore need to be devised in collaboration with the fishing community in order to minimize the adverse impacts on fish catches, but they may also require a legislative approach to ensure compliance or equability within a fishery. In this respect, managing the incidental capture of marine mammals may be seen as part of a much more wide-ranging and ongoing problem of managing a global industry that, in the last 50 years, has outgrown its resource base.

Indo-Pacific Beaked Whale

Indopacetus pacificus

ROBERT L. PITMAN
Southwest Fisheries Science Center, La Jolla, California

The Indo-Pacific (or Longman's) beaked whale (Ziphiidae) is one of the least known extant cetaceans. Its existence is known only from two skulls (Fig. 1), and it has never been identified in the flesh, alive or dead. It was originally described in 1926 as *Mesoplodon pacificus* from a beach-worn skull collected in Queensland, Australia, in 1882. The validity of the species was initially challenged by researchers who variously suggested that it was a subspecies of True's beaked whale (*Mesoplodon mirus*) or an adult female southern bottlenose whale (*Hyperoodon planifrons*). J. C. Moore later refuted these allegations and recognized it as a valid species. This was confirmed by the subsequent discovery of a second specimen, another skull, found on the coast of Somalia in 1955 (but not reported until 1968). After further study of both specimens, Moore found them sufficiently distinct to warrant a new genus, *Indopacetus*. The five diagnostic characters he cited for distinguishing *Indopacetus* from *Mesoplodon*, and the other living genera of beaked whales, were (1) a single pair of teeth alveoli (sockets), apical in the mandible, that become progressively shallower in the adult male to at least 30 mm; (2) frontal bones occupying an area of the synvertex equal to or greater than that of the nasal bones; (3) almost no posterior process of the premaxillary crest; (4) a deep horizontal groove in the maxillary bone just above, and about half as long as, the orbit; (5) about midlength in the beak, a swelling of the lateral margins so that the beak does not grow

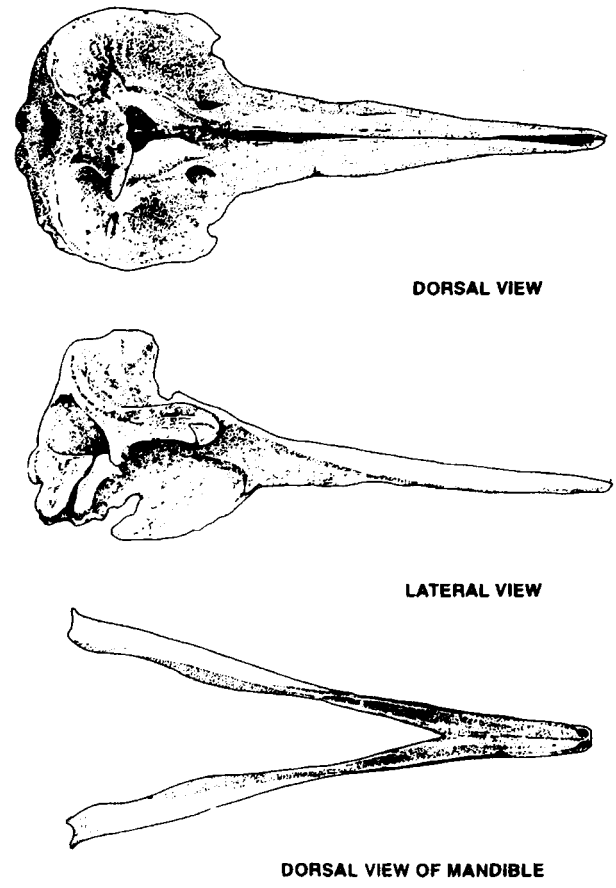

Figure 1 *Skull of* Indopacetus pacificus. *Courtesy of the Food and Agriculture Organization of the United Nations; from Jefferson* et al. *(1993). Marine Mammals of the World, FAO, Rome.*

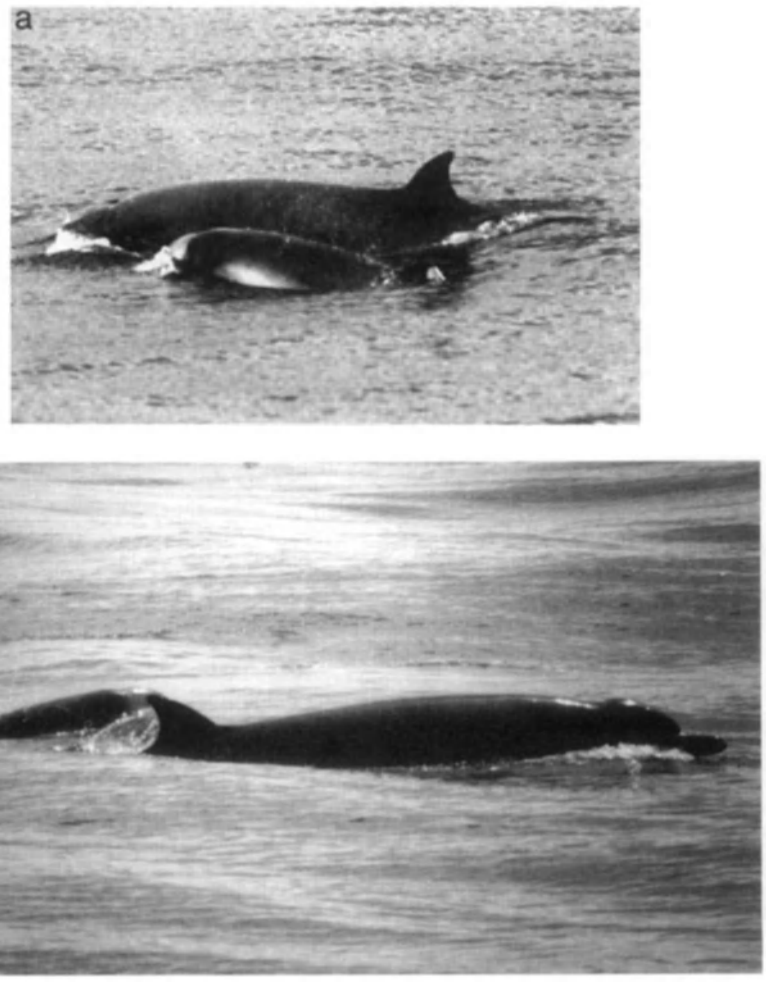

Figure 2 *(a) A presumed cow and calf pair of an unidentified bottlenose whale from the eastern tropical Pacific that is probably* Indopacetus pacificus; *notice the pigmentation pattern of the calf in the foreground. (b) Same cow/calf pair showing the crease between melon and beak of the adult. Courtesy of Bernard Brennan.*

narrower throughout its entire length. The validity of the genus *Indopacetus* has not been universally accepted, however, and some workers include the species in *Mesoplodon*.

All that can be surmised about the natural history of *Indopacetus* is that, based on the two STRANDING records, it appears to inhabit tropical waters of the Indo-Pacific, and based on skull size the total length may be 7.0–7.6 m, making it a fairly large beaked whale. Although the two teeth that erupt only in adult males have never been examined, based on alveoli shape they appear to be oval in cross section and point forward.

Indopacetus pacificus is perhaps the largest animal left on the planet that has not been positively identified alive in the wild, but there is reason to believe that it may not be as rare as the meager stranding record indicates. Recently, the existence of a large and distinctive, but as yet unidentified, species of beaked whale has been confirmed from 45 sightings scattered from the eastern tropical Pacific to the western tropical Indian Ocean. The calf of the so-called "tropical bottlenose whale" is dark with a pale melon that has a posterior margin confluent with the blowhole; it also has a whitish flank patch that extends high up on the sides of the animal and a small white "ear spot" (Fig. 2a). The adult is a large beaked whale (length estimates range from 7 to 8 m), which has a crease between the melon and the beak (Fig. 2b) identifying it as a bottlenose whale. These attributes are not referable to any known species of ziphiid, but are consistent with what little is known about *I. pacificus*, and the suggestion was made that the tropical bottlenose whale may well be that species. The question will remain unresolved until a suitable specimen becomes available.

Indo-West Pacific Marine Mammals

PETER RUDOLPH AND CHRIS SMEENK
National Museum of Natural History, Leiden, The Netherlands

The Indo-West Pacific is defined here as the tropical and subtropical waters of the Indian Ocean, from about 35°S off South Africa to the Red Sea and Persian Gulf and from Australia and Southeast Asia to about 30°N (Fig. 1).

The Indo-West Pacific probably offers the greatest diversity of marine mammal species in the world. Within it live representatives of 10 of the 14 families of the order Cetacea, with more than 40 of the 83 species treated as such by Rice (1998), as well as one member of the order Sirenia. We have not included species of the order Carnivora (sea lions, walruses, and seals), nearly all of which normally live in higher latitudes. Only the ranges of the Cape and Tasmanian fur seals *Arctocephalus pusillus pusillus* and *A. p. doriferus*, the south Australian fur seal *A. forsteri*, and the Australian sea lion *Neophoca cinerea* (family Otariidae) include the southernmost part of the area considered, in South Africa and southern Australia, respectively.

I. Endemic Taxa

Many species occurring in the Indo-West Pacific have a cosmopolitan or pantropical distribution, and several Northern and Southern Hemisphere species extend their range to within the confines of the area. However, a relatively large number (11) of species or currently recognized subspecies are endemic to the Indo-West Pacific, although the taxonomic position and distribution of some forms are still insufficiently known. Most of these occur mainly in shelf and/or fresh-water ecosystems; *Tursiops aduncus* is also found in deep oceanic waters. Three seem to be largely confined to shelf areas: *Balaenoptera edeni* (if correctly defined), *Delphinus tropicalis* (whether a valid species or a subspecies of *D. capensis*), and *Stenella longirostris roseiventris;* five have a decidedly coastal, estuarine, or even partly riverine distribution: *Sousa plumbea, S. chinensis, Orcaella brevirostris, Neophocaena phocaenoides*, and the sirenian *Dugong dugon;* and two are true river dolphins: *Platanista gangetica* (including *P. g. minor*) and *Lipotes vexillifer.* In addition, at least one oceanic species—*Mesoplodon ginkgodens*—is endemic to deep waters of the (sub)tropical Indo-Pacific at large and the same may hold true for *Indopacetus pacificus*, although the IDENTIFICATION and DISTRIBUTION area of the latter are still somewhat uncertain.

II. Zoogeography

The shelf areas of the Indo-West Pacific show a high primary productivity, the result of monsoon-related currents and strong upwelling. Although the shallow waters of Southeast Asia and Australia would seem to constitute a barrier between the Indian and Pacific Ocean basins, the deep passages through the eastern Indo-Malayan Archipelago offer suitable dispersal routes for oceanic species, most of which, including sperm whales, *Physeter macrocephalus*, have indeed been recorded from the deeper straits and seas between the islands. Not considering the river dolphins, none of the marine mammals in the area is restricted to either the Indian Ocean or the Pacific side of the archipelago, with the exception of the western form *Sousa plumbea*, which, if valid, probably is the result of a recent vicariant speciation within the genus.

The endemic marine mammal taxa of the Indo-West Pacific shelf waters differ in the extent of their present range. *B. edeni, S. longirostris roseiventris* (as far as known at present), and *O. brevirostris* seem restricted to the Sunda and Sahul Shelves and adjacent waters; all other species also occur further west and north in the Indian and Pacific Ocean, respectively. In the east, the deep waters of the Pacific seem to form a barrier to further dispersion, although the dugong has penetrated beyond the continental shelves, occurring as far as Micronesia and, as a vagrant, to Fiji; the eastern confines of *T. aduncus* are not known. In the north, *Neophocaena* has extended its range to Korea and Japan. In the southwest, *S. plumbea* and *T. aduncus* occur as far as South Africa. Here, the cold waters of the Cape apparently have prevented their dispersion into the Atlantic Ocean, although the geographic history of the West African *Sousa teuszii* is not clear. In the northwest, *S. plumbea* occurs in the Suez Canal; this species, as well as the dugong, has even strayed into the Mediterranean Sea.

III. Annotated Species Account

A. Rorquals, Family Balaenopteridae

Most baleen whales undertake extensive seasonal migrations between cold, productive summer feeding grounds in temperate or high latitudes and winter mating and calving areas in tropical or warm temperate waters, suggesting that there is only little mixing of Southern and Northern Hemisphere populations. Baleen whales in the Indo-West Pacific, particularly the Indian Ocean, are poorly known.

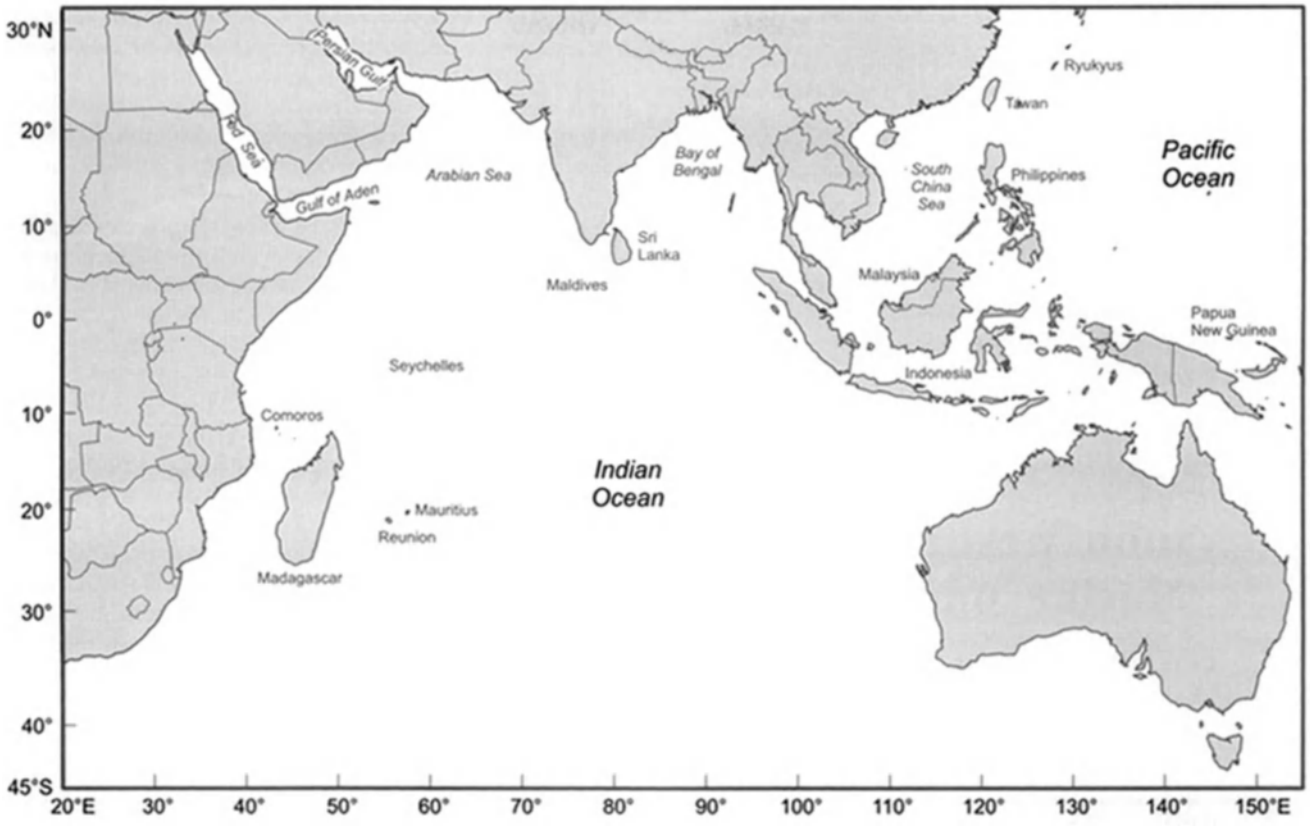

Figure 1 *The Indo-West Pacific is home to a wide variety of marine mammals, including many endemic taxa.*

The modern WHALING industry, following the invention of the explosive grenade harpoon, was initially based mainly on rorquals, although sperm and right whales were also taken. In the Indian Ocean, whaling stations existed in South Africa, Mozambique, and western Australia. Although most pelagic whaling occurred below 40°S, it was practice for whalers to take baleen whales as well as sperm whales in tropical waters on their passage to and from the Antarctic. Newly revealed data on illegal Soviet-Russian whaling operations between 1947 and 1972 have shown that baleen and sperm whales were taken in the central and northern Indian Ocean, near Madagascar and Australia, as well as in Indonesian waters. These included blue whales (*Balaenoptera musculus*) (caught mainly after 1965, when the species had already received protection from the IWC); humpback whales (*Megaptera novaeangliae*) off Oman, Pakistan, and India; as well as southern right whales (*Eubalaena australis*) around the Crozet and Kerguelen Islands and in the central Indian Ocean. Japanese whalers caught 232 Bryde's whales (*Balaenoptera brydei* and *B. edeni*) in the western Indian Ocean, south of Java and the Lesser Sunda Islands, and near the Solomon Islands during the seasons 1976/1977–1978/1979. Relatively small-scale, directed catches of baleen whales are today only known from the Philippines and from Lamakera on Solor Island, Indonesia. In the Philippines, baleen whales (mostly Bryde's whales) were or are still hunted off Pamilacan, Bohol, and Camiguin Islands. The fishery, now legally prohibited, at Pamilacan Island was seasonal and opportunistic. It started in January and ended in June, with most whales taken in April and May. The animals were caught using a hook of stainless steel, which was driven into the whale by one of the hunters jumping on the whale's back and using his weight to drive the hook in.

Humpback whale, *Megaptera novaeangliae*

Growing evidence shows that discrete populations of humpback whales remain in the Arabian Sea, including the Gulf of Oman and the Gulf of Aden, and in the Bay of Bengal year-round, with at least some of these animals both feeding and breeding there. Biological examination of 238 humpback whales caught illegally in these waters in November 1966 by Soviet-Russian whalers showed that they differed significantly from Antarctic humpbacks in size, COLORATION, body scars, and pathology (Mikhalev, 1997). The song structure of humpback whales recorded off Oman is also different from that in the North Pacific and North Atlantic. Southern Hemisphere humpback whales, which feed in Antarctic waters, winter near Mozambique, around Madagascar, off northwest and northeast Australia, and elsewhere in the tropical Pacific. In Southeast Asian waters, humpback whales have been reported from Vietnam, the Philippines, the South China Sea, and the waters around Taiwan; probably, these are animals that spend the summer in the Northwest Pacific. The occurrence in the Indo-

Malayan Archipelago has yet to be confirmed. In the 19th and 20th centuries, humpback whales were pursued off Mozambique, Madagascar, and northwestern Australia.

Minke whale, *Balaenoptera acutorostrata*

The North Pacific population, sometimes regarded as the subspecies *B. acutorostrata scammoni*, occurs in summer south to at least the East China Sea and the central Pacific to about 30°N; its winter range extends into (sub)tropical waters. A southern population, the "dwarf minke whale," is known to winter as far north as South Africa and northern Australia; the relationships of these animals with other stocks are not known. In the tropical Indian Ocean, minke whales have been reported year-round from the Red Sea, Gulf of Aden, Arabian Sea, Persian Gulf, and the seas around Sri Lanka. Reports of the species from Vietnam, the Indo-Malayan Archipelago, and the Philippines have yet to be confirmed.

Antarctic minke whale, *Balaenoptera bonaerensis*

The winter range of this Southern Hemisphere species is known to extend into tropical waters; it has been found north to about 7°S. Animals recorded from the Indian Ocean possibly belong with this species.

Bryde's whale, *Balaenoptera brydei*
Sittang whale, *Balaenoptera edeni*

These whales, which until recently were considered conspecific, have a primarily tropical and warm-temperate distribution. The larger form, the "true" Bryde's whale, ranges from the Cape of Good Hope north to the Red Sea and Persian Gulf, the Indo-Malayan Archipelago and South China Sea, south to Shark Bay and off Queensland, Australia. Inshore and offshore populations have been reported from South Africa and Japan, differing in body size, external appearance, feeding ecology, and reproductive behavior.

A distinct small form, the Sittang whale or pygmy Bryde's whale, has been identified in the eastern Indian Ocean and tropical West Pacific; in southeast Asia it has been found from Burma (Myanmar) to the southern Philippines, the South China Sea and the Solomon Islands, and apparently is restricted to coastal and shelf waters. Molecular evidence from allozyme and mtDNA analyses, as well as osteological comparisons, indicates that the small form does not belong genetically with the larger Bryde's whales and almost certainly constitutes a separate species, to which the name *B. edeni* may apply, if the holotype of the nominal species, which is from the mouth of the Sittang River, Burma, proves to be of that form (see species account).

Sei whale, *Balaenoptera borealis*

The sei whale appears to be uncommon in tropical waters. None of the published new records in the northern Indian Ocean is convincing. Sei whales have routinely been confused with Bryde's or fin whales by observers who were not familiar with all three species. Sei whales from the Southern Hemisphere generally winter as far north as South Africa and Western Australia (to about 25°S). Japanese scouting and research vessels reported sighting 10 sei whales south of Sumatra (5–10°S) during November in the period 1974/1975–1984/1985. In Southeast Asia its occurrence has been reported for the South China Sea (although this needs confirmation) and by one specimen from Java. The Javan animal is the holotype of the putative subspecies *B. borealis schlegelii*.

Fin whale, *Balaenoptera physalus*

The fin whale also seems to be uncommon in tropical waters. A North Pacific population is thought to winter from the Sea of Japan south to the Philippine Sea, with concentrations in the East China and Yellow Seas. Southern Hemisphere fin whales, which may belong to the southern subspecies *B. physalus quoyi*, winter in the Indian Ocean off South Africa, Madagascar, and Western Australia. Fin whale sightings reported by Japanese vessels in the period 1974/1975–1984/1985 were concentrated in two longitudinal areas: one west of 50°E and the other at 70–100°E. The northern limits of the species' range were about 20–25°S in November/December and 40–45°S in March. There are several published reports of fin whales from the northern Indian Ocean, Persian Gulf and off the Seychelles. There are a few records from Indonesian and Philippine waters.

Blue whale, *Balaenoptera musculus*

The blue whale occurs throughout the Indo-West Pacific. It has been recorded from around the Seychelles, from the Arabian Sea and Persian Gulf, and from Sri Lanka, and the Bay of Bengal. Strandings and sightings of blue whales in Southeast Asia have been reported from the Indo-Malayan Archipelago and southern China. In the Indo-Malayan Archipelago they have been recorded for the months of June, August, September, and December and probably occur there year-round. The "pygmy blue whale" *B. musculus brevicauda*, known from subantarctic waters of the Indian, southeast Atlantic, and southwest Pacific Oceans, may winter in tropical waters.

It is not known whether the blue whales found in the northern Indian Ocean and the Arabian Sea, which reside in tropical waters year-round, constitute a separate population. The name *B. musculus indica* has been given to this stock, but its distinguishing features are poorly defined. Animals observed in the Arabian Sea, around Sri Lanka and in the Indo-Malayan Archipelago have been tentatively identified as pygmy blue whales. However, the type specimen of *B. musculus indica*, collected in Burma (Myanmar), measured 25.6 m and an individual stranded on Java 27 m, whereas the largest pygmy blue whale ever taken measured only 24.1 m.

The year-round occurrence of blue and humpback whales in the northern Indian Ocean seems to be related to the high primary productivity of this region, the result of a combination of monsoon-related currents and strong upwelling.

Two other species of baleen whale occur in the Indian Ocean. The southern right whale *Eubalaena australis* (family Balaenidae) extends its range north to southern Mozambique and Western Australia. In the 19th and early 20th centuries, right whales were taken in the Indian Ocean between 30° and

40°S, around Crozet, Kerguelen, and Amsterdam Islands and on their calving grounds off South Africa and southeastern Australia. The pygmy right whale *Caperea marginata* (family Neobalaenidae) has been recorded north to nearly 33°S off southwestern Australia. The critically endangered western population of the gray whale *Eschrichtius robustus* (family Eschrichtiidae), known as the Korea/Okhotsk Sea stock, winters off southern China, with records from the Yellow, East China, and South China Seas, as far south as Hainan. It has been suggested that breeding and calving grounds may exist off Guangdong Province in southern China, but this should be investigated.

B. Sperm Whales, Family Physeteridae

Sperm whale, *Physeter macrocephalus*

The sperm whale occurs in all oceans of the world. Concentrations such as found in the traditional whaling grounds seem to be associated with oceanographic fronts, steep bottom topography, and high productivity. Whereas adult males reach temperate or even polar waters and return to lower latitudes to breed, females and immatures are restricted to tropical and warm-temperate seas. The sperm whale occurs throughout the deep waters of the Indian Ocean, including the Gulf of Aden and Gulf of Oman, and in the West Pacific; its main distribution is well known from records of 19th-century whalers. The species is sometimes found in shallow waters. The deep passages and seas between the islands of the eastern Indo-Malayan Archipelago have been supposed to be a migration route of sperm whales between the Indian and Pacific Ocean.

In the western Indian Ocean, exploitation of sperm whales began at about 1800 on the whaling grounds near the Cape of Good Hope and in later years extended east and north to Madagascar, Mozambique, and the "Zanzibar grounds" (Comoros, Seychelles, and the east African coast), Arabia, and west of Sri Lanka. In the eastern Indian Ocean and western Pacific, sperm whales were taken south of Sumatra and Java, in the Timor Sea and off Western Australia, in the Moluccan and Sulu Seas and north of New Guinea, and off the east coast of Japan. The fishery declined for economic reasons toward the close of the 19th century. Today, sperm whales are only hunted in a subsistence whale fishery in Indonesia. The whalers of Lamalera on Lembata Island specialize in catching sperm whales and other toothed whales. The animals are caught by using hand harpoons from open rowing boats called "peledang." During the whaling season, the boats search an area of up to a few kilometers south of the coast. When a whale is approached, the harpooner leaps from a small platform on the bow and adds his weight to drive the harpoon into the whale's back, similar to the technique used by Philippine whalers, who hunt baleen whales.

C. Pygmy and Dwarf Sperm Whale, Family Kogiidae

Our knowledge of the distribution of the pygmy sperm whale *Kogia breviceps* and dwarf sperm whale *K. sima* is sketchy and mainly based on specimens stranded or caught in fishing nets. Both species occur in tropical and warm-temperate seas, with the pygmy sperm whale extending its range into slightly colder waters. They are difficult to observe at sea and probably are much more common than sighting records would suggest. Although their diets overlap, prey composition indicates that the pygmy sperm whale has a more oceanic distribution, whereas the dwarf sperm whale prefers continental shelves and shelf edges.

In the Indo-West Pacific, both species have been recorded from South Africa north to Oman, east to Australia and the Indo-Malayan Archipelago, and north to southern Japan. Both are killed accidentally in Sri Lanka; the dwarf sperm whale is caught in directed fisheries and incidentally in gill net and seine fisheries in the Philippines. In Indonesia, the dwarf sperm whale is taken by subsistence whalers of Lamalera on Lembata Island.

D. Beaked Whales, Family Ziphiidae

Twelve species of beaked whales have been recorded from the Indo-West Pacific. Only four of these are distributed in tropical waters. The other eight normally live in temperate or cold waters of the Southern Hemisphere and occasionally migrate or stray into lower latitudes. All are oceanic species, mainly known from stranded animals.

Cuvier's beaked whale, *Ziphius cavirostris*

This species is the most widespread of the beaked whales, occurring worldwide in tropical and warm-temperate waters. It has been reported from South Africa, the Comoros and Seychelles, the Arabian Sea, Sri Lanka, Australia, the Indo-Malayan Archipelago, Taiwan, the Philippines, and southern Japan.

Ginkgo-toothed whale, *Mesoplodon ginkgodens*

This species is distributed in tropical and warm-temperate waters of the Indian and Pacific Oceans. In the Indo-West Pacific it has been found in Sri Lanka, the Strait of Malacca, the Indo-Malayan Archipelago, off Taiwan, and in southern Japan, with one record from the northern Yellow Sea.

Blainville's beaked or dense-beaked whale, *Mesoplodon densirostris*

This species occurs in tropical and warm-temperate waters of all oceans. It has been reported from South Africa, Mauritius, the Seychelles, Australia, the Philippines, China, Taiwan, and Japan.

"Tropical bottlenose whale," *Indopacetus pacificus*

Large, unidentified beaked whales that look much like *Hyperoodon* have been observed and photographed on many occasions in the Indian and Pacific Oceans, between about 20°S and 35°N. Records from the Indo-West Pacific are from the Gulf of Aden and the Arabian Sea, Sri Lanka, the Indo-Malayan Archipelago, the Philippines, and north to southern Japan. Pitman *et al.* (1999) presented good evidence that they represent Longman's beaked whale *I. pacificus*, so far only known from two skulls of stranded animals, in Somalia in 1955 and in northeastern Australia in 1882.

Two species—the strap-toothed whale *Mesoplodon layardii* and the scamperdown whale *M. grayi*—occur at least season-

ally within the southern confines of the area considered. The remaining six are irregular visitors: Arnoux's beaked whale *Berardius arnuxii*, Tasman beaked whale *Tasmacetus shepherdi*, southern bottlenose whale *Hyperoodon planifrons*, Hector's beaked whale *Mesoplodon hectori*, True's beaked whale *M. mirus*, and Andrew's beaked whale *M. bowdoini*. A skull of *H. planifrons* (the holotype of the species) was found in the Dampier Archipelago, Western Australia, at about 20°S.

E. River Dolphins, Families Platanistidae and Lipotidae

Two species of river dolphins are represented in the Indo-West Pacific region: the Indian river dolphin or susu *Platanista gangetica* (family Platanistidae) and the Yangtze dolphin or baiji *Lipotes vexillifer* (family Lipotidae).

Two subspecies of the Indian river dolphin are recognized: the Ganges dolphin *P. g. gangetica* in the Ganges/Brahmaputra River system of India, Bangladesh, Nepal, and possibly Bhutan, and the Indus dolphin *P. g. minor*, formerly common throughout the Indus River and its tributaries, but now only found in a restricted area in Pakistan. Both subspecies are regarded as endangered, particularly the Indus dolphin with an estimated population in the low hundreds, suffering from habitat degradation (pollution, construction of dams) and mortality in fishing gear.

Of all living cetaceans, the Yangtze dolphin in China probably is the closest to EXTINCTION, with an estimated number of less than 100 animals remaining. Baiji are found in the middle and lower course of the Yangtze River and may enter its tributary lakes during periods of flooding.

F. Dolphins, Family Delphinidae

Rough-toothed dolphin, *Steno bredanensis*

This species mainly inhabits deep, warm oceanic waters. In the Indo-West Pacific it ranges from South Africa to the Gulf of Aden and Arabian Sea, east to Australia, the Indo-Malayan Archipelago and the Philippines, and north to southern Japan. Small numbers are killed in gill nets off Sri Lanka.

Humpback dolphins, genus *Sousa*

Humpback dolphins inhabit tropical and subtropical coastal waters of the Indo-West Pacific and often occur in mangroves, river deltas, and estuaries. They ascend far up the main rivers of Asia, e.g., the Ganges and Yangtze.

Rice (1998) recognizes two species in the Indo-West Pacific. The Indian humpback dolphin *S. plumbea* occurs from South Africa and Madagascar to the Red Sea, including the Suez Canal, and from the Persian Gulf to the western Bay of Bengal.

The Pacific humpback dolphin *S. chinensis* ranges from the Strait of Malacca, Gulf of Thailand, and the northwest coast of Borneo to southern China. It also occurs in northern Australia, down the east coast to about 34°S. Humpback dolphins are reported to decline in the two areas where they have been studied in some detail. Off South Africa they seem to be killed in antishark nets at an unsustainable rate and it has been suggested that they are declining in Hong Kong waters. They are caught for oceanaria along the coast of Thailand. Incidental catches are known from shallow-water fisheries throughout its range.

Bottlenose dolphins, genus *Tursiops*

Bottlenose dolphins are distributed throughout the Indo-West Pacific, where they occupy a wide range of habitats. Some populations inhabit bays, lagoons, and estuaries, whereas others live in more open coastal or even oceanic waters. The taxonomy of the genus is largely unresolved. Until recently, most authors have recognized one cosmopolitan species, *T. truncatus*. In the Indo-West Pacific, two types can be distinguished: a larger form that is very similar to *T. truncatus* and one that is more slender, has a longer beak, and often a spotted abdomen. To the latter, the name *T. aduncus* is commonly applied, although that species is not very well defined. Morphological and osteological studies as well as molecular genetic analyses of mitochondrial and nuclear DNA have confirmed that the two forms are indeed specifically distinct (Wang *et al.*, 1999, 2000 a, b; Hale *et al.*, 2000). Based on an analysis of complete mtDNA cytochrome B sequences, LeDuc *et al.* (1999) concluded that the smaller form may even belong in the genus *Stenella*. Most authors assume that *T. aduncus* is the more common species throughout the Indo-West Pacific, ranging from South Africa to the Red Sea and Persian Gulf, east to eastern Australia and New Caledonia, the Indo-Malayan Archipelago, and north to the Ryukyu and perhaps Ogasawara

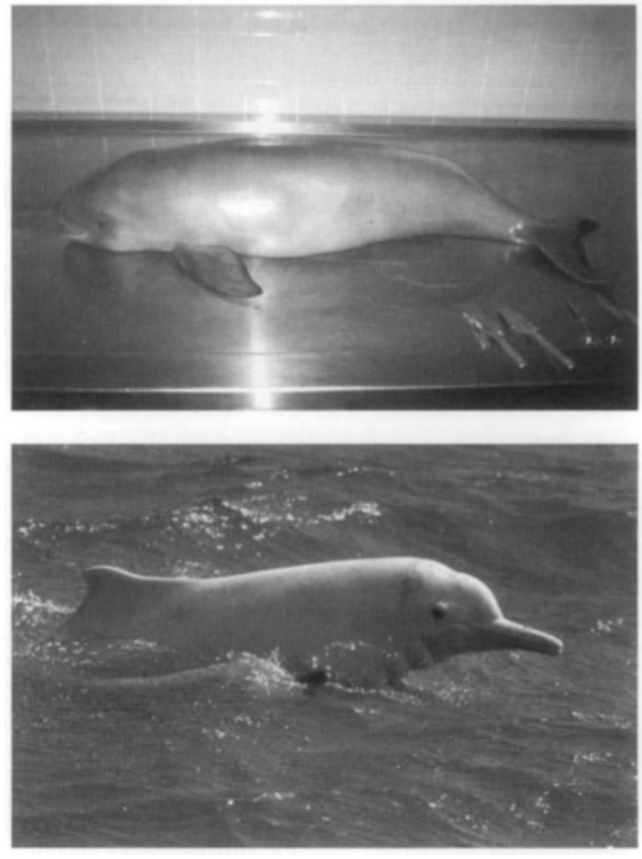

Figure 2 *The finless porpoise (top) and the Indopacific humpback dolphin (bottom) are endemic to the Indo-West Pacific. Photographs by Thomas Jefferson.*

(Bonin) Islands. It occurs mainly, but not exclusively, in coastal waters.

It is not clear to what extent the larger species occurs in the area. Thirteen bottlenose dolphins from east of Mauritius and near the Maldives were identified by genetic analysis as *T. truncatus*. Animals of this type have also been reported from South Africa, the Seychelles, the Red Sea, Oman, southern and eastern Australia, and from the Northwest Pacific, south to Hong Kong, Taiwan, and the Philippines. It occurs in both oceanic and coastal waters.

Incidental and directed takes of *Tursiops* sp. occur in several fisheries in the Indo-Pacific. Directed catches have been reported for Sri Lanka, Thailand, the Philippines, and Taiwan. A large incidental take has occurred in a Taiwanese gill net fishery off Australia, with perhaps over 2000 animals killed per year.

Pantropical spotted dolphin, *Stenella attenuata*

The pantropical spotted dolphin occurs throughout the tropical and subtropical Indo-West Pacific, from South Africa to the Red Sea and Persian Gulf, east to Australia, the Indo-Malayan Archipelago, and the Philippines, and north to southern Japan. Mixed groups of *S. attenuata* and *S. longirostris* have been reported from the western Indian Ocean, Red Sea, and the Indo-Malayan Archipelago, often associated with concentrations of seabirds and tuna. The spotted dolphin is taken in harpoon fisheries in the Philippines, Laccadive Islands, Sri Lanka, and Indonesia. A former drive fishery at Malaita in the Solomon Islands took several hundred animals per year in the 1960s. The species is incidentally caught in gill net fisheries in Pakistan, Sri Lanka, the Philippines, and northern Australia.

Spinner dolphin, *Stenella longirostris*

The spinner dolphin ranges throughout the tropical and subtropical Indo-West Pacific, from South Africa to the Red Sea and Persian Gulf, east to Australia, the Indo-Malayan Archipelago and the Philippines, and north to southern Japan.

Perrin *et al.* (1999) identified two forms of spinner dolphin in the Indo-West Pacific based on external, osteological, and behavioral differences, as well as habitat preferences. They distinguish the "dwarf spinner dolphin" as a subspecies, *S. l. roseiventris*. This form has been found in shallow inner waters of Southeast Asia (Gulf of Thailand, Borneo, Moluccan Sea, and northern Australia). Dwarf spinner dolphins are smaller, with fewer vertebrae and teeth than the pelagic form *S. l. longirostris*. The latter inhabits the Indian Ocean and West, Central, and South Pacific. Dwarf spinner dolphins feed mainly on benthic and coral reef fishes and invertebrates, whereas the larger form primarily feeds on mesopelagic fish and squid. Off Oman, two types of spinner dolphin are recognized, one of them consisting of very small, dark-colored and often pink-bellied animals (Van Waerebeek *et al.*, 1998). The taxonomic position of the latter is still unresolved. Spinner dolphins are taken in harpoon fisheries in Sri Lanka, the Philippines, and Indonesia. Incidental catches in fishing gear have been reported for Pakistan, India, Sri Lanka, the Philippines, and northern Australia.

Striped dolphin, *Stenella coeruleoalba*

Although the striped dolphin is primarily a warm water species, its range extends into higher latitudes than that of spotted and spinner dolphin. The species generally seems to be restricted to oceanic waters and approaches the shore only where deep water occurs close to the coast. The striped dolphin has been reported from South Africa to the southern Red Sea, east to Australia, and from the Philippines north to Japan. Records from the Indo-Malayan Archipelago have not yet been confirmed. INCIDENTAL CATCHES occur in gill nets in the northern Indian Ocean (e.g., Sri Lanka).

Common dolphins, genus *Delphinus*

Common dolphins are distributed in warm-temperate and tropical waters throughout the Indo-West Pacific. Morphological and genetic analysis has revealed the existence of at least two species: the short-beaked common dolphin *D. delphis* and the long-beaked common dolphin *D. capensis*.

In the Indian Ocean, only the occurrence of long-beaked animals has as yet been confirmed; *D. capensis* has been reported from South Africa and Madagascar. In the northwest Pacific, this form may occur as far south as Taiwan.

In coastal waters of the northern Indian Ocean and southeast Asia, a very long-beaked form exists, which by some authors is regarded as a separate species: *D. tropicalis*. Its taxonomic status is still unclear, but it exceeds *D. capensis* in rostral length and the average number of teeth. This form has been documented for the Arabian Sea, Gulf of Aden and southern Red Sea, Gulf of Oman and Persian Gulf, Pakistan and western India, the Gulf of Thailand, Gulf of Tonkin, and the South China Sea, north as far as Taiwan. Reports that it occurs sympatrically with *D. delphis* or *D. capensis* off Oman seem erroneous. The situation around Taiwan is not clear.

The short-beaked common dolphin *D. delphis* has been reported from various areas in the West Pacific: in the northwest from Taiwan and southern Japan, in the southwest from New Caledonia and Australia, particularly the south coasts.

Fraser's dolphin, *Lagenodelphis hosei*

Fraser's dolphin was described in 1956 from a skeleton found on a beach in Sarawak, Borneo, prior to 1895. The species occurs primarily in deep tropical and subtropical waters. In the Indian Ocean it has been reported from South Africa and Madagascar, the Seychelles, southern India and Sri Lanka, Borneo (type specimen) and the deeper waters of the eastern Indo-Malayan Archipelago, the Philippines, China, Taiwan, and southern Japan. In Australia, strandings have occurred south to about 38°S. In Indonesia and the Philippines, Fraser's dolphin has been observed in mixed groups with various other dolphin species. Directed catches have been reported for the Philippines and Indonesia.

Genus *Lagenorhynchus* [= *Sagmatias*]

Two species of this genus occur marginally within the confines of the Indo-West Pacific. The (North) Pacific white-sided dolphin *L.* [*S.*] *obliquidens* has been found as far south as Taiwan. The dusky dolphin *L.* [*S.*] *obscurus* in some years enters the coastal waters of southern Australia.

Risso's dolphin, *Grampus griseus*

Risso's dolphin is distributed throughout tropical and temperate seas, particularly seaward of steep continental shelf edges. In the Indian Ocean it is found from South Africa to the Red Sea and Persian Gulf, east to the Bay of Bengal, the deeper waters of the eastern Indo-Malayan Archipelago and Australia, and throughout the West Pacific. Risso's dolphins are known to be directly taken off Palawan in the Philippines and in the Indonesian whale fishery of Lembata and Solor Islands. Between 1983 and 1986, 241 individuals were reported landed in the Sri Lanka gill net fishery, but the actual numbers taken here may be about 1300 animals per year.

Melon-headed whale, *Peponocephala electra*

The melon-headed whale is mainly found in deep tropical and subtropical, oceanic waters. In the Indo-West Pacific it has been recorded from the Seychelles to the Arabian Sea and Bay of Bengal, Australia, the deep waters of the Indo-Malayan Archipelago, the Philippines, Gulf of Thailand, Taiwan, and southern Japan. There are a few records from South Africa at 34°S and from southern Australia. Mass STRANDINGS are known from the Seychelles, Indonesia, Australia, and Japan. There is a direct catch of melon-headed whales in the harpoon fishery off Pamilacan Island in the Philippines and off Lembata and Solor Islands in Indonesia.

Pygmy killer whale, *Feresa attenuata*

The pygmy killer whale is mainly found in deep tropical and subtropical, oceanic waters. In the Indo-West Pacific it has been recorded from South Africa, to the Gulf of Aden and Gulf of Oman, east to Australia, the Indo-Malayan Archipelago, the Philippines, Taiwan, and southern Japan. Incidental and directed catches have been reported for Sri Lanka, with an estimated 300–900 animals taken annually. Although not confirmed by a specimen yet, the species may also be taken in the subsistence whale fishery in Indonesia.

False killer whale, *Pseudorca crassidens*

The false killer whale is found primarily in deep tropical to warm-temperate waters. It occurs throughout the Indian Ocean from South Africa to the Red Sea and Persian Gulf, east to Australia, the Indo-Malayan Archipelago, and the Philippines, north to the Yellow Sea and southern Japan. In Australia, mass strandings occur relatively often, about once every 2.5 years since 1970, on the average involving about 100 individuals. Mass strandings have also been reported from Tanzania and Sri Lanka. In ancient times, false killer whales were hunted for their ivory in the Arabian Sea. Although not reported yet, the species might be taken in the subsistence hunt in Indonesia. Incidental catches have been reported for South Africa, India, Sri Lanka, and northern Australia.

Killer whale, *Orcinus orca*

The cosmopolitan killer whale occurs throughout the Indian Ocean, including the Gulf of Aden and Red Sea, and in the West Pacific. In the Indian Ocean there are records for all months and all latitudes. The existence of three migratory stocks in the southern Indo-Pacific has been postulated: near the coast of Africa, off the west coast of Australia, and in oceanic waters of the central Pacific. Their distribution may be linked to the movements of rorquals, particularly minke whales, on which killer whales occasionally feed.

Usually, killer whales were only secondary targets of whalers, but some have been taken by whalers operating from Durban in South Africa and probably by Soviet-Russian pelagic whaling operations in the 1970s, although the localities of the catches were not reported to the IWC. Killer whales are caught in the whale fishery at Lembata Island, Indonesia, where the landing of 24 animals was recorded between 1960 and 1994. Catches in net fisheries, though rare, have been reported for Sri Lanka.

Pilot whales, genus *Globicephala*

Two species are recognized, with largely parapatric distributions. The short-finned pilot whale *G. macrorhynchus* mainly occurs in tropical and subtropical waters. In the Indo-West Pacific it occurs from South Africa to the Red Sea and Gulf of Oman, east to Australia, the Indo-Malayan Archipelago, the Philippines, and north to Japan. Mass strandings have been reported for India, the Indo-Malayan Archipelago, and Australia. The long-finned pilot whale *G. melas* has a bipolar distribution in temperate waters. Southern animals are distinguished as *G. m. edwardii*. In the Indo-West Pacific, its northern limits overlap the range of the short-finned pilot whale off the Cape Province in South Africa and off southern Australia; occasionally, the species strays further north.

Short-finned pilot whales are taken in coastal fisheries off Sri Lanka and Pakistan. They are caught in subsistence whale fisheries in Indonesia and the Philippines.

Irrawaddy dolphin, *Orcaella brevirostris*

This species has distinct riverine, estuarine, and coastal populations. It is distributed discontinuously in muddy, shallow coastal waters of the Bay of Bengal, Strait of Malacca, the Indo-Malayan Archipelago, Gulf of Thailand, and northern Australia. It enters the systems of the Ganges/Brahmaputra, Irrawaddy, Mekong, and several other rivers, with populations living as far as about 1300 km upstream in the Irrawaddy and 1000 km up the Mekong/Sekong. Along the Asian mainland, the Irrawaddy dolphin occurs in northeastern India, Bangladesh, Burma (Myanmar), Thailand, Malaysia and Singapore, Cambodia, Laos, and Vietnam. In the Indo-Malayan Archipelago it has been found on northeastern Sumatra, the Seribu Islands, Java, and in many places on Borneo: Kendawangan, Kumai Bay, and the Barito River in the south, the Kajan and Mahakam Rivers and their major tributaries and lakes in the eastern, central, and northern part of the island, and from Sarawak, Brunei, and Sabah in the northwest. In 1978 the population in the Mahakam River was estimated to number at least 100–150 animals, whereas an unpublished account from 1993 reported only 68 individuals. A 1997 survey in the Mahakam River did not give a population estimate (Kreb, 1999), but in 1999 the numbers in this river were estimated at not more than 50. The species has further been found in southwestern Sulawesi and in northwestern and southern New Guinea and the Philip-

pines. In northern Australia it ranges from Point Cloates in Western Australia to Gladstone in Queensland. Incidental catches are known for many areas.

G. Porpoises, Family Phocoenidae

Finless porpoise, *Neophocaena phocaenoides*

The finless porpoise is distributed along a narrow band of shallow water along the coasts of southern and eastern Asia. The species occurs in inshore waters, mangrove zones, and delta areas, including the lower reaches of the major river systems such as the Indus, Ganges/Brahmaputra, and Mekong. Three subspecies are reasonably well differentiated: *N. p. phocaenoides* occurs from the Persian Gulf to the South China Sea and southern part of the East China Sea, and in the Indo-Malayan Archipelago east to Java; *N. p. sunameri* is found along the coast of northeastern China, Korea, and southern Japan. The only population exclusively inhabiting fresh water, *N. p. asiaeorientalis*, occurs in China in the lower and middle course of the Yangtze River and adjacent lakes, ranging over an area of almost 1670 km. Some populations seem to be seriously depleted, mainly due to incidental mortality in fishing gear and to habitat degradation.

H. Dugongs, Family Dugongidae

Dugong, *Dugong dugon*

Dugongs live in tropical and subtropical coastal waters of the Indo-West Pacific. Two subspecies are recognized: *D. d. hemprichii* occurs throughout the Red Sea and *D. d. dugon* is distributed discontinuously from Mozambique to the Gulf of Aden and from the Persian Gulf east to Australia. Its range includes many islands in the western and northern Indian Ocean, the Indo-Malayan Archipelago, the Philippines, north to southern China, Taiwan (where probably extinct), and the Ryukyu Islands, east to Guam, Palau, Yap, Pohnpei, the Bismarck Archipelago, Solomon Islands, Vanuatu, New Caledonia, and, as a vagrant, to Fiji. The waters of Papua New Guinea and northern Australia are the most important stronghold for the species. Dugongs live in areas where there are large quantities of seagrasses (families Potamogetonaceae, Zosteridae, and Hydrocharitaceae). In many areas, the species has been reduced to widely separated relict populations, mainly by overhunting. Although the dugong has become protected over most of its range, direct hunting for food and indirect catches in fishing gear are still substantial in many areas (east Africa, India, Sri Lanka, the Indo-Malayan Archipelago, the Philippines and Australia), although few data on numbers taken are available.

For a review of work in the Indian Ocean, see Leatherwood and Donovan (1991). A compilation of recent publications and information on cetaceans in southeast Asia is found in Perrin *et al.* (1996) and Smith and Perrin (1998).

Infanticide and Abuse of Young

CLAUDIO CAMPAGNA
Centro Nacional Patagónico, Puerto Madryn, Argentina

The killing and abuse of young by conspecifics is a widespread phenomenon. Parental and nonparental infanticide have been reported in almost 100 species of mammals, most of which are terrestrial (Hausfater and Hrdy, 1984; Parmigiani and vom Saal, 1994). Infant killing can be the direct outcome of a violent interaction or can result from the indirect neglect of a young or an accident. This article focuses on violent, nonparental forms of infanticide in aquatic mammals. Parental killing in this group is apparently restricted to the indirect effects of maternal neglect (see Le Boeuf and Campagna, 1994) and will not be treated here. Infant abuse is a much more common behavioral occurrence than infanticide. It may imply active violence or passive neglect, and it does not necessarily involve the intended death of the victim. Death in the context of abuse is usually perceived as accidental, a by-product that often follows a process of infection and starvation (Le Boeuf and Campagna, 1994). Infant or young refers to a lactating or recently weaned pup, calf, or cub.

Except for otariids and phocids, data on killing and abusing young are sparse for aquatic mammals. Infanticide is an event that may pass unobserved or unreported. Spotty research coverage, with some species being well known and others virtually unstudied, suggests that the relevance and diversification of abuse and killing of young may be more widespread than reported here. Explanations of the well-documented cases of abuse and infanticide in aquatic mammals rarely support the adaptive hypotheses that would account for similar episodes in terrestrial species.

I. Abuse and Killing of Young by Males

Violent behavior toward young was described in four out of seven sea lion species (with the closely related *Zalophus californianus, Z. japonicus* and *Z. wollebacki* being the exceptions). Subadult and juvenile males of the South American sea lion, *Otaria flavescens*, abduct (seize), abuse, and kill pups during the breeding season (Campagna *et al.*, 1988). The BEHAVIOR was observed in coastal Patagonia (Campagna *et al.*, 1988), Uruguay (Vaz Ferreira, 1965), Chile (H. Paves Hernandez and C. Espinoza, personal communication), Peru (Harcourt, 1993; P. Majluf and K. Soto, personal communication), and the Falkland Islands (C. Duck and D. Thompson, personal communication). At Punta Norte, Península Valdés, Argentina, 163 successful abductions were recorded in four breeding seasons. More than 20% of the 400 pups born each season were abducted by males. In a typical abduction, a juvenile or subadult male approached the breeding area alone or as part of a group raid (Campagna *et al.*, 1988), dashed toward a pup, and grabbed it. The pups were then abducted away from the breeding group and some were carried out to sea (11% of the abductions), whereas others were released and held close to the abductor. Pups that attempted to escape were shaken violently from side to side, tossed in the air, held crushed against rocks, or submerged. Males defended their abducted pup from other males. Some abductors mounted pups, fully covering them with their massive bodies. About 6% of the pups abducted and 1.3% of the pups born during a season died as a consequence of physical abuse. Dead pups showed tooth puncture wounds and extensive hematomas.

Australian (*Neophoca cinerea*) and Hooker's (*Phocarctos hookeri*) sea lions abduct and abuse pups in a similar fashion described for *O. flavescens*, with the important difference that adult Hooker's cannibalize the killed pups. Adult male Australian sea lions grab pups that may be alone or with the mother and bite, shake, and toss them several times (Higgins and Tedman, 1990). Eight attacks recorded in two breeding seasons resulted in four dead pups (5% of the pups observed) and accounted for 19% of pup mortality in the rookery (Higgins and Tedman, 1990). Adult and subadult male Hooker's sea lions grab pups by the neck, violently thrash them from side to side, and sometimes carry them out to sea and drown them (Wilkinson *et al.*, 2000). Adult abductors were also observed eating pups. Opportunistic observations on Hooker's sea lions report males abducting pups on two occasions and eating them on nine occasions (Wilkinson *et al.*, 2000). After thrashing the victim repeatedly from side to side, males bit the flesh off the carcass and consumed it. This is the only otariid species for which cannibalism has been described. Immature males do not apparently kill pups, although they may try to keep them under control and occasionally mount them.

Steller sea lions, *Eumetopias jubatus*, may trample or crush pups or push them over a cliff as an indirect consequence of territorial disputes. In some instances, however, pups are killed as a direct violent action by males (B. Porter, personal communication).

Episodes of violent behavior toward pups are rare or absent among fur seals. Juvenile male northern fur seals, *Callorhinus ursinus*, occasionally abduct conspecific pups in a context that suggests a form of mate substitution (R. Gentry, personal communication). Male Antarctic fur seals, *Arctocephalus gazella*, rarely respond to pups, even to the extent that they will fail to respond if they happen, apparently accidentally, to lie on

top of a pup (I. Boyd, personal communication). Pups may be killed accidentally by males if they come between fighting individuals, a relatively common occurrence in otariids.

Among the other pinnipeds, infant abuse and killing were described in at least four phocids and the walrus. Male northern and southern elephant seals, *Mirounga* spp., of different age classes, kill suckling pups and weanlings (Le Boeuf and Campagna, 1994). Pups are trampled accidentally by bulls in the context of male–male competition and may then die of internal injuries. Weaned pups are abused by pubertal males that attempt to mate with them and, in the process, injure and kill individuals of both sexes (Rose *et al.*, 1991). At the time of departure, 30–50% of northern elephant seal (*M. angustirostris*) weaned pups show signs of having been mounted by a male that range from neck bites, scraps, cuts, and puncture wounds to deep gashes exposing BLUBBER and profuse bleeding. An adult southern elephant seal, *M. leonina*, male from the Patagonian colony of Península Valdés killed and apparently ate pups (J. C. López, personal communication). He grabbed weaned pups from the beach, dragged them out to sea, kept them underwater until struggling ceased, and then tore off chunks and consumed them. The cannibal returned to the same place at least during two consecutive breeding seasons and killed dozens of weanlings. Male gray seals, *Halichoerus grypus*, occasionally shake, toss, bite, mount, and kill pups (D. Boness and P. Pomeroy, personal communication). There is also evidence of cannibalism in this species (Bédard *et al.*, 1993; Kovacs, 1996). An adult male was involved in the killing and eating of pups during three breeding seasons. In a similar modality to the southern elephant seal cannibal, the gray seal male grabbed his victims by the hind flippers, dragged them into the water, and drowned them. He later tore off chunks of the pup's body with a biting–shaking action and consumed the blubber, skin, and muscle. Hawaiian monk seals (*Monachus schauinslandi*) males mount pups, suffocate, or drown them (Hiruki *et al.* 1993; M. Craig, personal communication). Some individuals persist in this behavior and may kill many pups. Finally, adult male, female, and immature walruses, *Odobenus rosmarus*, can jab a pup with their tusks and cause lethal injuries.

In summary, adult, subadult, and juvenile males of several pinniped species injure, abuse, or kill suckling and recently weaned pups in the following contexts: (a) accidentally, often as an indirect outcome of trampling and crushing during dominance, female defense, and territorial disputes; (b) as a direct or indirect consequence of misdirected sexual assault, such as during abductions and abuse by pubertal males; (c) as a direct or indirect consequence of misdirected aggressive behavior with no clear sexual component, such as attack of pups by territorial males not associated to mounting, herding, or harassing; and (d) as an apparent source of food (cannibalism). The age class involved in the abuse and killing varies with the species. In Australian and Hooker's sea lions, adults are the most aggressive toward pups, but subadult and juvenile males also sequester pups and engage in biting, mounting, and holding them underwater. In the South American sea lion, subadult and juvenile males do most of the abductions; adults are rarely involved in pup abuse. Among phocids, young males seem to be involved more often in abuse than adults; adults may cause pup death or injury as an epiphenomenon of male–male competition.

Reports of violence toward young in the rest of the aquatic mammals are rare. Male polar bears, *Ursus maritimus*, occasionally kill and eat cubs, a behavior that is apparently generalized throughout the Arctic (Taylor *et al.*, 1985). Indirect evidence suggests infanticide in the bottlenose dolphin, *Tursiops truncatus* (Patterson *et al.*, 1998). Stranded dolphin calves were found with internal injuries that included contusions around the head and thorax, bone fractures, and lacerated organs compatible with violent behavior. The interactions that may have caused the death of the calves were not observed. However, an adult dolphin was observed to interact violently with a dead conspecific calf, and dolphins were also seen to chase and hit harbor porpoises, *Phocoena phocoena*, hard enough to toss them into the air. Stranded harbor porpoises had evidence of trauma similar to that reported for the stranded dolphin calves. Additional indirect evidence of conspecific killing in *T. truncatus* is available for a population of the southeast Virginia coast (D. Dunn, personal communication). Nine bottlenose dolphins within their first year of life, thus still dependent on their mothers, stranded with multiple skeletal fractures, hematomas, organ lacerations, contusions, and hemorrhages, indicating multidirectional trauma. External signs of trauma were absent, an observation incompatible with predation, boat strike, and fisheries interactions, but similar to antemortem injuries reported for harbor porpoises and dolphins (Patterson *et al.*, 1998).

II. Abuse and Killing of Young by Females

Adult pinniped females repel alien young in the context of aggressive protection of resources intended for their own pup. In the northern elephant seal, females aggressively reject alien pups that approach them (references in Le Boeuf and Campagna, 1994). They shake, throw, and viciously bite unrelated pups. Attacks may be violent enough to cause extensive wounds or fractures, with subsequent infection and death. Orphans attempt to nurse from any female, thus being particularly vulnerable to attack and injury.

An unusual behavior involving females and resulting in the death of unrelated pups was described for the South American sea lion rookery at Islas Ballestas (Peru; K. Soto, personal communication). During the 1997–1998 El Niño breeding season, virtually all pups born starved to death. The following year, only about one-quarter of the females gave birth. These mothers had to defend their newborn pups from the sustained attempts of neighboring females to abduct the latter. It often occurs that otariid females close to parturition attempt to bring alien pups near them. However, the particular breeding context of the post-El Niño year resulted in an unusually high incidence of a behavior that may be related to confusing alien pups with their own pup. Abductions occurred at a rate of one pup every 2.7 hr of observation. Females did not nurse the abducted pups, which were later abandoned. Those that failed to reunite with their mother died from starvation or were killed by young males. Almost 300 female abductions resulted in 11 pup deaths,

and the incidence of pup mortality due to male abductions increased from the regular 1.5 to 8.0% of the pups born.

III. Male Violent Behavior toward Mature Females and Interspecific Pups

From a behavioral standpoint, abuse and killing of conspecific young by male pinnipeds resemble male violent behaviors directed toward mature females of the same species and toward females and pups of other species. Attributes that allow males to physically overpower competitors would also promote aggressive sexual behaviors related to achieving access and maintaining control of breeding females. For example, adult and subadult *O. flavescens* males abduct females from established harems (Campagna *et al.*, 1988). Abductions involve grabbing, tossing, herding, mounting, and biting. Some females are badly injured and killed in the process. Male harassment of conspecific females may be relatively common in phocids; it has been reported for both species of elephant seals: the Hawaiian monk seal and the gray seal (Mesnick and Le Boeuf, 1991; Hiruki *et al.*, 1993; Boness *et al.*, 1995).

Strong and large pinniped males with an indiscriminate sexual urge often injure and kill females of other species. Males killing interspecific females during mating attempts were reported in all sea lions (Miller *et al.*, 1996). *O. flavescens* males kill *A. australis* females, and *E. jubatus* kill *Z. californianus* females and even males. Mating attempts with dead females of the same and of a different species occur in some otariids and phocids, such as the South American sea lion and the elephant seal. Abnormal escalation of aggressive sexual behaviors may lead to instances such as a Steller sea lion male killing at least 84 California sea lion females and 12 males over three seasons (see references in Miller *et al.*, 1996) or a southern elephant seal male killing more than 100 *A. pusillus* breeding female over successive breeding seasons (Best *et al.*, 1981).

Sea lion predation of pups of other otariid species typically involves grabbing a pup by the neck, shaking it from side to side, tossing and recovering, dragging it to sea, submerging and drowning, biting off flesh, and consuming it. It has been described for at least three species. Steller sea lion prey on northern fur seal neonates (pups under 5 months of age; Gentry and Johnson, 1981). Adult South American sea lions prey on South American for seal *Arctocephalus australis*, pups (Harcourt, 1993). Hooker's sea lions, a species for which cannibalistic behaviors have been described (Wilkinson *et al.*, 2000), prey on New Zealand fur seals, *A. forsteri*, and on Antarctic and subantarctic fur seals, *A. tropicalis*.

In the South American sea lion, interspecific predation and conspecific abuse may be particulary associated. Juvenile and subadult sea lion males abduct and kill *A. australis* pups but do not consume them. Interspecific pup abduction was observed in Peru (Harcourt, 1993) and in Uruguay (Vaz Ferreira and Bianco, 1987), where sea lion and fur seals live sympatrically. Males grab a fur seal pup, take it to a neighboring beach and toss and shake the pup. However, instead of killing and eating the pup, as adult male behaving as predators would do, these younger males defend them from other sea lions, mount them, and behave as they do with pups of their own species. Fur seal pups may be killed as an indirect consequence of violent treatment, but are not consumed by their abductors.

In summary, pup killing in some species (e.g., Steller sea lions) is more common in the context of interspecific predation, whereas in others (e.g., South American and Australian sea lions) it occurs more often in a sexual or aggressive social context. In general terms, pup abuse follows a similar pattern as female abuse, with the most aggressive species toward pups being also violent toward conspecific and interspecific females.

IV. Adaptive Meaning of Infant Abuse and Killing

Several hypotheses have been proposed to account for infanticide in terrestrial mammals (Hausfater and Hrdy 1984): (1) exploitation or predation, young are killed for nutritional benefits; (2) resource competition, adults kill unrelated young to increase access to food or breeding space for themselves or their offspring; (3) sexual selection, males kill unrelated offspring to achieve reproductive access to females; (4) parental manipulation, a parent reduces litter size by eliminating all or part of a litter; and (5) social pathology, a maladaptive behavior. Adaptive explanations for the killing of young in aquatic mammals have been suggested for bottlenose dolphins (sexual selection; Connor *et al.*, 1996) and Hooker's sea lion (cannibalism; Wilkinson *et al.*, 2000).

Cannibalism is exceptional among aquatic mammals, and social pathology would be involved in cases such as the cannibal adult male gray seal and the subadult male southern elephant seal described earlier. However, cannibalism in *P. hookeri* was suggested to fit the food resource hypothesis. Several males kill and eat pups in a fashion similar to that described for the same species preying on fur seals. Pups are easy targets for males and may supply calories in excess of the daily energy requirement of a male, as has been suggested to explain the predation of *O. flavescens* on *A. australis* (Harcourt, 1993). Cannibalism in polar bears appears to occur as carrion feeding and as attacks by males on cubs. There is also evidence of a polar bear male feeding on an adult female (I. Stirling, personal communication), but this is a rare observation of difficult interpretation.

Most instances of infant abuse and killing in pinnipeds are better understood as epiphenomena of indiscriminate sexual and aggressive behaviors (Le Boeuf and Campagna, 1994). Social context, SEXUAL DIMORPHISM, and sexually selected behaviors would set the context for the occurrence of injury and death of young. Pinniped colonies are often dense, parental investment is limited to females, males are large relative to pups and females, and male movements are frequent in the vicinity of pups. At times during the breeding season, pups may be the most abundant age class in a rookery, increasing the opportunity of social interaction. Reproductive females are aggressive toward conspecifics in general and alien pups in particular. Female aggressive behavior in this context would be explained by the cost of producing milk for individuals that are fasting while nursing. A large proportion of the breeding males do not have sexual access to females and males have an indiscriminate sexual behavior. Pups, particularly those close to being weaned,

may be almost as large as young mature females and are often confused as females. South American sea lion and northern and southern elephant seal males would kill pups in the context of misplaced sexual behavior. Abducted *O. flavescens* pups, for example, are treated as female substitutes, perhaps a practice of herding or harem keeping (Campagna *et al.*, 1988). Pups born in a harem are not likely to be the offspring of the dominant male, as they were sired the previous season. Behavioral mechanisms that can protect pups from direct and indirect violence (e.g., being crushed during male fights) would not then be under selective pressure. Infanticide in the Australian sea lion would be the consequence of misdirected aggression. It was suggested that territorial males may perceive pups as a threat. After killing a pup, males return to their usual position in the territories (Higgins and Tedman, 1990).

It is not yet clear to what extent the abuse and killing of conspecific pups may have on a common evolutionary substrate with violent behaviors directed to mature females of the same or other species and toward young of other species. Examples among otariids suggest that a circular gradation may exist from simple predation to infanticide to cannibalism. Steller sea lions kill pups of other species as predators but rarely or never abuse conspecific pups as abductors; South American sea lions prey on pups of other species when adults and abduct (but do not eat) pups of the same and other species when young; and Hooker's sea lions abduct, abuse, kill, and eat conspecific and interspecific pups. It remains to be determined if this progression is actual or deceptive. It is possible, however, that in the behavioral similarities among these phenomena may underlay a key to understanding the evolutionary origin of abuse.

Intelligence and Cognition

BERND WÜRSIG
Texas A & M University, Galveston

Dolphins and sea lions are wonderful crowd pleasers in oceanaria: they leap, toss balls, swim through hoops or other obstacles, and vocalize on demand. In nature, they race toward boats, surf in the bow wave, and perform amazing acrobatics for—it seems—the pure joy of it. They are highly social, communicate, enjoy contact with humans, and appear to spend much of their time playing. It is therefore easy to understand why one of the most common questions asked by nonmarine mammal researchers is: "They are very intelligent, are they not?" This question is an excellent one, for it forces us to attempt to analyze what we mean by intelligence and how marine mammals might fit our definition of the concept.

Intelligence and cognition go hand in hand. The former refers to the mental capabilities of a human or nonhuman animal and usually is described by assessing problem-solving skills. The latter refers to the information processing within the animal and may be inferred by an analysis of how it appears to plan an action or alter it based on past experience. A "more intelligent" animal responds to an environmental stimulus faster or more accurately than the "less intelligent" one; the "more cognitive" action or animal may indicate more insight and more awareness of the problem than the "less cognitive" one. Unfortunately, past determinations of the concepts tended to be biased by our own human problem-solving skills and sensory systems and, to large degree, still are. However, we now know that indicators of intelligence can even be very different for different human societies or cultural backgrounds, i.e., within species. Can we say that the nature-living Australian aborigine who scores very low on an "intelligence" test designed with problem-solving questions of our modern industrial/electronic society is less intelligent than the student who takes the test in the industrialized world? If we answer "yes," we should be forced to "take the test" on the Aborigine's terms, perhaps by coming up with solutions of survival in the alternately extremely hot and cold, rugged, and food-poor outback. Similarly, it is not reasonable to study intelligence in dolphins and sea lions by asking them to solve problems relative to our linguistic communication or hand manipulation skills (in cognitive psychology, this is called the comparative approach). It is also unreasonable to compare "intelligences" of river dolphins with those of oceanic species by asking them to solve the same problems of space or objects.

An alternative to the comparative approach of describing intelligence and cognition is often called the "absolute method." It involves an attempt to find out how an animal thinks about things. Thinking is defined as mental manipulation of the internal representation of the external world, the stimulus. The cognitive animal is influenced to change its internal manipulations in part by past experience, and the more adept animal does this better than the "less intelligent" one. While it is difficult to judge mental processes, approximate tests and observations to do so have been devised and will be described later on.

One important window into intelligence and cognition for social species (and all marine mammals show a reasonable to very high level of sociality) is certainly communication. The individuals and species that communicate among each other in sophisticated and at times novel, interactive ways are likely the "more intelligent" (by, in this case, the prime criterion of communication) than those whose communication may be structured more rigidly or less complicated. The great U.S. ethologist Donald Griffin has argued persuasively that communication is a major "window into the mind," not only of humans, dolphins, and other mammals, but of ants and honeybees as well (Griffin, 1981). He went on to postulate that it may be more parsimonious to explain the dance language of bees by considering them to be aware of their actions than it is to consider them reacting to complicated chains or sets of stimuli in unthinking ("noncognitive") fashion. This intriguing idea is not yet widely accepted by behavioral researchers and cognitive ethologists. However, most researchers now accept the possibility of "intelligences" and cognition in nonhuman animals, potentially very different in operating modes from our own, and not testable by traditional comparative approaches.

I. Brain Size and Characteristics

A BRAIN is needed to think and to have the chance of being aware (as a modern book, we need to mention the "brain" of artificially intelligent computers as well). Within a particular taxonomic group, larger and more complex brains tend to show a crude relationship to greater flexibility of behavior, adaptiveness to novel situations, and communication skills, i.e., intelligence. The relationship is imperfect, however, and is notoriously difficult to measure. For example, the entire brain has usually been used for descriptions of size and relative complexity, but there are motor, body function, and sensory parts of the brain that have very little to do with storing, processing, and integrating aspects of memory and thought (the latter occur only in the cerebrum).

Large mammals tend to have larger brains than small ones so brain size to body size ratios have been devised. One of these is the encephalization quotient (EQ), championed by Jerison (1973) and accepted by many researchers, albeit with often slightly different forms of calculation. The EQ is the ratio of brain mass observed to the brain mass predicted from an allometric equation of brain mass/body mass ratio of mammals as a whole. Therefore, an EQ of 1 means that the animal has an "average" brain size. It has been found for terrestrial mammals that EQs tend to be higher for those species that have few offspring, delayed physical and sexual maturity, long parental care, and generally high behavioral complexity (as estimated by degree of sociality and amount of behavioral flexibility). Examples are primates and social carnivores such as cats and canids. Within the primates, EQs tend to be higher for those in the categories just mentioned than for others, demonstrating that meaningful life history–brain size comparisons can be made at least in that group. Some aspects of general intelligence appear to be correlated with those higher EQs, from tree lemurs at the low end of the scale to the great apes at the pinnacle. Nevertheless, the very concept of EQ represents a general statement for potential comparison within or between taxa, but does not represent a fundamental phenomenon per se.

Polar bears (*Ursus maritimus*), sea otters (*Enhydra lutris*), and pinnipeds have EQs around 1, as predicted by the overall regression line of brain weight to body weight among mammals. Their brains tend to weigh between 0.1 and 0.3% of their bodies. In other words, there is nothing unusual in brain size of these mammals relative to their terrestrial carnivore cousins. Because brains are energetically expensive, it has been postulated that those of pinnipeds that dive to great depths and hold their breaths for long periods of time might be smaller. At first glance, this appears to be the case for such divers as Weddell (*Leptonychotes weddellii*) and elephant seals (*Mirounga* spp.), but an analysis by Worthy and Hickie (1986) showed that brain size and dive capability have no clear relationship.

Dolphins and whales have large brains but not all have large brain to body weights or EQs. The sperm whale has the largest

brain on earth, weighing about 8 kg. This brain is in a body that weighs about 37,000 kg, however. The brain is only 0.02% of the weight of the body, or one-fifth of the size ratio of the smallest-brained pinnipeds. However, at large sizes, a straight-line allometric comparison is probably not fair by any measure, and perhaps the body of the sperm whale (*Physeter macrocephalus*) simply does not need relatively much brain mass for muscle movement, skin sensation, visceral action, and so on. The common bottlenose dolphin (*Tursiops trumcatus*), however, has a brain weighing 1.6 kg in a body that weighs about 160 kg, making it—at 1% of body weight—one of the largest relative brains on earth. This competes only with several other dolphins, great apes, and humans (whose brains are about 1.5 kg in a 65-kg body, or about 2.3%) (Table I).

Baleen whales, like sperm whales, have large absolute brains (about 7 kg in an 80,000-kg fin whale, *Balaenoptera physalus*), but none have brain to body weight ratios as large as even the relatively small ones of the sperm whale. Sirenians have neither absolute nor relatively large brains, with the Caribbean manatee (*Trichechus manatus*) having a 300-g brain in a 750-kg body (0.04% of body weight). It has been postulated that the sirenian, a herbivore, increased body size to house a large gut for processing low-energy food, and a concomitant increase in brain size was not needed to support this size. Similarly, the huge size of baleen whales allows them to have huge mouths and to fast for extended periods. Again, this is a very different allometric growth than that of a cow, for example, that is "simply" scaled up in size from a sheep.

Brain weight/body weight relationships are of general interest and have some relationship to relative information-processing capabilities. However, a larger absolute or relatively sized brain than that of another animal does not necessarily serve a "smarter" animal. The concept of intelligence is not a linear one; because there are so many "intelligences" depending on measure or the describer's concept of what is important, intelligence is not definable in absolute terms. All of the marine mammals have well-developed cerebrums. The brains of toothed whales have especially high amounts of neocortical folding and therefore high surface areas (Fig. 1). This quality is believed to be related to thought processes and behavioral flexibility. Whereas polar bears, sea otters, and pinnipeds show a general "terrestrial carnivore" level of folding, baleen whales and sirenians have very smooth cerebrums, with minimal surface areas. Nevertheless, the internal structure of whale and sirenian cerebrums is as well developed as those of other social mammals, and there is no reason to believe that these animals are "dumber" than others based on brain size and gross morphology. Perhaps their ways of finding and securing food, without the need of sophisticated hunting strategies as by toothed whales and carnivores, coupled with some aspects of their communication and society interactions, simply do not require the elaborate neocortical folding seen in many other mammals.

TABLE I
Brain and Body Weights of Some Marine Mammals as Compared to Humans[a]

Species	*Brain weight (g)*	*Body weight (ton)*	*(Brain weight/body weight) × 100*
Pinnipeds			
Otariids			
Northern fur seal (*Callorhinus ursinus*)	355	250 (male)	0.142
California sea lion (*Zalophus californianus*)	363	101	0.359
Southern sea lion (*Otaria flavescens*)	550	260	0.211
Phocids			
Bearded seal (*Erignathus barbatus*)	460	281	0.163
Gray seal (*Halichoerus grypus*)	320	163	0.196
Weddell seal (*Leptonychotes weddellii*)	550	400	0.138
Leopard seal (*Hydrurga leptonyx*)	542	222	0.244
Walrus (*Odobenus rosmarus*)	1020	600	0.170
Odontocetes			
Common bottlenose dolphin (*Tursiops truncatus*)	1600	154	1.038
Short-beaked common dolphin (*Delphinus delphis*)	840	100	0.840
Pilot whale (*Globicephala* sp.)	2670	3,178	0.074
Killer whale (*Orcinus orca*)	5620	5,448	0.103
Sperm whale (*Physeter macrocephalus*)	7820	33,596	0.023
Mysticetes			
Fin whale (*Balaenoptera physalus*)	6930	81,720	0.008
Sirenian			
Florida manatee (*Trichechus manatus latirostris*)	360	756	0.047
Human	1500	64	2.344

[a]Modified from Berta and Sumich (1999). Pinniped data from original sources listed in Bryden (1972), Spector (1956), Sacher and Staffeldt (1974), Bryden and Erickson (1976), and Vaz-Ferreira (1981); cetaceans from Bryden and Corkeron (1988); and sirenians from O'Shea and Reep (1990).

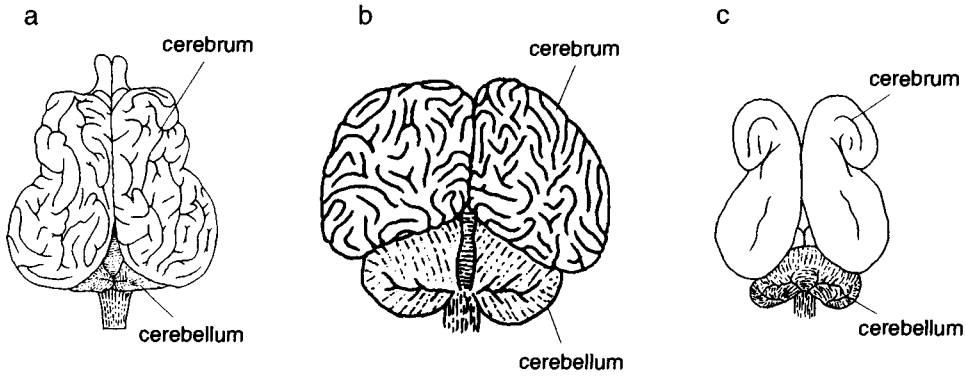

Figure 1. *Comparison of pinniped,* Otaria flavescens *(a); cetacean,* Tursiops truncatus *(b); and sirenian,* Dugong dugon *(c) brain, dorsal views. Illustrated by P. Adam. From Berta and Sumich (1999).*

While much more work on brain size and sensory capabilities needs to be done, it is known that toothed whales and dolphins, who echolocate and use sounds intensively for communication, have well-developed auditory processing lobes. Pinnipeds and especially polar bears, however, have well-developed areas for processing smell.

While brain size and complexity issues used to dominate our thinking about relative intelligence, it is becoming apparent that these can give only vague indicators of complexity of thought. It is likely that brains are structured more along lines of how an animal interacts with others and with its ecology. Higher brain function is a complex mixture of sensory inputs; processing, storing, and reactions to stimuli; innovation; and retrieval and use of previously stored events. Our inability to find clear links of these with measures of brain size and aspects of gross complexity may simply be because of the relatively primitive state of cognitive science, or it could be that clear "all-encompassing" rules of relationships simply do not exist. Promising avenues for future brain studies are noninvasive electrobiological and chemobiological studies from remote sensing of brain tissue while it is undergoing particular tasks. The findings to come from such work will make our present discussions of brain function seem very primitive indeed.

II. Learning

We know that dolphins and sea lions do marvelously complex things in captivity, but we also know that most of these behaviors have been reinforced from existing simpler ones and shaped into that dramatic leap to catch a fish. It is positive reinforcement behavior, or operant conditioning, that is at work; the animal gets a food or other reward for having done a good job. Typically, a sea lion or dolphin reward is one to three small fish per performed action. This is not unlike "training" a cat to run into the kitchen when it hears the sound of a can opener or the guppies in a home aquarium all aggregating near the top when a drawer with dried shrimp is opened. Operant conditioning can be performed on just about all animals on earth, and only speed of learning and some aspects of the amount of behavioral shaping can be indicators of a measure of "smartness" or relative intelligence. The animals learn, but there is not necessarily insight to their learning.

A. Language Studies

It has long been known that dolphins have squeaks and whistles that appear to be used for communication. In captivity, bottlenose dolphins at times appear to imitate or mimic human and other sounds. These observations led an early dolphin communication researcher, John Lilly (e.g., Lilly, 1961), to attempt to communicate with dolphins by teaching them human speech. The results were a total failure, with not one clearly definable mimicked human sound; although dolphins are quite good at matching the staccato rhythm, in the form of bursts of sounds emitted in air (or underwater), of human speech. Dolphins obviously do not have the vocal apparatus to produce human speech and may not have the neural wiring for it either. Nevertheless, Lilly's association with dolphins did not stop him from postulating that dolphins have great "extraterrestrial" intelligence. He used their large brains and their purported friendliness as arguments, but could not muster communicative interactions with humans as a part of the argument. Unfortunately, his popular writings have swayed countless laypersons, and a substantial "cult" of believers in extremely high dolphin intelligence and sophisticated human–dolphin communication, even at the nonverbal extrasensory level, has evolved. No other scientists have made similar claims, but the unscientific nature of Lilly's assertions deterred many others from studying dolphin and whale communication, and early on addressing intelligence and cognition in an obviously behaviorally flexible taxonomic order of mammals. By the way, some seals and beluga whales (*Delphinapterus leucas*) do have the ability to mimic human sounds, and one now-deceased harbor seal, *Phoca vitulina,* ("Hoover") at the New England Aquarium used to delight visitors with his rendition of simple sentences mimicked from a human pool cleaner, replete with the pool cleaner's Maine harbor-side accent. This ability does not indicate greater intelligence than in other seals and toothed whales who do not mimic. Instead, the ability (generally found in male pinnipeds) may relate to the way the animals use natural sounds in order to work out dominance relations for mating access to females and for other social interactions.

Two researchers who were not scared off by the unfounded claims of John Lilly and who nevertheless began language communication research, were Lou Herman of the University of Hawaii and Ron Schusterman, now of the University of California at Santa Cruz. Their studies began in the 1970s and are still ongoing, with a cadre of graduate students and postdoctoral researchers.

Lou Herman's work represents the only truly pioneering language study conducted on dolphins. As in some of the successful studies with chimpanzees, who like dolphins also cannot utter sophisticated human sounds, Herman uses a modified form of sign language, with volunteers' arms at poolside "talking to" common bottlenose dolphins. This is thus a gestural, not vocal, language. While Herman and his team have delved into many fascinating aspects of dolphin abilities, the basic study goes somewhat like this. Teach a dolphin a simple sentence, such as "fetch ball hoop," to indicate taking the ball from the hoop and bringing it to poolside. Once this command, reinforced by operant conditioning, is perfected, then the dolphin is presented with new, untrained challenges. Perhaps it is asked to "fetch hoop ball," or either hoop or ball or both objects are replaced with novel items never before put into this context. It is clear that dolphins quickly grasp the basic concept of "object 1," "object 2," and "command" and act correctly a large percentage of the time. These sentence structures have been made more complicated, with similarly positive results. The dolphins are reasonably good at syntactic structure, and they also seem to be able to conceptualize general categories of items. In others words, the ball used in training can be substituted successfully by another ball, and a gestural symbol ("word") can be made to refer to an item very specifically or to be more general, just as in human word use (Herman, 1986).

Ron Schusterman has repeated many of Herman's studies and invented other experiments of his own, but with California sea lions (*Zalophus californianus*). His results are essentially the same: sea lions are also adept at learning and extrapolating from human-like syntactic structure (Schusterman and Krieger, 1986). Interestingly, the conclusions drawn by these two fine researchers are quite different, indicating the state of knowledge and vibrant nature of the field of animal language and cognition. Herman interprets his findings as the animals using language. "Fetch hoop ball" represent a verb, a direct object, and an indirect object. Schusterman, however, states that there is no reason to believe that the animal perceives this interaction as anything more than an action command and that the linguistic concept "verb" need not enter into the equation. It is true that human children, for example, do not learn language in the structured operant conditioning style as performed here. Instead, we learned (mainly) from people talking around us and from acquiring words and syntactic rules as we went along. It was not until language was already well formed that we were required in school to understand syntactic structure by diagramming or labeling the parts of sentences.

Language acquisition learning in dolphins and sea lions has taught researchers much about imitation, learning, and mental processing abilities. It is undeniable that dolphins learn the basic concepts very rapidly (sea lions a bit less rapidly) and faster than most mammals except for chimpanzees and humans. This by itself indicates a high level of that nebulous and poorly defined "intelligence." However, whether these studies can be called language, or whether that is even an important question, is open to debate. We humans have taken human syntax and foisted it on nonhuman species. Nevertheless, the animals have done remarkably well with what they were given. Perhaps they can do even better as they communicate among each other with signs and symbols and emotive content for which they have evolved.

B. Inventive Dolphins

Pinnipeds, sea otters, polar bears, and sirenians show elements of learning and play in captivity, but do not show the same kind of quick thinking or innovation as do some dolphins. However, most work has been done with dolphins, so there is some element of bias. Nevertheless, bottlenose dolphins and rough-toothed dolphins (*Steno bredanensis*), both with very large brains, are known as "the best" of performers in oceanaria. It is not clear whether these animals adjust better to captivity than others or whether they are innately more behaviorally flexible than others.

One interesting story of behavioral flexibility comes from a study done on two rough-toothed dolphins at Sea Life Park, Hawaii, in the mid-1960s. Karen Pryor, then head trainer at Sea Life Park, introduced a new demonstration into her onstage performance with one of her dolphins named Malia. The intent was for Pryor to demonstrate to the audience how a previously unconditioned behavior could be reinforced by operant conditioning. In order to do so, she could not use a previously trained repertoire, but each day had to choose a simple behavior (such as a particularly high surfacing or loud blow) that the animal did and then reinforce it. After several days of this, Malia "spontaneously" recognized that "only those actions will be reinforced which had not been reinforced previously" (Pryor *et al.*, 1969). In order to receive rewards rapidly (or for the pure fun of it), Malia "began emitting an unprecedented range of behaviors, including aerial flips, gliding with the tail out of the water, and 'skidding' on the tank floor" (Pryor *et al.*, 1969). None of these behaviors had been shaped, none had even been seen before in the basic repertoire of dolphin behaviors at Sea Life Park! Pryor and her colleagues then repeated the work with an untrained female rough-toothed dolphin named Hou in order to assess experimentally whether creativity could be induced by operant conditioning in another dolphin and how long it would take. The experiment succeeded splendidly, and in a few trials, Hou was also presenting a new "act" after each one that received an operant reward.

Pryor *et al.* (1969) discussed their results very cautiously and reminded the reader that such training for novelty can probably be successful in horses and perhaps even pigeons as well. Many students of animal behavior and intelligence agree and are content to explain the development of novel behavior as simply a trained response. However, others have taken the experimental results further and suggested that much more insight than normal is required for the animal to "learn to learn" (the great philosopher Gregory Bateson called this "deuterolearning") and that the relatively quick manner in

which dolphins "caught on" confirms their high intelligence. By the way, similar nonverbal training of reinforcement for novel behaviors has also been conducted for humans; the humans took about as long to realize what was being trained as did the dolphins (Maltzman, 1960). For Hou and for the humans, there was a period of strong frustration (even anger, in the humans) where they had not "caught on." They would be reinforced for a behavior, do it, and then not be rewarded for it ever again. It took some time for the "realization" to come that they then needed to exhibit a new behavior to get a reward. Once realized, the humans expressed great relief at having figured out "the problem," whereas the dolphins raced around the tank excitedly and displayed more and more novel and body-twisting behaviors— to the obvious delight of the researchers.

An interesting observation about dolphins is that they—at least bottlenose dolphins—readily recognize images of humans and of themselves in mirrors and on television screens. Herman *et al.* (1990) were able to elicit correct answers from the televised image of a human giving sign-based directions, even to the point where only white-gloved hands were shown going through the signaling motions. This demonstrates that the animals were able to use representations of the gestural instructions. Several investigators have shown dolphins mirrors and real-time video images of themselves; the dolphins react to the images with curiosity and playfulness, moving their rostrums rapidly and following their own eye movements. Furthermore, the reactions to video images of other dolphins appear to indicate that the viewing animals recognize different individuals on the screen, including themselves. This indicates a "sense of self" and has been described as an important insight into cognition. Interestingly, chimpanzees and other apes do not have this innate capability to see images on a flat screen as representations of themselves, others, or humans. They can be taught to process the images meaningfully, but only after prolonged exposure.

III. Behavioral Complexity in Nature

A. Carnivores and Sirenians

Most marine mammals are highly social, and we would expect that they have sophisticated ways of communicating with each other by showing innovative and variable behaviors in the face of social strategies and interactions. However, the less social species are obviously also behaviorally complex. Examples are polar bears and sea otters. Polar bears have a large repertoire of "sneaking up" on their generally ice-bound prey. They move against the wind, come from the side of the sun glare, and use ice obstructions and stealth in order to surprise their prey. It has been reported that in captivity, they figure out rapidly how to unlatch (and unhinge) doors in order to escape or to move from pen to open enclosure. Sea otters are tool users, prying mussels and abalone from the substrate with rocks or stones they keep cached in an armpit while not in use. At the surface, they retrieve the tool in order to break open their shellfish food; at times using the rock as a hammer and at times laying it on their stomach and using it as an anvil. Individual sea otters have preferred methods of tool use, implying learning and innovation. Polar bears and sea otters are obviously "bright," but few behavioral studies or systematic investigations of learning have been conducted.

Pinnipeds are also behaviorally adept, and—as we have seen—sea lions can learn tricks and some aspects of language in captive training settings. They are all social mammals, especially while hauled out on land in order for males (of most species) to work out dominance relations with each other and for females to mate, give birth, and take care of their altricial (not well developed) young. Vocalizations, body postures, and smell are important aspects of communication. In the sea, most pinnipeds are less social (with the walrus being a strong exception), but they likely use more individualized but sophisticated strategies for finding and securing enough prey to survive. We expect that the animals need to periodically adapt to different types of prey, learn which could be physically harmful or poisonous, and learn how to detect and avoid large sharks, killer whales, and leopard seals. Many pinnipeds do not take their young out to sea with them, and therefore all learning to hunt and to survive needs to be without substantial help from more experienced adults. The author suspects, but has no proof for, that the brains of pinnipeds are adapted for relatively quick self-learning to survive and are less adapted or structured for social communication except as that needs to develop for procreation. Polar bears, sea otters, and sirenians would be an exception, although while generally less social then other marine mammals, mothers take prolonged care of their young while the young develop feeding and other skills. We assume, but again have no direct proof for this assertion, that the young learn more easily and completely in the presence of their mother.

B. Baleen Whales

Baleen whales are social creatures, especially during mating times. Vocal communication is extremely important to them, with drum-like sounds of gray whales (*Eschrichtius robustus*), long low-frequency moans of blue whales (*Balaenoptera musculus*), short low-frequency grunts of fin whales, and the rich repertory of groans, moans, and scream-like sounds of the right (*Eubalaena* spp.) and bowhead (*Balaena mysticetus*) whales. Whereas all whales appear to produce sounds, the most elaborate (and best-studied) sounds are the songs of male humpback whales, which likely serve as a male–male (intrasexual) dominance signal, male–female (intersexual) mating advertisement, or both. The songs are copied from listening to each other, are long and complicated, and must require reasonably formidable powers of learning and memory. Baleen whales on the mating grounds also sort out dominance relationships in either aggressive (humpback) or more gentle but highly maneuvering surface-active groups of gray whales, right whales, and bowhead whales. In the latter grays and right-bowhead groups, it is likely that multiple males allow each other to inseminate a particular female and practice a form of sperm competition instead of physical competition to increase the chances of fathering a young. It is also likely, although behavioral researchers have gathered only incomplete glimpses of the possibility, that female whales make it more difficult for some males than others to mate with them, thereby performing mate choice of preferred partners. If true, it must be important for females to gauge the relative "goodness" of males from the complicated

matrix of social sounds and close-up interactions that present themselves. In right whales and bowhead whales, an adult female has only one young every 2 to 5 years. The calf gestates in her body for 1 year and then is nursed for another. This low reproductive rate means that she must take very good care of the young to attempt to assure its survival, and researchers would not be surprised at all to find that she also wants to choose the father of her young with care.

Baleen whales tend to be less social on the feeding grounds, although recent behavioral research indicates that at least some long-term bonds of affiliation persist between breeding and feeding grounds. This does not appear to be the norm, however. Generally, blue whales, humpback (*Megaptera novaeangliae*), gray whales, right whales, and bowhead whales (these five are the best-studied baleen whale species) aggregate at particular areas because of food concentrations. An aggregation due to an outside stimulus is not necessarily a social unit, although it can result in one. Some social interactions do occur, and it is even likely that the whales are paying close attention to each other in order to detect perhaps new or better feeding opportunities somewhere else. As well, blue whales often lunge into their food in tandem, apparently so as to provide a wall next to each other toward which fast-moving krill will not escape. Bowhead and right whales will swim in staggered formations of "echelons," side by side, apparently for the same purpose (Würsig, 1988).

The winner in the baleen whale feeding complexity department must surely be the amazing humpback whale. Humpback whales lunge into their fish food, alone and in coordinated groups up to an observed 22 animals. They are not merely aggregated in such a case, but all lunge (from below and toward the surface) at essentially the same time, coming to the surface within about 6 sec of each other. Apparently, although this is not yet proved, there is a vocal signal at the beginning of these highly coordinated lunges. One whale signals and others follow. Hitting the prey, a huge fish or bait ball, at one time presumably allows for each mouth to be better filled in the resultant prey's confusion than if one or a few mouths attacked. Humpback whales also flick their tails at prey and then circle to engulf it; they flick their long foreflippers forward as their mouths open, presumably to flash the white undersides of these flippers at the prey and to herd it more efficiently into the mouth. Finally, they release a stream of bubbles from their blowholes while circling around the prey and upward. The rising bubble screen forms an effective net around the prey, and the humpback (alone or with several others) then lunges toward the surface in the center of the "net," filling its capacious mouth with concentrated prey. It is unclear how flexible the several feeding behaviors are, but it is certain that several need social coordination. It is also likely that young humpbacks need to learn and perfect the techniques, and we assume that social learning is the major vehicle to do this.

C. Toothed Whales

Toothed whales are highly social creatures, except for older adult male sperm whales who tend to be loners, some lone killer whales (*Orcinus orca*), and an extremely ("aberrant") low level of singles in many species of dolphins. Some of the deep-ocean beaked whales may be loners as well, but we have no good data on this point. Whereas most species are social, there are very different forms. Hector's dolphins (*Cephalorhynchus hectori*), harbor porpoises (*Phocoena phocoena*), and river dolphins tend to occur in small groups of up to a dozen animals, rarely more. We surmise that in at least some of these dolphins, individuals know each other well. Pantropical spotted (*Stenella attenuata*) and striped (*S. coeruleoalba*) dolphins of the open ocean, however, travel in "herds" of thousands of animals. While there appear to be subgroups with at least some interindividual fidelity, it is very unlikely that all members of the herd know each other; some may never even meet each other. However, the herd acts as a coordinated unit, traveling at the same speed (which must be near the speed of the slowest animals), turning in essential unison, often diving in synchronized fashion. If a disturbance occurs along a flank or somewhere below, e.g., a shark zooms out of depth, there is rapid information transfer from animal to animal so that the group cascades away from the perceived danger in coordinated fashion. The information transfer is so rapid that we assume that animals are aware not only of their nearest neighbors, but are "looking beyond others," by sight when possible and probably also by echolocation. This is sort of a chorus line effect, where dancers coordinate their movements better by not merely paying attention to their nearest neighbors, but by anticipating the wave of raised legs, for example, as it (the wave) approaches. As well, it is likely that each dolphin pays attention to the vocalizations and movements of others nearby and thus integrates response information in what the great cetacean researcher Ken Norris called a sensory integration system for dolphins (Norris *et al.*, 1994). Jerison (1986) used the idea of shared echolocation among dolphins to postulate that the animals share sensory inputs in a way that might synergistically enhance an expanded sense of "self." A human analogy would be if several people of a group could know their world and their place in it better by sharing neural data of aggregate visual systems. Jerison postulated that this potential sharing of echolocation data might itself account, at least in part, for large dolphin brains, but we have no direct information on this provocative point.

Coordination of group movements and activities need not be a matter of high intelligence and cognition, of course; and sensory awareness and a collective sensory integration system are well developed in schooling fishes, flocking birds, and so on. Instead, we might do better to look at the complexities of social interactions to gain "a window into the dolphins' minds" (after Griffin, 1981). Alas, we do not yet know very much about details of communication in delphinid cetaceans, but we do know enough to call it "complex."

Dolphins in a group are constantly aware of each other. A flipper touch here, a glance there, a slow echolocation-type click, a whistle. They interact by all sensory modalities available to them. We guess (and it is only a guess) that they are constantly gauging each other, deciding dominance/subservience relationships, seeking the comforting presence of relatives or those that they have found to be helpful in previous encounters, and avoiding those that might be aggressive. We know that there are at least occasions of political intrigue. Indian Ocean bottlenose dolphin (*Tursiops aduncus*) males of Shark Bay,

southwestern Australia, have a strong tendency to form alliances to kidnap females. They apparently do so to gain access to reproductive females—access that might otherwise not be available because these males may not be of sufficiently high dominance status or would not be chosen by the females. Interestingly, super alliances of two or more alliances form in order to steal females from another male alliance (Connor *et al.*, 2000). Richard Connor is presently attempting to find out whether males that cooperate together in this fashion are more often closely related or whether alliances are formed along lines of friendship more than kinship.

Toothed whales appear often to be structured along matriarchal (female-based) lines. Sperm whales, killer whales, pilot whales (*Globicephala* spp.), and bottlenose dolphins (of at least several populations) have close ties between mother and female young even after weaning, and in sperm and pilot whales, these ties appear to last for life. This means that potential cultural transmission of knowledge, from generation to generation, is expected to flow especially efficiently along female lines. Mom teaches young, young teaches its children, and so on. In a society of relatively resident killer whales of the U.S. and Canadian Pacific Northwest, female and male offspring stay within the pod for life. This society is thus socially "closed." However, females mate with males outside, and the males mate with females of neighboring pods. Each pod is therefore reproductively matriarchal. These societies of relatively stable long-lived individuals are likely to develop behavioral cultures of their own. We have some evidence: killer whale pods have individually distinctive sound repertoires, or dialects. Individuals of pods can recognize each other easily as of that pod. It is likely, but not proved, that individuals also recognize each other as individuals by sound. In the more open but still matriarchal societies of at least one population of common bottlenose dolphins, studied by Randy Wells and colleagues, of Sarasota, Florida, male offspring develop signature whistles (individually distinct sounds) more like those of their mothers than do female offspring. The moms and female offspring stay together as daughters mature. The sons, however, leave the natal group, roam elsewhere, and only now and then interact with their natal groups as adults. It is hypothesized that the similar signature sounds of moms and sons may provide an efficient means of recognition and thereby inbreeding avoidance (Sayigh *et al.*, 1995). Signature whistles are also copied by dolphins who are answering the original whistler. This rapid imitation may serve as a societal binding mechanism. It has been postulated that basic greetings and verbal recognition were prerequisite to the development of human language. Dolphins have the signature recognition portion of this capability (Janik, 2000).

Sound has been studied recently relative to kin and others of a society, and much more sound-based learning is likely to come to light as studies progress. This is to be contrasted with the relatively stereotyped sounds of the great apes, for example, that do not change much with age or social association (but then, in all fairness, apes are generally less vocally communicative and more visually based than cetaceans). However, it is also likely that not only vocal evidence for learning and social transmission will come to light. We have some hints, and only hints, here as well. Killer whales of Patagonia, Argentina, beach themselves in order to take sea lion (*Otaria flavescens*) and elephant seal pups. The beaching maneuver requires great skill, as the predator needs to gauge exactly where the prey is on the beach, after having seen the prey only from a distance and through murky nearshore waters, beyond the surf zone through which it needs to make its rush to the beach. As well, it needs to beach with such velocity and angle as to be certain that the spilling waves will allow it to reach deep water again. Killer whale adults have been described as making sham rushes at a beach and then waiting along the sides while young killer whales attempt the maneuver, usually clumsily and ineffectively, again and again. Now and then, the adult makes an intervening rush and then retreats to the side again. This behavior was pointed out as probable teaching by Argentine killer whale researchers Juan Carlos and Diana Lopez (1985) and has been studied in greater detail and verified since. It is unclear how well youngsters would learn beaching "on their own," but it is likely that it is transmitted culturally, as killer whale beaching behavior is found in only several populations worldwide. In Galveston Bay, Texas, certain female bottlenose dolphins and their young follow shrimp boats much more so than others, even maneuvering into the shrimp nets to take live fish and then wriggling out again while the shrimper is underway. This activity, video taped underwater, requires skill and dexterity to avoid being entangled in the fishing gear. The dolphins who exhibit this behavior do so "with ease," whereas others do not fish at all in this manner. Again, we wonder whether cultural learning and societal transmission of knowledge is important here. While culture has been explored in birds and nonhuman primates, very little has been written on this subject for marine mammals (but see Whitehead, 1998).

Even on an hour-to-hour basis, dolphins of a group are likely to be coordinating their activities superbly well. While there are many potential examples (and each behavioral observer has his or her favorite ones), the author prefers one that he and his wife have studied for some time. Dusky dolphins (*Lagenorhynchus obscurus*) of the shallow waters of Patagonia, Argentina, coordinate activities to corral fish schools. It appears, and much more work is needed to properly describe the individual behaviors, that dolphins (circling while vocalizing, tail swiping, and blowing bubbles) surround the prey ball and thereby cause it to tighten. They also herd the prey ball to the surface and then use the surface as a wall through which the prey cannot escape. Interestingly, dolphins do not appear to feed until the prey has been tightened and is at the surface. There may be a form of "temporary restraint," with all animals working toward the common good of getting the prey secured. This coordinated activity stands in stark contrast to taking individual advantage of the prey by grabbing a mouthful here or there and causing the prey to scatter and escape. As an example, sea lions that enter the area work on their own and are highly disruptive to the herding efforts of the dolphins. While we still need to look at the details of this behavior, to see whether kin, for example, help each other more often, we assume that much communication, learning, and individual trust need to go into such coordination. It is likely, but unknown at present, that animals know each other well enough as to have preferred "working" partners and have mechanisms for detecting and effectively ostracizing those

cheaters who do not help or are disruptive at critical phases of prey gathering (Würsig *et al.*, 1989).

Such activities require individual recognition, concepts of strategies for dealing with different behaviors of fish schools, coordination, memory of past events, and potential teaching or at least learning from others; in short, considerable behavioral sophistication and flexibility. In New Zealand, far from Argentina and in a different deep-water environment, most dusky dolphins feed not on schooling fishes but on mesopelagic ("midwater, deep ocean") fishes at night. It has been found that a small subsegment of the dolphin population—the same individuals on a regular basis—travels to bays where dolphins take seasonal advantage of fish stocks to herd prey into tight balls as described earlier for Argentina. Because it is apparently the same animals doing so year after year, we believe that there might be cultural transmission of information here as well; only some have learned (or care) to take advantage of this particular foraging style.

A final example of at-times sophisticated-seeming behavior is certainly play. Almost all young mammals play, and this has been interpreted as gaining skills necessary to survive. It certainly seems like much fun as well. In dolphins and a handful of other mammals, adults habitually engage in behavior that is difficult to rationalize as anything but play. Dusky dolphins pull on the legs of floating birds, and individuals of several species perfect the balancing of pieces of kelp or other objects on their rostrums, flippers, dorsal fin, and tail. Play is not the purview of only dolphins, however. Adult baleen whales, sea lions, sea otters, and polar bears play with objects, at times for up to an hour or more. Play seems less common in phocid seals, but the imitative sounds of "Hoover" the harbor seal may have represented a form of vocal play. Play seems more rare (or absent?) in wild adult sirenians, but then long-term studies underwater have not been conducted.

IV. Conclusions

Marine mammals are not of one taxonomic group and live in many varied ways; we therefore are not surprised to find that they have different brain sizes and ways of adapting to their ecologies, social structures, and behaviors. Because all use marvelously adaptive behaviors to help them survive, they are all "smart." However, such a general definition is not very satisfying. The polar bear, sea otter (and marine otter, *Lontra felina*, of Chile), pinnipeds, sirenians, and baleen whales all have behavioral characteristics and ways of living that might refer to "intelligences" not all that different from terrestrial mammals. Several of the dolphins (not all) stand out as being exceptionally large brained and behaviorally sophisticated; they are quick learners in captivity and have social structures and behaviors that appear to be highly complex and variable. While much of the large brains of these odontocetes may well be taken up by the neural processing required for ECHOLOCATION and other senses, as has often been speculated, it is highly likely that a large part of it also deals with relationships, learning, and long-term memory of events (Schusterman *et al.*, 1986).

Much more needs to be learned about dolphin whistle and click communication. However, it does not seem likely that their combinations of whistles and clicks can be termed "language" in the sense of putting sets of (for example) whistles together as referential communication for different objects or constructs (ideas). Instead, vocalizations seem to carry emotive content, signature information, and may well serve as an important tool for binding social relationships (Janik, 2000). Nevertheless, there are certain to be surprises to be gained from studies on delphinid communication as more information is gleaned. One important avenue for exploration is the extent to which communication and behavior have been transmitted from generation to generation, resulting in distinct cultures in such animals as sperm whales, killer whales, and several species of dolphins (Whitehead, 1998).

While we think of dolphin and other marine mammal "intelligences" and cognitive processes and realize what marvelous animals they are, it is also fair to contemplate their limits. Dolphins are beautifully tuned to the environments in which they have evolved for millions of years, but they do not necessarily have the capability to make behavioral extrapolations that seem to us very simple. A prime example is the fear (or mental incapability) of wild dolphins to leap over obstructions. This has been a major problem for the tuna purse seining industry—dolphins caught in a net could easily all leap to freedom as the net is pursed. They do not do so because it is not in their repertoire to do so and are caught (and at times entangled and killed) as a result. Only dolphins trained to leap over nets will do so or some animals that seem to have "accidentally" (perhaps the most innovative ones?) discovered the capability in nature. This article ends on this theme of focused mental capabilities because it illustrates two related points: (1) dolphins are not those "super-intelligent" beings as claimed by some aspects of the news media and many books and films and (2) dolphins are indeed "intelligent" for those things that they need to solve and interact with in their natural world, but their natural world is very different from ours.

International Whaling Commission

GREGORY P. DONOVAN
International Whaling Commission, Cambridge, United Kingdom

The International Whaling Commission (IWC) is the intergovernmental body established in 1946 to conserve whale stocks and regulate whaling. Membership is open to any sovereign state. There were 40 member nations (Table I) in the year 2000.

I. Historical Background

Whaling cannot be put forward as an example of the successful sustainable management of a renewable resource. From the start of the "commercial" exploitation of whales, the story was usually one of eventual overexploitation. Modern commercial whaling began with the invention of the explosive harpoon

TABLE I
List of Members of the IWC in August 2000[a]

Contracting government	*Date of entry into force*
Antigua and Barbuda	1982
Argentina	1960
Australia	1948
Austria	1994
Brazil	1974
Chile	1979
People's Republic of China	1980
Costa Rica	1981
Denmark[b]	1950
Dominica	1992
Finland	1983

[d]Commercial whaling.

combined with the development of steam-powered catcher boats in the 1860s. This allowed whalers to take the faster swimming rorquals (e.g., blue and fin whales, *Balaenoptera musculus* and *B. physalus*). The promise of large numbers of whales caused whalers to investigate the Antarctic, and the first whaling station was established on South Georgia in 1904 and took 195 whales. By 1913, there were 6 true land stations and 21 floating factories that had to be moored in suitable harbors; the total catch was 10,760 whales. The invention of the stern slipway in 1925 allowed vessels to operate in offshore waters and by 1930/1931, 41 factory ships took over 37,000 whales. This overproduction led to a catastrophic decline in the price of whale oil.

It was the fear of low prices rather than the fear of overexploiting whale stocks that was the driving force behind early moves to limit catching. Despite attempts under the auspices of the League of Nations to establish some international control, the production agreements negotiated among themselves by the whaling companies produced the first effective limitation of catches in the early 1930s.

World War II caused a world shortage in the supply of fats, and several nations had their eyes on profits from pelagic whaling. It was in this light, and with the experience gained in developing international agreements just before the war, that discussions were held in London in 1945 and in Washington in 1946 on the international regulation of whaling.

II. Establishment of the International Whaling Commission

The International Convention for the Regulation of Whaling was signed at the 1946 conference. It was a major step forward in the international regulation of natural resources, as it was one of the first to place "conservation" at the forefront. The convention was established "to provide for the proper conservation of whale stocks and thus make possible the orderly development of the whaling industry." This was a laudable aim, but finding the difficult balance between "conservation" and the development of the whaling industry has dominated the history of the IWC.

An important feature of the convention was that it established a mechanism whereby regulatory measures included in the Schedule to the convention (catch limits, seasons, size limits, inspections, etc.) could be amended when necessary by a three-quarters majority of members voting (excluding abstentions).

The convention also formally assigned importance to the need for scientific advice, requiring that amendments to the regulations "shall be based on scientific findings." To this end, the commission established a scientific committee comprising scientists nominated by member governments (and later invited experts when appropriate).

Despite this, there are aspects of the convention that have attracted criticism. For example, any government can "object" to any decision with which it does not agree within a certain time frame. This (along with the right of nations to unilaterally issue permits to catch whales for scientific purposes) has led to accusations that the IWC is "toothless." However, it should be recognized that without these provisions, the convention would probably have never been signed.

From a management perspective, a more serious flaw was that the IWC could neither restrict operations by numbers or nationality nor allocate quotas per operation. Although it may be questioned whether the IWC could have agreed to national quotas or numbers of vessels, certainly if such limitations had been reached, this would have reduced the management problems associated with increasing numbers of vessels chasing limited quotas.

The convention formally established the International Whaling Commission. The IWC comprises one commissioner from each government who has one vote and may be accompanied by one or more experts and advisers.

III. The IWC before 1972

Perhaps the most serious problem of early management was the use of the blue whale unit (BWU). In terms of oil yield, one blue whale was considered equal to 2 fin, 2.5 humpback (*Megaptera novaeangliae*), or 6 sei (*B. borealis*) whales. In 1945, a catch limit of 16,000 BWU was set (suggested by three scientists as being a "reassuring" value in the middle of their estimate of 15–20,000). The flaw in the BWU system is apparent: it allows catching of depleted species below levels at which catching that species alone would be economically unviable. This is apparent from catch data up to the 1970s, which reveal that as blue whale catches declined, so fin whale catches (the next largest species) increased until they too were overexploited and sei whale catching began.

The lack of national quotas resulted in an "Olympic" system, where it became a race to catch as many whales as possible before the total quota was reached, leading to waste during processing and the use of increasing numbers of catcher boats (129 in 1946/1947 and 263 in 1951/1952). This neither made economic sense nor encouraged conservation.

As early as 1952, it was recognized that the catch quota was too high. The difficulty was in getting all the whaling nations to agree to a reduction: if one nation objected, then all objected. This was the start of a difficult period for the IWC, trying to match the evidence of science against the needs of the industry. At one stage, both the Netherlands and Norway withdrew from the commission and its survival seemed in doubt. After considerable argument and controversy, by 1971/1972, the catch limit had been reduced to 2300 BWU, and certain species, including the blue and humpback whales, had been protected from commercial whaling.

IV. A Period of Change: 1972 to the "Moratorium"

In 1972, the UN Conference on the Human Environment called for an increase in whale research, a 10 year "moratorium" on commercial whaling and a strengthening of the IWC. Although proposals for 10 year moratoria were subsequently tabled at the IWC, they failed to reach the required three-quarters majority, largely because the IWC scientific committee believed that management on a stock-by-stock basis (Antarctic catches were first set by species in 1972) was the most sensible approach; if required, each stock could be independently protected. The UN

resolution was, however, taken seriously by the IWC. By 1976, a permanent secretariat had been established in Cambridge, an international decade of cetacean research had been declared, and a management procedure [the new management procedure (NMP)] had been adopted. The NMP was aimed at bringing all stocks of whales to an optimum level at which the largest number of whales can be taken consistently [the maximum sustainable yield (MSY)] without depleting the stock. It also gave complete protection to stocks at 54% of their estimated preexploitation size, i.e., well before they became endangered. The NMP was regarded as a major step forward in the management of whaling. It appeared to take the issue of catch limits largely out of the hands of the politicians and place them in those of the scientific committee. In addition, from 1973, the long-awaited international observer scheme was in operation (from 1973) that aimed at ensuring that new catch limits were enforced.

A major feature over this period was the increase in IWC membership. In 1963, there were 18 member nations, of which only 4 were nonwhaling countries; in 1978, there were 17, of which 8 were nonwhaling, and by 1982, membership was 39. Of the 13 whaling nations, 3 had only aboriginal/subsistence operations (Denmark, the United States, and St. Vincent and the Grenadines).

The 1979 meeting was a turning point in the commission's history. Doubts had been expressed by some over (1) the theoretical and practical application of the NMP and (2) the morality of whaling, irrespective of the status of the stocks. At that meeting, a proposal to end pelagic whaling for all species except minke whales was adopted and a sanctuary was declared for the Indian Ocean outside the Antarctic. Whereas the onus in the past had been for positive evidence of a decline in stocks before a reduction in catch limits was agreed, positive evidence was now required if a catch limit was to be set. By 1982, a *Schedule* amendment was adopted that implemented a pause in commercial whaling (or to use popular terminology, a "moratorium") from 1986. Originally, four whaling nations, Japan, Norway, Peru, and the USSR, lodged objections to this decision, although Peru and Japan subsequently withdrew theirs. In the year 2000, only Norway carries out commercial whaling under an objection.

One obvious question to ask as the IWC's moratorium came into effect was whether the commission had been a success? At one level the answer must be no; indeed, it could be argued that it had been a disaster. For example, in the Antarctic, the most important area to the IWC initially, (i) blue and fin whales had been reduced to at best 5 and 20% of their original numbers, and possibly much less, respectively; hardly a good example of "conservation of whale resources"; (ii) the 1983/1984 catch was 6655 minke whales (*Balaenoptera bonaerensis*), a species not considered worth catching in 1947/1948 when the catch in BWU was 25 times greater; hardly "the orderly development of the whaling industry."

So, had the IWC achieved anything? First of all, while it is easy with current levels of knowledge to criticize the IWC's performance, it has to be said that modern whaling had not resulted in the extinction of any species; IWC actions, while insufficient, were better than nothing. Since the 1970s, the trend has been very much toward conservative catch limits based on scientific advice, to a degree probably unparalleled in any fisheries commission. It has been argued by some that this trend reached unreasonable limits with the introduction of the "moratorium." It is indicative of the inherent problems within the commission that the same decision is hailed by some as its greatest success and by others as its most abject failure.

V. The Commission Today

Since 1976, the IWC has had a full-time secretariat (of 15–20 people) with headquarters in Cambridge, UK. Each year, the annual meeting of the commission is held, either by invitation in any member country, or in the United Kingdom. The scientific committee (comprising up to 120 scientists) meets in the 2 weeks immediately before the main commission meeting and may hold special meetings during the year. The information and advice it provides form the basis upon which the commission develops the regulations for the control of whaling.

A. Management Issues

The primary function of the IWC is the conservation of whale stocks and the management of whaling. In addition to commercial whaling, the IWC has recognized the discrete nature of aboriginal subsistence whaling, and allowed aboriginal catches from stocks that have been reduced to levels at which commercial whaling would be prohibited.

1. Commercial Whaling At the outset of its discussions on the work to be carried out after the moratorium came into place, the scientific committee recognized the need to develop management procedures that did not repeat past mistakes and recognized the limitations of both data it had and data it was likely to obtain. Clearly, it was not acceptable to try out experimental management procedures in the wild. Apart from the serious consequences of getting it wrong, on long-lived species such as whales, it would take a considerable time to assess whether it really worked. The approach adopted was therefore to use computer simulations of whale populations over a long (100-year) period.

The most important part of any development process is the determination of *management objectives*. These were set by the commission and can be summarized as: (1) catch limits should be as stable as possible; (2) catches should not be allowed on stocks below 54% of the estimated carrying capacity (as in the NMP); and (3) the highest possible continuing yield should be obtained from the stock. The highest priority was given to the second objective.

After 8 years of intense work, the committee developed a procedure for determining safe catch limits that required knowledge of only two essential parameters: estimates of current abundance taken at regular intervals and knowledge of past and present catches. Intensive testing of the procedure against numerous assumptions and problems had been undertaken; some of these are summarized in Table II.

The way in which catch limits are calculated from the required information is specified by the *Catch Limit Algorithm* (CLA). This is a "feedback" procedure; as more information accumulates from sighting surveys (and catches if taken), then the estimates of necessary parameters are refined. In this way, the

TABLE II
Examples of Trials

Several different population models and associated assumptions
Different starting population levels, ranging from 5 to 99% of the "initial" population size
Different MSY levels, ranging from 40 to 80%
Different MSY rates, ranging from 1 to 7% (including changes over time)
Various levels of uncertainty and biases in population size
Changes in carrying capacity (including reduction by half)
Errors in historic catch records (including underestimation and underreporting by half or more)
Catastrophes (irregular episodic events when the population is halved)
Various frequencies of surveys

procedure monitors itself constantly. Catch limits are set for periods of 5 years. The CLA was initially tested on the assumption that it is applied to known biological stocks. To date, testing for specific species and areas has only been carried out for minke whales in the North Atlantic and Southern Hemisphere. Without such trials, catch limits will be zero under the *Revised Management Procedure* (RMP). It is clear that for very many populations, such as blue whales in the Southern Hemisphere, it will be a very long time before catches would be allowed under the RMP.

The CLA plus the rules about, *inter alia*, stock boundaries, allocation of catches to small areas, and what to do if many more of one or other sex are caught form the RMP. The RMP sets a standard for the management of all marine and other living resources. It is very conservative, and this is a reflection of the relative priorities assigned to the objectives, the level of uncertainty in the information on abundance, productivity and stock identity of whale stocks, and the fact that many years are required before the CLA refines its estimates of the required parameters.

Although these scientific aspects were adopted by the IWC in 1994, its actual implementation is a political decision. The IWC will not set catch limits for commercial whaling until it has agreed and adopted a complete *Revised Management Scheme* (RMS). Any RMS will also include a number of nonscientific issues, including inspection and enforcement, and perhaps humaneness of killing techniques. The importance of an international inspection scheme was highlighted by the discovery of widespread falsification of catch data by Soviet whaling operations prior to 1972.

2. *Aboriginal Subsistence Whaling* Aboriginal subsistence whaling is permitted by Denmark [Greenland: fin and minke (*Balaenoptera acutorostrata*) whales], the Russian Federation [Siberia: gray (*Eschrichtius robustus*)] and bowhead [(*Balaena mysticetus*) whales)], St. Vincent and the Grenadines (Bequia: humpback whales) and the United States (Alaska: bowhead and gray whales). It is the responsibility of the committee to provide scientific advice on safe catch limits for such stocks. With the completion of the RMP, the scientific committee began the process of developing a new procedure for the management of aboriginal subsistence whaling (AWMP) that takes into account the different objectives for the management of such whaling as compared to commercial whaling. The commission will be establishing an aboriginal whaling scheme that comprises scientific and logistical (e.g., inspection/observation) aspects of the management of all aboriginal fisheries. The scientific component will comprise some general aspects common to all fisheries and an overall AWMP within which there will be common components and case-specific components. The first components are expected to be completed in 2002.

3. *Scientific Permit Whaling* A major area of discussion since the moratorium has been the issuance of permits by national authorities for the killing of whales for scientific purposes. The right to issue them is enshrined in Article VII of the convention (that furthermore requires that the animals be utilized once scientific data have been collected), and prior to 1982, over 100 permits had been issued by a number of governments, including Canada, the United States, USSR, South Africa, and Japan. Since the "moratorium," Japan, Norway, and Iceland have issued scientific permits as part of their research programs. The discussion has centered on accusations that such permits have been issued merely as a way around the moratorium decision contrasted by claims that the catches are essential to obtain information necessary for rational management and other important research needs. All proposed permits have to be submitted for review by the scientific committee, but the ultimate responsibility for their issuance lies with the member nation. Only Japan has issued scientific permits for the year 2000 [400 ± 10% Antarctic minke whales in the Antarctic, the 12th full-scale survey of a 16-year program; 100 northern minke whales, 50 Bryde's whales (*Balaenoptera edeni*), and 10 sperm whales (*Physeter macrocephalus*) in the western North Pacific]. As in previous years, a majority of the commission members urged Japan to refrain from issuing the permits.

4. *Small Cetaceans* It can be argued that no species of large whale is endangered by whaling today and will not be by any resumption of whaling under the RMS. Threats to those species, such as the North Atlantic right whale (*Eubalaena glacialis*), which remain severely reduced, do not include direct hunting. The most seriously threatened cetaceans (by direct hunting and incidental captures in fisheries) are a number of species and populations of the smaller cetaceans. At present, there is no single international body responsible for their conservation and management. There is considerable disagreement within the IWC as to whether the present convention is sufficient to allow the IWC to assume such a role. Fortunately, there is general agreement that the IWC scientific committee can consider the status of small cetaceans and provide advice to governments even though the IWC cannot set management regulations; it is to be hoped that governments respond individually and collectively. It remains a matter of some urgency that an international agreement or series of regional agreements be reached to ensure the conservation of small cetaceans.

5. *Whale Watching* The IWC has become involved (in a monitoring and advisory capacity) with aspects of the manage-

ment of whale watching as one type of sustainable use of cetacean resources. It has adopted a series of objectives and principles for managing whale watching proposed by the scientific committee.

B. Other Scientific Issues

The commission funds and acts as a catalyst for a good deal of cetacean research. In the year 1999/2000 some $400,000 was allocated to scientific research in addition to the IWC-related work undertaken by individual member governments. One major program is a series of Antarctic cruises to estimate abundance that has been carried out since 1978. These are now called Southern Ocean Whale and Ecosystem Research (SOWER) circumpolar cruises and include a component dedicated to blue whales.

With increasing awareness that detrimental environmental changes may threaten whale stocks, the IWC has accorded priority to research on the effects of such changes on cetaceans. While the RMP addresses such concerns adequately, the scientific committee has agreed that the species most vulnerable to such threats would be those reduced to levels at which the RMP, even if applied, would result in zero catches. It has developed two major research programs: one (POLLUTION 2000+) on the effects of chemical pollutants on cetaceans and another on the effects of climate change and ozone depletion (SOWER 2000). It is also increasing collaboration and cooperation with governmental, regional, and other international organizations working on related issues.

The work carried out by the IWC scientific committee is recognized worldwide. The commission has increasingly published scientific reports and papers; this culminated in the launch of the *Journal of Cetacean Research and Management* in 1999.

C. Politico-ethical Issues

Of prime consideration from both a scientific and an ethical viewpoint is the possibility of extinction of any population due to whaling. No population of whales is currently under threat of extinction from whaling, and it is clear that any acceptable management procedure will ensure that this cannot happen. However, this presumes an acceptance that whales are a natural resource to be harvested. While this is certainly the stated position of many members of the IWC, it is not universally accepted. A wide range of opinions have been expressed, ranging from the belief that whales are such a "special" group of animals that they should not be killed under any circumstances, through the view that they should not be killed commercially as whale products are not essential, to the view that the whales are a natural resource like any other.

In this regard, the question of humane killing has once more arisen within the IWC, with some nations stating that even if a safe management procedure is adopted, catch limits should not be set unless a "satisfactorily humane" killing method is available. This subject has been addressed several times during the history of the IWC, and the commission has been active in promoting work on more humane killing techniques for both commercial and aboriginal subsistence whaling. However, obtaining agreement on what comprises a "satisfactorily humane" technique will not be simple. In particular, in the case of aboriginal subsistence whaling, arguments of tradition and culture can clash with the adoption of modern technology.

VI. Conclusion

Many of the "politicoethical" issues listed are linked to questions of culture and freedom; they are complex and almost inevitably will not be resolved unanimously. There is clearly a divergence of opinion within the IWC on such matters to an extent unparalleled in any similar organization. It is, for example, difficult to think of any fisheries organization where some of the members believe it is immoral to catch fish under any circumstances. This is not the place to enter into a philosophical debate over the rights of nations or groups of nations to impose their moral values on others, but merely to point out the necessity of such a debate and the need for a degree of compromise if the IWC is not going to fragment, with potentially serious consequences for the world's cetaceans.

Inuit is a northern Alaskan term meaning "people" that has come to include the native "Eskimo" peoples of Chukotka, northern Alaska, Canada, and Greenland (Fig. 1). Inuit represent one extreme of the hunter–gatherer paradigm,

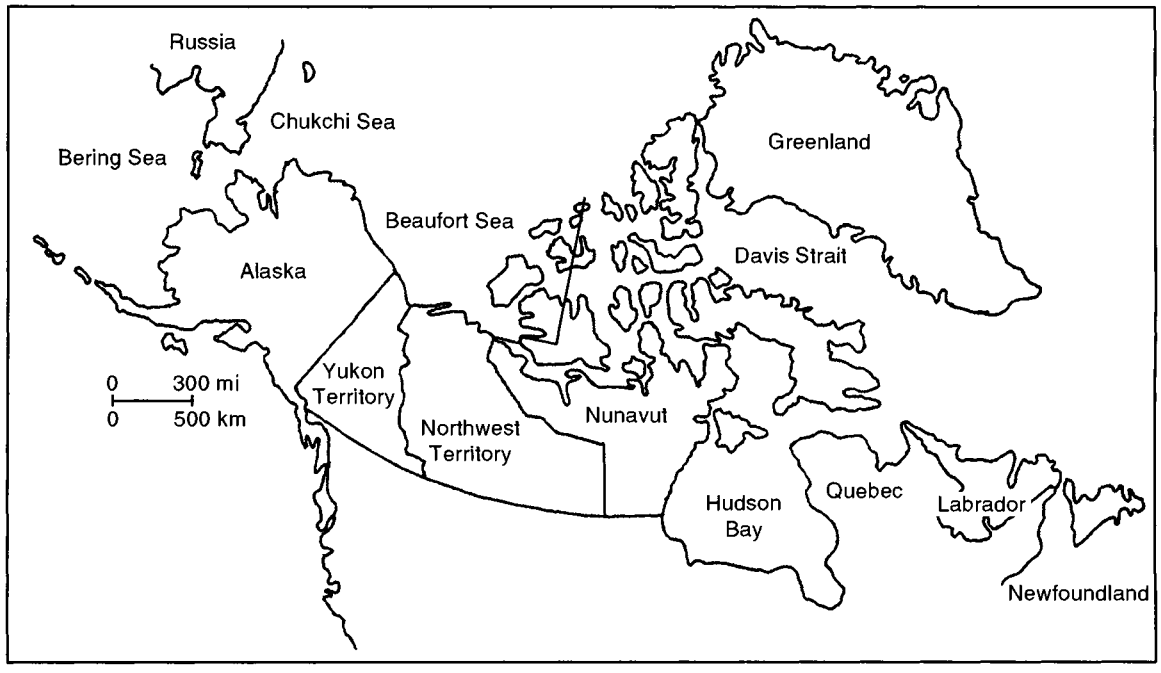

Figure 1 *Coastal Arctic inhabited by the Inuit. Redrawn from Freeman* et al. *(1998).*

relying almost exclusively on hunting to thrive in one of Earth's harshest environments, the Arctic. Most Inuit hunting has focused on marine mammals, with the bowhead whale (*Balaena mysticetus*) making up a central part of the harvest. Whaling was important to Inuit from Alaska to Greenland and underwrote the formation and survival of permanent sedentary villages on Alaska's arctic coast.

Inuit have depended on hunting marine mammals and caribou for thousands of years. The Birnirk culture (A.D. 400–800) was the first to successfully incorporate whale hunting into their subsistence regime. Whaling was completely integrated into the succeeding Thule culture starting around A.D. 800. Around A.D. 1000, Thule folk and their whaling culture spread out of Alaska and into Canada and Greenland.

The ancestral Inuit tool kit employed raw materials from hunted species plus some worked stone and driftwood. Their technology depended heavily on compound tools made from several types of raw materials and incorporating several parts. A harpoon might employ a driftwood shaft, a foreshaft made from caribou antler, a socket piece from walrus (*Odobenus rosmarus*) bone, a finger rest made from walrus ivory, lashings made from caribou sinew, a head made from whale bone, a blade made from slate, a line made from walrus hide, and a sealskin float.

The harpoon head toggled, or turned, 90° once it was thrust into the animal, preventing withdrawal. As the head toggled, the shaft fell away, leaving a hide cord running from the head back to the hunter or to a float. The float was a sealskin with all but one of its orifices sewn shut. The remaining orifice was used to inflate the float through an ivory inflation nozzle, which was then plugged with a piece of driftwood. The float marked the prey's location and slowed it down, tiring it as it attempted to swim or dive.

The first commercial whalers to enter the northern sea near Greenland in the 14th century found Inuit hunting bowhead whales from umiat (skin-covered driftwood framed boats), using compound harpoons with toggling heads. By the early 17th century, Greenlandic Inuit were severely impacted by commercial whaling, which decimated the whale stocks, perhaps even eliminating the Svalbard stock upon which the east Greenlanders seem to have depended. In Canada, much commercial WHALING for the European trade came to be shore based and carried out by local Inuit crews, entailing major alterations to Inuit lifestyles compounded by the destruction of the whale stocks.

Westerners first reached northern Alaska in 1826. However, Inuit lifestyles there were relatively unaltered by contact with the West until the second half of the century, when depredation of the bowhead whale stocks by commercial whaling and the spread of European diseases had disastrous consequences for the Inuit.

Inuit clothing was superior to Western cold weather gear and was often sought by Yankee whalers in Alaskan waters. Entire Inuit families were often hired to travel aboard commercial whaling ships in the Arctic; women skin sewers made and mended clothing for the crew while the men hunted with the Yankees. By the late 19th century, Yankee whalers also adopted the Inuit toggling harpoon head (Bockstoce, 1986).

The Inuit diet relied upon meat and blubber from whales, seals, and polar bears (*Ursus maritimus*). Caribou meat was eaten with seal oil or whale oil. Inland Inuit relied upon traded seal oil for a critical part of their dietary intake (Sheehan, 1997). Skins for boats came from seals and walruses. These, along with caribou and birds, also provided skins for clothing. Whale and seal oil provided fuel for lamps, the only source of heat other than body heat in houses.

In Alaska, driftwood semisubterranean houses incorporated long entrance tunnels made up of whale bones, while in areas of Canada and Greenland, where driftwood was scarce, even the houses were constructed with whale bones, or with stone and bone. The only prehistoric qargi, or whalers' ceremonial house, that has been excavated in north Alaska was made almost entirely of whale bones.

Pokes (seal skins) filled with seal oil were used to preserve meat. Prehistorically in Alaska, i.e., prior to 1826 and even past the middle of the 19th century, seal oil and whale oil pokes were major trade items from coastal areas (Maguire, 1988). Return trade from inland Inuit was primarily caribou skins for clothing and blankets. The economy left nothing to waste, with dog teams consuming old clothing as well as any of the harvest not used directly by the Inuit.

Whaling provided a dependable food surplus to the prehistoric coastal Alaskan communities, allowing them to organize their lives around the whale hunt (Sheehan, 1997). This whaling culture was successful for a thousand years. Whaling remains the organizing focus of Inuit life today in northern Alaska and is still an important part of Inuit ideology in other parts of the Arctic. Marine mammal hunting continues to underpin Inuit subsistence activities and social interactions.

I. Precontact Whaling

It is commonly believed that indigenous whaling developed in the Bering Sea and Bering Strait region about 2000 years ago with the Okvik and Old Bering Sea cultures. An increase in the diversity and complexity of tools used for hunting marine mammals took place from approximately 100 B.C. to A.D. 600. This suggests an increased dependence on large whales and other marine mammals (Stoker and Krupnik, 1993). There appear to be two significant differences between the early groups that hunted whales but did not rely upon them and later groups that were dependent for their survival on the whale hunt. One of these differences was technological, the other social.

The introduction of drag float technology may have transformed whale hunting from a "status" activity resulting, when lucky, in a "windfall," into a "normal" activity resulting in a regular and substantial payoff. Transformation of the umialik (whaling captain) from a temporary hunt leader into a permanent political leader responsible for distributing the whaling surplus throughout the community allowed the population to thrive and grow. The combination of technological and social change culminated in the period of the Punuk and Thule cultures starting at A.D. 800.

Although it is generally agreed that widespread large whale hunting did not occur until the Thule culture spread across North America to Greenland, whaling may have developed independently in several areas at different times. The earliest of these may be the Maritime Archaic tradition of Labrador and Newfoundland, dating from approximately 3000 B.C. The Maritime Archaic is believed to be one of the earliest cultures to use the toggling harpoon head. Møbjerg (1999) reported that the Saqqaq culture of Greenland's west coast, part of a broader Arctic small tool tradition, which stretches across the North American Arctic, may have been hunting baleen whales as early as 1600–1400 B.C. One of the most interesting cases is the old whaling culture of Cape Kruzenstern, near Kotzebue Sound in Alaska, which appeared suddenly around 1800 B.C. but disappeared shortly thereafter. These people used large lance and harpoon points, possibly to hunt for baleen whales. The abundance of whale bones in the area suggests that whaling was practiced, but there is no evidence that the technology was passed to later cultures (Giddings, 1967).

The Thule whaling culture developed in northwestern Alaska around A.D. 800 and spread very quickly across arctic Alaska and Canada as far as Labrador and Greenland within a few hundred years. The rapid spread of the Thule whaling culture was perhaps influenced by a period of climatic warming. The warmer weather may have resulted in seasonally open water across the entire coast from northwest Alaska to eastern Canada and Greenland, making Pacific and Atlantic populations of whales contiguous and more numerous. These conditions would encourage the expansion of a shore-based whaling culture.

The climate of the far north did not remain warm and stable for long. Colder weather and a resulting increase in expanse and duration of ice cover reduced the distribution and numbers of whales in the Arctic, with a concomitant reduction in the geographic range that could sustain a whaling-focused economy, and made reliance on whales risky in areas that were more marginal. Thule people who could no longer succeed in whaling focused more heavily on smaller marine mammals and other small game. Some parts of the central Canadian Arctic were depopulated.

The climatic variations resulted in dramatic changes to the Thule whaling culture throughout its range. The remnant Thule cultures gave rise to the contemporary Inuit cultures of present-day Canada, Greenland, and Alaska. In Alaska, whalers were able to continue their primary reliance on whale hunting by clustering in large permanent villages at points of land, where every spring they could rely on currents and geography to place them within walking distance of nearshore leads in the ice. Whales followed the leads as they went north for the summer. The leads became the foci of the whale harvest, supplemented by fall whaling in open water, as the whales passed the points on their way south.

II. Mysticetes

A. Bowhead Whale, agviq

The bowhead whale is the largest animal hunted by any prehistoric or historic hunter–gatherer society. Adults reach at least 20 m and weigh 50,000 kg or more. The slow moving, blubber-rich whale is a particularly suitable target, as it often travels close to shore in predictable migration patterns.

The advent of commercial whaling and the consequential contact with Europeans forever changed the patterns of indigenous bowhead whaling. Commercial whalers reduced bowhead populations to levels too low to support a subsistence hunt in most of the whales' range. The Chukotkan natives continued bowhead whaling until the late 1960s when Soviet authorities replaced the shore-based hunt with a catcher-based hunt, primarily for gray whales (*Eschrichtius robustus*). In

1997, the INTERNATIONAL WHALING COMMISSION (IWC) allotted a quota of five bowheads to Chukotkan natives. With assistance and training by Alaskan whalers, the Chukotkan Inuit have begun to hunt bowhead whales again. One whale was landed in 1997 and another in 1998. The Canadian Inuit ceased traditional bowhead hunting around World War I due to low whale numbers and active discouragement by the Canadian government. In 1991, the Canadian Inuit at Aklavik, in the Mackenzie River delta, landed a bowhead for the first time since the early 20th century. An unsuccessful hunt was carried out in 1994 and a successful hunt in 1996. Greenlandic Inuit hunted bowheads for many centuries before commercial whaling depleted the Atlantic stocks nearly to extinction. Greenlandic Inuit were employed by Danish commercial whalers from the late 18th century until 1851, when depleted bowhead numbers brought a halt to commercial hunts. Currently the bowhead whale is hunted under the quota system in northern Alaska, in the villages of Savoonga, Gambell, Little Diomede, Wales, Kivalina, Point Hope, Wainwright, Barrow, Nuiqsut, and Kaktovik, along the Bering, Chukchi, and Beaufort Seas.

After commercial whaling ceased in the early 20th century, Alaskan Inuit returned to a strictly subsistence bowhead hunt. Bockstoce (1986) estimated that an average of 15–20 whales were landed each year from 1914 to 1980. After 1970 there was a significant increase in the number of bowheads landed in Alaska. This was a result of a combination of factors. There was an increase in cultural awareness by Native Americans in general and Alaska Natives in particular, brought about by the passage of the Alaska Native Lands Claim Settlement Act in 1971. The discovery of oil in Prudhoe Bay in 1968 and the construction of the Trans-Alaska pipeline provided significant cash input into the economy of northern Alaska, which prompted a large increase in the number of whaling captains. The position of whaling captain in northern Alaskan Inuit whaling communities has always been one of great respect and authority. Traditionally, only those hunters who demonstrated great hunting success and respect for customs rose to the position of whaling captain. The expense of obtaining whaling gear limited the number of crews and ensured that only experienced whalers rose to the position of captain. The influx of money and employment in the 1970s resulted in a doubling of the whaling crews in northern Alaska from 44 in 1970 to 100 in 1977. The number of whales landed also increased from an average of 15/year to about 30/year from 1970 to 1977. There was also a large increase in the number of whales struck but lost and presumably killed.

The increase in the number of struck but lost whales, combined with an estimate from the IWC that only 600–2000 bowheads remained in the Arctic, prompted the IWC to call for a total ban on bowhead whaling. The Inuit reacted strongly to this ban. They formed the Alaska Eskimo Whaling Commission (AEWC), composed of whaling captains from each whaling village. In 1978 the AEWC, through the U.S. delegation to the IWC, negotiated a quota of 12 bowheads landed or 18 struck for the 9 Alaskan whaling villages. Since then the IWC has established quotas for Alaskan whalers, and the AEWC has distributed strikes to the 10 Alaskan whaling villages (Little Diomede joined AEWC in 1992). Research paid for and conducted through the AEWC and the North Slope Borough (NSB, the regional government in northern Alaska) Department of Wildlife Management indicates that the Eskimo whaling captains were correct when they asserted that there were many more whales than the IWC estimated. Careful censuses of the Bering–Chukchi–Beaufort Seas bowhead population have shown that the bowhead population in the western Arctic actually numbers around 8000 and is increasing about 3% per year. In consequence, the number of strikes allotted to Alaskan whalers has also increased. In 1997, a block quota was set for the years 1998–2002. The quota of 280 whales to be landed during that period includes five whales to be taken per year in Chukotka.

Alaskan Inuit hunt bowhead during the spring and fall migration. In spring, bowheads migrate from wintering grounds in the Bering Sea north through the Bering Strait to feeding areas in the eastern Beaufort Sea. The whales move along open leads in the ice created when drifting pack ice shears away from the grounded, shore-fast ice. These leads occur in predictable places along the Alaskan coast. Bowheads begin the migration north from the Bering Sea in late March through early April and pass the whaling villages of Gambel and Savoonga soon thereafter. The whales pass by Pt. Barrow from mid-April to early June and arrive in the eastern Beaufort Sea in May. Bowheads begin the fall migration across the central Beaufort Sea in early September and pass Alaska's north coast from mid-September to early October. Some whales may continue across the northern Chukchi Sea arriving in Chukotka in November, and others may move southward, likely crossing the central Chukchi Sea.

Equipment used in the modern whale hunt is a combination of precontact technology and tools adopted from Yankee whalers. The boat used for the hunt is a skin-covered frame called an umiaq. The frame was traditionally made of driftwood lashed with baleen with some whale bone fittings, but now is made from prepared lumber. The cover is made from the skins of bearded seals or walrus hunted the previous summer. The skins are left to ferment, which softens the skin and allows the hair to be stripped off easily. The skins are sewn together using a special waterproof stitch and stretched over the frame using rawhide thongs or, more recently, jute or nylon line. The average umiaq in Barrow (Fig. 2) requires six bearded seal skins for the cover, is 6.5–8.5 m long, 1.5–1.8 m across the beam, and weighs approximately 160 kg when dry (Stroker and Krupnik, 1993). The skins are usually replaced every 1 or 2 years, depending on their condition. In some places, aluminum or wooden boats powered with outboard motors have replaced the umiat (plural of umiaq). However, in areas where heavy ice is often encountered, umiat are still used because they are easier to move across and through heavy ice. During fall whaling in Barrow, Nuiqsut, and Kaktovik and during spring whaling in areas where leads are wide and whales travel farther from the lead edge, aluminum or fiberglass boats powered with outboard motors are used.

Weapons used for hunting are essentially the same equipment used by commercial whalers at the end of the 19th century. The darting gun and shoulder guns were introduced by Yankee whalers soon after the Civil War and were adopted by

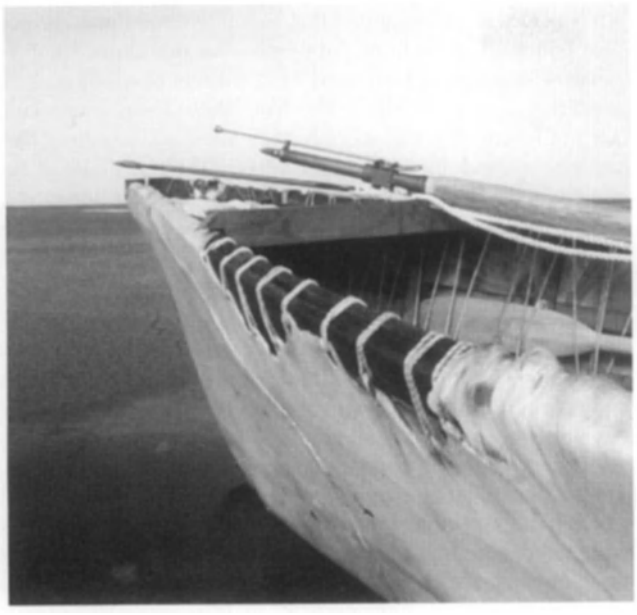

Figure 2 *Umiaq (skin boat) and harpoon used by Eskimo whalers in Barrow, Alaska. Photo by Steve A. MacLean.*

Inupiat hunters in the last decades of the 19th century (Bockstoce, 1986). The harpoon consists of a wooden shaft 1.5–2 m long tipped with a detachable steel harpoon with a brass toggling head attached to a float with 55 m of strong nylon line. The harpoon is tipped with a plunger trigger-driven gun that fires an 8-gauge, brass bomb simultaneously with the harpoon strike. A second darting gun that resembles the harpoon but without the toggling head harpoon is used to deliver a second bomb. Heavy brass shoulder guns are also used to fire bombs from distances greater than can be attempted with the darting gun. The brass-encased bombs are charged with penthrite, which replaced black powder in 1998. Penthrite bombs deliver a sudden concussion and kill by shock rather than laceration and tissue damage. This reduces the number of whales that are struck but lost. Other equipment includes flensing tools hand made of steel blades (often from hand saws) attached to long wooden handles, heavy-duty block and tackle to haul the whale onto the sea ice, an aluminum or fiberglass boat used to chase and retrieve a whale after a strike is made from the umiaq, and snowmobiles used to tow equipment to and from camp and to carry meat and maktak back to the village.

Preparations for whaling begin well before the whales arrive. Male members of the crew clean weapons and the ice cellar for storing meat and build sleds and other equipment needed for the camp on the ice. The wives of the captain and crew members sew a new skin cover for the umiaq frame. When the skins are dry, the umiaq is lashed to a sled for the wait until a lead opens.

Sometime before the arrival of the first bowheads the captain will decide where to place his camp. One or several "roads" are built across the ice to the selected sites. The roads are built to smooth the route across the maze of pressure ridges on the ocean ice. Smoothing the route eases the task of hauling sled loads of meat and maktak in the event of a successful hunt and provides a quick escape route if ice conditions become unsafe. Stakes with colors or symbols are often placed along the roads. Camps are located on the ice edge, often in "bays" in anticipation of whales swimming under projecting points and surfacing in those bays, or on points that provide good views of approaching whales.

Inuit believed, and many continue to believe, that whales give themselves willingly to hunters worthy of their sacrifice. Traditionally, many taboos governed activities in whaling camps, and these taboos were strictly followed to ensure a successful hunt. Tents, sleeping gear, and cooking were prohibited in camps. Most taboos have been dispensed with, but traditions still govern activity in camps. One tent is set up in camp to allow crew members to sleep in short shifts and for cooking meals. The tent is placed away from the lead and to the right of the boat to prevent approaching whales from seeing the camp. The umiaq is kept ready at the water's edge with a smooth ramp cut into the edge so that it can be launched silently. The harpoon and darting gun are positioned in the bow of the umiaq with the line from the harpoon neatly coiled on the bow. The weapons, lines, and floats are always kept on the right side of the boat, and the strike is always made over the right side of the boat to prevent ENTANGLEMENT in the line. At least one crew member remains on watch at all times, scanning the lead for any sign of an approaching whale.

When a whale comes within range and is determined suitable, the umiaq is launched silently with the harpooner ready in the bow. Two to five paddlers are situated along each side of the umiaq, with a steersman in the stern to steer the umiaq toward the whale. The umiaq is paddled silently, with all crew members stroking in unison. The steersman directs the umiaq to where he or the captain hopes the whale will surface next. The harpooner strikes the whale from as close as possible, often from point-blank range. The preferred target is the postcranial depression just forward of the back. A hit here will often kill the whale instantly. If this target is not available, the spine, heart, or kidney regions are targeted. As soon as the whale is struck, the float is thrown overboard on the starboard (right) side. If possible, a senior crew member other than the harpooner will fire the shoulder gun to plant another bomb into the whale. Other crews, alerted by VHF radio, quickly converge on the site of the strike in aluminum boats powered by outboard motors and may fire another bomb into the whale in an attempt to kill it quickly. Aluminum boats are much faster than umiat and help ensure that a struck whale will not be lost.

Immediately after the whale is killed the captain of the crew that first struck the whale says a prayer (to the Christian God). The prayer is often broadcast over VHF radio and is the first signal of a successful hunt to villagers waiting on shore. The whale's pectoral flippers are then lashed together and the flukes may be removed to reduce drag. A long line is attached to the caudal section forward of the flukes and all available boats attach to the line, with the successful crew at its head, to tow the whale tail first to the butchering site on the ice. Word of the successful hunt is sent to the village by snowmobile, and the whaling flag of the successful crew is raised over the captain's home. Many members of the community then travel to the

butchering site to help with hauling the whale onto the ice and butchering it.

At the butchering site a large block and tackle is attached to the ice and used to haul the whale onto the ice. Every available crew member and community member hauls on the free end of the line running through the block and tackle, pulling on commands from the whaling captains. If the whale is too large to haul onto the ice, some butchering may commence in the water. The tongue or SKULL may be removed to ease the task of hauling the carcass onto the ice. Butchering begins as quickly as possible after the whale is hauled onto the ice because the thick blubber layer retards heat loss and the meat in an unbutchered whale quickly spoils. The whale is butchered according to strict customs governing the distribution of shares (Fig. 3). Parts of the whale are reserved for the captain of the crew that struck the whale. Most of that portion will be shared with the community at feasts and festivals that occur throughout the year. Additional shares are divided among the successful crew and the crews that assisted in killing, towing the whale to the butchering site, hauling the whale onto the ice, and butchering. Individuals not representing a crew are also offered shares of meat and maktak. A group of 20–25 people can butcher an average size bowhead in 6 or 7 hr. No shares are distributed until the butchering is complete. Traditionally, following butchering some skulls were rolled into the ocean to allow the spirits of the whales to enter other bodies and again be hunted. The spirit of the whale would remember that the captain treated it well and so sacrifice itself to that captain again. Other skulls were brought ashore and placed at the beginning of the tunnels that led to the entrances of villagers' semisubterranean homes. These symbolically placed skulls suggested that as you entered the home you also entered the world of the whale. The prehistoric qargi or whalers' ceremonial house was built entirely of whale parts to represent a complete whale (Sheehan, 1990). Today, some skulls are not returned to the ocean but are taken ashore where they are cleaned and displayed in the village. The remainder of the skeleton is left on the ice for gulls, foxes, and polar bears.

Bowhead maktak, served boiled fresh, or raw and frozen, is the most prized food in the Arctic. Shares of meat and maktak are widely distributed among family and neighbors, often to family members living in cities who would not receive traditional foods otherwise. Meat is eaten raw and frozen, boiled, or fermented in blood. Many internal organs are also eaten. The kidney, intestines, and heart are boiled. The huge tongue of the bowhead is considered a delicacy when boiled. BALEEN was traditionally used to make toboggans, for lashing of umiaq frames, for bird snares, and to make fish nets and seal nets that could easily be freed of the ice that forms on nets immediately as they are removed from the water. A simple snap of the net broke off the ice from this resilient material. Now baleen is crafted into artwork and sold.

On the day following butchering, the captain of the successful crew opens his home to the community in celebration. All comers are offered food and drink. In early June the umiat of the successful whaling crews are hauled off the ice in ceremonies (apugauti). Once again, the captain supplies food and drink to all who attend. Nalukataq, the formal whaling festival, takes place in June. Each successful crew will have their own nalukataq, or several crews will hold one together. At nalukataq, the members of successful crews distribute the majority of the

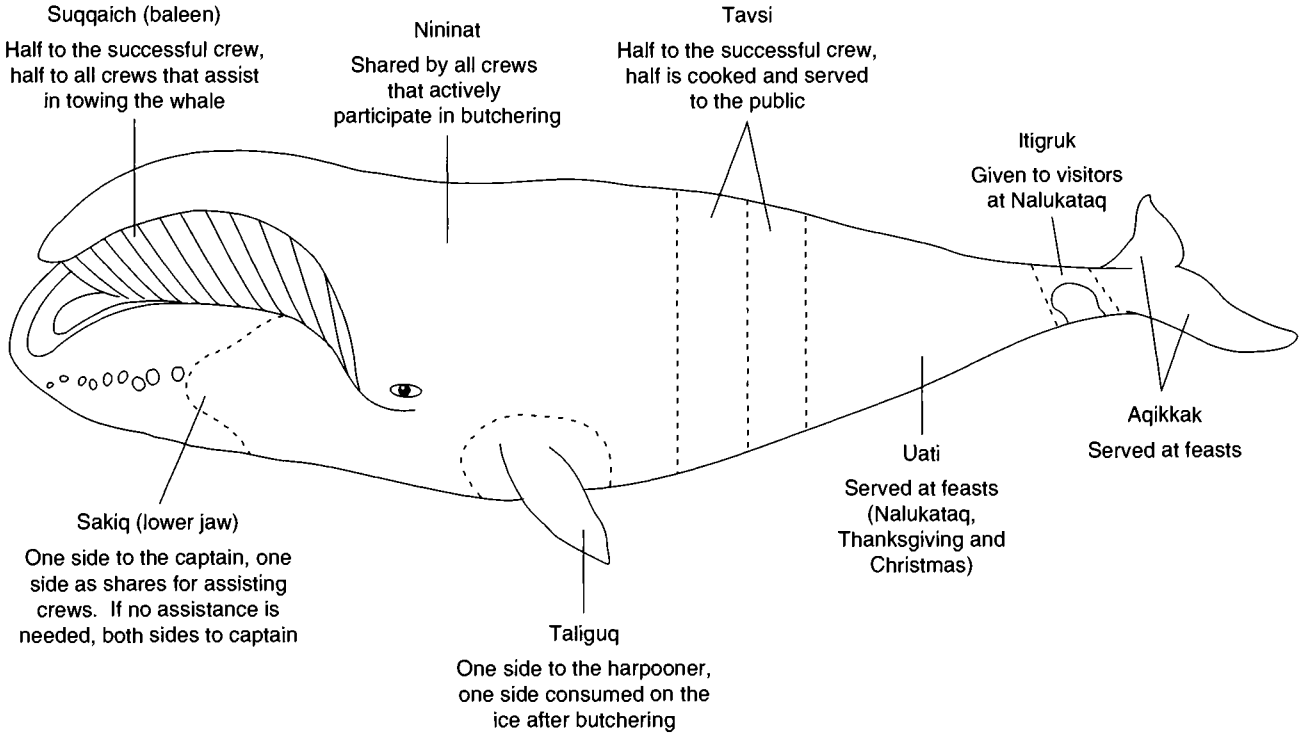

Figure 3 *Division of bowhead whale shares in Barrow, Alaska. From Harry Brower, Jr.*

meat and maktak reserved for the community. The captain and crew also distribute other foods collected during the year, such as caribou meat and soup, duck soup, goose soup, and many other traditional foods. Fruit and candy are also distributed, and coffee, tea, and soft drinks are served throughout the day.

After the food is distributed, the blanket toss begins. Skins from the successful umiaq are removed from the boat and resewn to form a blanket with rope handles along the edge. Community members climb onto the blanket, one at a time, and are thrown into the air by people pulling on the handles in unison. The objective is to jump as high and as many times as possible without falling. Members of successful crews will often climb onto the blanket with bags of candy to fling to the crowd while jumping. After the blanket toss a traditional dance is usually held in the community center. Each successful crew and their families will dance by themselves, but most dances are open to anyone. Nalukataq is one of the most joyful times in the village, and the traditional dance that is the culmination of nalukataq can last late into the night.

B. Gray Whale (*Eschrichtius robustus*)

Only the Chukotkan Inuit of the Russian Far East regularly hunt gray whales. Historically, Chukotkan Inuit hunted both bowhead and gray whales from shore-based stations. The traditional shore-based hunt was banned by the Soviets and replaced by a catcher boat-based hunt in 1954 (Freeman *et al.*, 1998). As a result, the cultural traditions were lost and few people now remember traditional hunting methods. The Soviet catcher boat *Zvyozdnyi* last hunted in 1992 (Freeman *et al.*, 1998). After the catcher boat stopped whaling, the villagers began to hunt marine mammals again to supplement dwindling food supplies.

The return to traditional, shore-based whaling was a difficult and costly endeavor. The lack of equipment and knowledge had serious consequences in several villages. Hunters from the village and Nunlingran died in several hunting accidents, and one whaling boat from Sireniki was sunk, killing all aboard. However, the hunters from seven Chukotkan villages landed 51 gray whales in 1994 (Freeman *et al.*, 1998). In Lorino, several experienced marine mammal hunters were able to teach younger hunters the proper use of harpoons, spears, and rifles. Hunters from Lorino landed 38 gray whales in 1994. Several other villages solicited aid from Lorino, and with training from experienced hunters began to successfully hunt gray whales. The hunt is now sanctioned and controlled by the IWC, with a quota of 120 gray whales landed in Chukotkan villages from 1998 to 2002. Gray whale hunting has again become an important part of Chukotkan Inuit cultural and dietary lives.

Gray whale hunting is carried out in the summer when gray whales move into the Bering Sea from their wintering grounds. Whaling is conducted from shore stations using skin boats (baidara) or wooden whaling boats. The harpoon–spear is a special whaling implement traditionally used by the Inuit of Chukotka (Freeman *et al.*, 1998), consisting of a wooden shaft with a detachable metal spear that is attached to a line with a small float. Each boat carries 7 to 10 of the metal spears and one wooden shaft. The spear is thrown by hand and the metal spear detaches from the wooden shaft. The wooden shaft is retrieved from the water, fitted with another harpoon–spear, and the whale is approached again. The harpooner aims for the back of the whale, trying to hit the main blood vessels or vital organs. Once harpoons have been set, the whales are shot with large-caliber rifles. This form of hunting is often dangerous. Gray whales are known to fight aggressively. Two boats are used to ensure the hunters' safety. The hunters also try to take small or medium sized whales.

Gray whales are taken for their meat and blubber. The meat and maktak are eaten frozen, thawed and raw, or boiled. Oil is rendered from the blubber and used as food by itself or added to edible roots, willow leaves, and other vegetables.

In northern Alaska during the early historic period, commercial trade for baleen from bowhead whales created wealth that allowed people to increase the number of dogs in their teams. As a consequence, some gray whales were hunted primarily to feed sled dogs, although some hunters also found the meat to be very tasty. Gray whales are no longer hunted in Alaska.

C. Humpback Whales (*Megaptera novaeangliae*) and Fin Whales (*Balaenoptera physalus*)

Greenlandic Inuit hunted humpback whales from skin boats in much the same way they hunted bowhead whales. Humpback whales are slow-swimming whales, and the techniques used for bowhead whales were successful for humpbacks as well. Although Greenlandic bowhead hunting ceased in the mid 19th century, humpback whaling continued until the 1980s.

In the 1920s, changing sea ice conditions caused food shortages among the Greenlandic Inuit who could no longer catch seals or humpback whales using traditional means. The Danish government operated a steel catcher boat, the *Sonja*, with a Danish crew from 1924 to 1949. The *Sonja* was able to catch larger and faster-swimming whales. In 1927 the *Sonja* caught 22 fin whales, 9 humpbacks, 7 blue whales, and 2 sperm whales. The meat was provided to Inuit of western Greenland and the blubber was shipped to Denmark, where it was rendered to oil and sold. In 1950, the *Sonja* was replaced with the larger *Sonja Kaligtoq*. From 1954 onward, the whales were taken to a single flensing station where meat and maktak were frozen for distribution and sale throughout Greenland. In addition to the government catcher boats, in 1948 some local fishermen began installing harpoon cannons on their boats and hunting whales. Fin and humpback whales were taken to the community where meat and maktak were sold. In the late 1980s the IWC eliminated the humpback whale quota, so fin and minke whales are currently the only baleen whales that are hunted in Greenland.

D. Minke Whales (*Balaenoptera acutorostrata*)

Minke whales have been hunted in Greenland since 1948. The minke whale hunt is now controlled by quotas set by the IWC and administered by the Greenland Home Rule Authority. The variable quotas consider the socioeconomic, cultural, and nutritional needs of the people and the regional abundance of whales. In the 1990s the quota varied from 110 to 175 per year. Minkes are hunted in summer and fall when ice conditions permit.

Hunts from fishing boats and small skiffs are opportunistic. Hunts take place from fishing boats whenever whales are sighted or from skiffs when enough small boat hunters are available. Whalers on fishing boats use deck-mounted harpoon cannons, whereas those aboard skiffs use hand-thrown harpoons and rifles. In each case the whales are towed back to the community for flensing and distribution. Shares are distributed to the vessel owner and crew members, and a large share is reserved for the boat. Little personal share of meat or maktak is sold, but the boat share is sold to contribute to the cost of operating a commercial fishing boat. In the small skiff hunt, shares are divided equally among the participants of the hunt and those helping with the flensing.

III. Odontocetes

A. Beluga Whales (*Delphinapterus leucas*)

Beluga whales are hunted across their range in Chukotka, Alaska, Canada, and Greenland. Ancestors to the modern Inuit were involved in beluga hunting as early as 5500 years ago in Alaska (Freeman *et al.*, 1998). The techniques used by the ancestral Inuit are the same as those used in Alaska, Canada, and Greenland before contact with commercial whalers. Entire communities were involved in a collective whale hunt or drive. A shaman typically guided the hunt, which was led by a distinguished hunter from one of the communities involved. Freeman *et al.* (1998) quoted an elder from Escholtz Bay, Alaska, describing a traditional drive from around 1870: "They made a line and moved together. They hollered, splashed their paddles, waved their harpoons to scare them into real shallow water. . . . When a hunter got a beluga, he ties it to his qayaq (kayak) and brought it to shore; if he get two, he'd tie one on each side. . . . If wind came up while men were out hunting, women would take umiaqs (skin boats) off the racks and go to help those hunters who were towing two belugas. People always helped together when they landed and pulled those beluga on the shore." Friesen and Arnold (1995) determined that beluga whales were a focal resource for precontact Inuit of the Mackenzie delta, constituting up to 66% of their meat. Two or more hunters would cooperate in a beluga hunt. The whales were approached by hunters in kayaks who threw harpoons attached to sealskin floats. After the whale tired, it was lanced in the heart with a blade attached to one end of the kayak paddle. In some locations, hunters in kayaks working cooperatively would drive belugas into shallow water where they were killed. In northern Greenland, and possibly elsewhere, belugas were hunted at large cracks in the ice where the whales congregated to breathe.

In the 18th, 19th, and early 20th centuries, Canadian Inuit were hired by commercial whaling enterprises to hunt belugas. Skins and blubber from the belugas were shipped to European markets. The Inuit hunters kept the meat and some of the maktak and received trade goods, which often included wooden boats.

Methods changed with the introduction of rifles, fiberglass and aluminum boats, and outboard motors. Today, hunters in Alaska use one of four methods to hunt belugas: harpooning or shooting from the ice edge in spring, shooting from motorized boats in open water, netting, or driving the whales into shallow water. Ice edge hunting occurs during the northward migration, sometimes concurrently with bowhead whaling. Belugas can also be shot directly from shore if the migrating whales are close enough, as happened in Barrow in 1997. Open water hunting is common in summer and fall when the ocean is free of ice. Netting occurs at headlands where predictable movement patterns make netting practical. Shallow water drives are most common in shallow bays and estuaries, such as Pt. Lay and Wainwright, Alaska.

Sealskin kayaks were last used to hunt belugas in the 1960s in communities in northern Quebec and the Belcher Islands. Now hunters use skiffs or freighter canoes powered with outboard motors. Harpoons with detachable heads attached to floats are still used, although now floats are made from man-made materials rather than seal skins. Rifles (.222 to 30.06 caliber) are used to kill the whales after harpoons have been attached.

Belugas are the most commonly and widely taken whale species in Canada (Freeman *et al.*, 1998). Beluga maktak is highly prized by Canadian Inuit. After a successful hunt the meat and maktak are distributed to family members and neighbors according to traditional customs. In some communities a successful hunt is announced over community radio and all community members are invited to collect a share. Because beluga maktak is so highly prized, very little of it is sold for redistribution through retail outlets in the Canadian Arctic. Beluga maktak is usually eaten raw and fresh, although some now deep-fry it. The meat is usually air dried before being eaten. In some communities, sausages are made by placing meat in sections of intestine that are lightly boiled before being dried or smoked. Beluga oil was used for lamp oil, softening skins, and cleaning and lubricating guns and other equipment.

Beluga hunting in Greenland has followed a history similar to hunting of other larger whale species. For many centuries, local hunters supplied meat and maktak to meet community needs. In colonial times, beluga blubber and oil became an important trade commodity. As a result, the Greenland Trade Department established commercial beluga drives and hired local hunters to carry out the hunt. Commercial drives continued until the 1950s when the European market for whale oil disappeared. Commercial whale drives reappeared in the 1960s when improved coastal communication and refrigeration made it possible to transport beluga meat and maktak from northern hunting communities to southern Greenland. Today, belugas are hunted with rifles (30.06 caliber to 7.62 mm) from small boats. Typically, kayaks and motorized skiffs are used to hunt belugas, often singly or in pairs, but sometimes a larger number of small boats cooperate to hunt belugas swimming together. Meat and maktak are distributed throughout the community, including sale at the local market, and in retail stores throughout Greenland.

Beluga hunting in Russia only occurs in a few villages in Chukotka, and the numbers taken are small. Belugas in Russia are associated with the distribution of fish, especially arctic cod and arctic char. Hunting occurs opportunistically when belugas are encountered during other activities. Hunting occurs either from shore or from the ice edge. Hunters hide behind hummocks of ice and shoot the whales with rifles (7.62 or 9 mm). Meat is dried, frozen, boiled, or fried. Maktak is eaten raw, fresh, boiled, or fried. The skin is used for boot soles, belts, and lines. The oil is used with fish and salad plants. Historically, beluga oil was traded for reindeer meat and skins, although

when Soviet state-run fur farms were operating the oil was sold to the farms (Freeman *et al.*, 1998).

B. Narwhal (*Monodon monoceros*)

Narwhals have been hunted in Greenland and eastern Canada for centuries, and may have brought the Greenlandic Inuit in close contact with the Norse in Greenland beginning in the 10th century. Narwhal ivory was bartered among Inuit long before European contact. Narwhal tusks were highly valued by European traders in the Middle Ages, who sold the tusks in Europe mislabeled as unicorn horn, sometimes for their weight in gold. The royal throne of Denmark, made in the 15th century, is made almost entirely of narwhal ivory. Narwhal tusks were the basis of trade between Greenlandic Inuit and Europeans from the 10th through the 19th centuries and were important to Canadian Inuit after the collapse of commercial bowhead whaling in the late 19th century. Inuit in Greenland and Canada used the tusks to create durable and functional tools, especially harpoon foreshafts.

Narwhals were hunted from kayaks either along the flow edge, in ice cracks, or in open water. Near ice, the narwhals were harpooned and hauled ashore. In open water, hunters worked together to drive the narwhals into shallow water where they were killed. Another method was to station hunters with rifles on cliffs who would shoot the whales as they swam by. Several hunters in kayaks would wait offshore and harpoon the whales once they were shot. Now, hunting in Canada takes place with small skiffs, rifles, and harpoons attached to floats. Narwhal hunting in northern Greenland is still accomplished with kayaks. Five-meter skiffs or 10- to 12-m cutters are used in southern Greenland, although occasionally narwhals are shot from shore or netted.

Maktak from narwhals is prized and is eaten fresh raw or aged. Narwhal oil was considered of higher quality than seal oil and was used in lamps for heat and light. The tusk remains the most highly prized product from narwhal. Today tusks are used for artwork or sold. Narwhal ivory sold for an average of $100 per foot (30 cm) in 1997 (Freeman *et al.*, 1998). Narwhal meat was used to feed hunters' dog teams.

C. Other Small Cetaceans

Small numbers of other cetaceans are taken in eastern Canada and Greenland. The principal species taken in Canada are common bottlenose dolphin (*Tursiops truncatus*) and harbor porpoise (*Phocoena phocoena*). In Greenland, killer whales (*Orcinus orca*), long-finned pilot whales (*Globicephala melas*), northern bottlenose whales (*Hyperoodon ampullatus*), harbor porpoise, white-beaked dolphins (*Lagenorhynchus albirostris*), and Atlantic white-sided dolphins (*Lagenorhynchus acutus*) are taken.

IV. Pinnipeds

A. Ringed Seal (*Pusa hispida*), natchiq, Bearded Seal (*Erignathus barbatus*), ugruk, and Harp Seal (*Pagophilus groenlandicus*)

Seals are probably the most widely distributed, abundant, and reliable food resource available to coastal Inuit populations. Ringed seals are available near shore for much of the year. Bearded seals are also important, although less abundant and less widely available than ringed seals. They are important not only for their meat, but also as a source of raw materials, particularly their hides (Jensen, 1987). Harp seals are seasonally very abundant in certain areas of Greenland and eastern Canada, and were taken when present. Ribbon seals (*Histriophoca fasciata*), Larga seals (*Phoca largha*), and harbor seals (*Phoca vitulina*) are only occasionally encountered. All of these pinnipeds are hunted in similar ways and have been combined for the following discussion.

Natchiq are ice adapted. They are hunted at breathing holes, in subnivean lairs, on drift ice, and in open water. Other seals are not as ice adapted as the natchiq. They can also be hunted on drift ice and in open water. Harbor seals and Larga seals tend to stay away from ice if it is present in significant amounts. Ugruk are common on ice pans and commonly hunted on pans or in open water. Harbor seals tend to be more common than natchiq in more southerly areas (southern Greenland, Labrador), although they have been regarded as shy and also potentially aggressive. Harp seals were generally taken from kayaks in open water or when hauled out on offshore drift ice, although they could be harpooned from shore or from the ice edge under certain circumstances.

Traditionally, natchiq were hunted at breathing holes on the ice, at pupping dens, while basking in the sun, by netting at the breathing hole, from the ice edge, or from boats in open water. Breathing-hole hunting was most common, as the ocean is ice covered for much of the year. Ringed seals carve out and maintain breathing holes in the ice throughout the winter. In flat ice the breathing holes may be visible from the surface, but often they are covered with snow, and practically invisible. Ringed seals maintain numerous breathing holes, so there was never any guarantee that a seal would visit the hole where the hunter was waiting.

Breathing-hole hunting was a difficult, cold endeavor and is no longer practiced to any great extent anywhere in the Arctic. Boas (1964) presented an excellent description of pre-rifle seal hunting methods and equipment. A hunter would first locate a breathing hole with the use of one of his sled dogs. Once the hole was found, the hunter set up his equipment around the hole. The hunter sat on an ice block with his feet resting on a piece of fur or stood on the fur with his harpoon in his hand or at his side and waited for the seal to arrive at the breathing hole. There was never any way to determine how long the hunter would have to wait. If the village needed food, it was not uncommon for hunters to wait 24 hr or longer for a seal to arrive. Now, more efficient and less strenuous methods are preferred.

When a seal arrives at a breathing hole, the first breath is a short, shallow sniff for any sign of danger. If the seal does not detect danger, the next breath will be deeper. On this second breath, the hunter thrust his harpoon straight down the hole striking the seal on the head or neck. The toggling head detached, preventing the seal from escaping. The seal was killed and the breathing hole enlarged to pull the seal through. Once rifles became available, seals were shot when they came to the hole, then immediately harpooned to prevent the seal from drifting away or sinking.

After the breeding season, seals enlarge their breathing holes located on large areas of flat ice so they can climb out and bask in the sunshine. Traditionally, Inuit had several methods for hunting seals at this time, described in detail in Nelson (1969) and Boas (1964). A hunter might simply wait near one of the holes for a seal to surface. The water within the hole pulsates when a seal arrives at its hole. When the seal broke the surface of the water, it was speared or shot. Occasionally, hunters placed lines with several hooks along the wall of a breathing hole to catch seals backing into the water after surfacing.

Another traditional seal hunting technique required great stealth and skill. The hunter emulated the behavior of a seal, sliding along the ice on his side, often with a piece of sealskin beneath him to reduce friction and keep his clothing dry. Often hunters would scrape the ice with seal claws attached to a piece of wood to mimick the scratching sound made by resting seals. A skilled hunter could approach very close to a seal basking in the sun. In this way hunters were often able to kill 10–15 seals in 1 day. In a variant of this method, the hunter pushed a small sled with a white shield that hid him from the seals.

Seals could also be netted at their breathing holes. Netting was done at night to prevent the seal from seeing and avoiding the net. This also reduced the hunters' vision and exposed the hunter to many dangers. Four holes were cut around a breathing hole and the net lowered into the water to approximately 10 feet. Seals generally approach breathing holes along the surface, so they did not encounter the net. When the seals dove from the hole, they dove straight down and became entangled in the net. Seal netting was discontinued in the 1960s.

In spring, pregnant ringed seals hollow a natal den in the snow covering one of their breathing holes. Hunters again use one of their dogs to find the dens. The hunter cut a small hole in the wall of the den through which he could watch for the return of the mother seal. When the seal returned, the hunter jumped through the snow between the seal and its hole, trapping it. Prior to the introduction of rifles the seals were killed with a spear or club; later they were shot through the wall of the den.

Traditionally, ice-edge hunting was accomplished with a small harpoon that was thrown at seals swimming near the edge. A line was attached to the harpoon to retrieve struck seals. Hunters were limited by how far they could accurately throw the harpoons, usually 10–20 feet. The introduction of the rifle changed the nature of seal hunting. Hunting seals from the ice edge using rifles is easier and more efficient than breathing-hole hunting, and the range of the hunters has been increased greatly by the rifles. The increased range brought about two new inventions specifically for use in ice-edge rifle hunting: the retrieving hook (manaq or manaqtuun) and a small skin boat (umaiggaluuraq). The manaq consists of a rope up to 200 feet long, attached to a piece of wood with four hooks extruding from the sides. A float is attached to keep the hooks afloat for winter hunting (when seals float after being shot), and a sinker is attached for summer hunting to retrieve seals that sink to the bottom. Once a seal is shot, the hunter grabs his manaq to retrieve the seal from the water. The line is coiled and held in the left hand, while the right hand holds the line 3–5 feet from the hooks. The hook is thrown beyond the seal, the line is slowly drawn in until the hooks are near the seal, a sharp tug sinks the hooks into the hide, and the seal is carefully pulled to the ice edge.

The umaiggaluuraq (literally "small umiaq") is 7–10 feet long and 36–40 inches wide (Nelson, 1969). Two bearded sealskins are used to cover a wooden frame. Once a hunter shoots a seal, he pulls the boat to the ice edge, often with the help of another hunter to prevent damage to the skins by dragging the boat. The boat is rowed to the seal with two short oars lashed to the gunwales. When the hunter reaches the seal, he tows it back to the ice edge with a small hook and line.

Open water hunting and hunting of seals basking on drift ice became most popular after the introduction of rifles. Before rifles were introduced, hunters occasionally harpooned seals from kayaks, but only in calm water. After rifles and outboard motors became readily available, several men would hunt together from a single umiaq. The hunters were often members of the same whaling crew using the captain's boat. Seals were shot with rifles ranging from 22 to 30.06 caliber and harpooned. Now, aluminum boats have replaced skin boats, but the same methods are used. Open water hunting from aluminum boats is currently the most popular way to hunt both the ringed and the bearded seal in northern Alaska. Harpoons are still used in the Yukon-Kuskokwim Delta because people feel that shot seals sink too quickly. In Greenland, certain areas still forbid motorized boats in the hunt, although they may be used to travel to the hunting area.

B. Walrus, aiviq

Walruses are almost always associated with pack ice and are only hunted when the pack ice is close to shore. They do haul out on shore in certain locations, although this has become less common. Nelson (1969) reported that hunters in Wainwright, Alaska, only traveled offshore as far as land was still visible on the horizon. However, Spencer (1959) reported that hunters in Barrow often traveled 50 to 100 miles into the ocean to find walruses. The distances traveled are probably dependent on the proximity of the pack ice to shore and undoubtedly changed with the introduction of outboard motors.

Hunting walruses was, and remains, a collective hunt. The size of the walrus and the logistics of butchering and transporting the meat back to the village make it necessary for several hunters to work cooperatively. Traditionally, walruses were hunted using large harpoons similar to the harpoons used in bowhead whaling. Long lines, often made of walrus skin, were attached to the harpoons and fastened to a large piece of ice or were held by the hunter who used a smaller spear to drive the end of the line into the ice. Walruses were harpooned while they were lying on the ice. When the harpooned walrus dove, the line prevented it from escaping. When the walrus tired, it was killed with a lance through the heart. Occasionally, walruses were hunted from umiaqs when they were encountered away from the pack ice. In those circumstances, floats were attached to the line or the line was fastened to the umiaq. The walrus was killed with a lance once it tired. Nelson (1969) summarized an elder recounting one traditional method of hunting walruses in which two hunters harpooned two walruses facing

opposite directions. The lines from the two harpoons were quickly tied together, and the walruses pulled against each other until they tired enough to be killed with lances through the neck. Now, large rifles are used instead of harpoons, but the methods used to approach the walruses are the same. When a walrus herd is sighted, the ice surrounding the herd is evaluated. There must be enough ice-free water to allow approach and to allow sufficient time for the killed walrus to be butchered before ice closes in.

Walruses are approached slowly with the outboard running. Generally, walruses are approached to within 10 feet before they are shot. All hunters shoot at the same time and continue the volley until enough have been taken or the herd escapes into the water. Walruses must be shot in the brain or the anterior portion of the spinal cord to ensure a kill. Walruses will not float once killed, so any dead or seriously wounded walruses that fall into the water are considered struck and lost. Fay *et al.* (1994) reported that up to 42% of walruses struck in Alaskan hunts from 1952 to 1972 were lost. Wounded walruses are often dangerous, and Nelson (1969) recounted several instances in which wounded walruses damaged boats. In fact, walruses can be so aggressive that they have disrupted mail delivery by kayak and even forced the abandonment of a settlement in Greenland.

Walrus flippers "ripened" in seal oil are considered a delicacy in much of the Arctic. Select portions of meat are eaten, but the bulk of the walrus was used to feed the hunters' dog teams. The skin, bones, and especially the tusks were the most valuable parts of the walrus. Walrus skins often replaced bearded seal skins on umiaqs in places where bearded seals were not abundant. Walrus skins were also used to create strong lines that were attached to harpoons used in seal, walrus, and whale hunting. The bones of walruses were used to make tools, and the ivory tusks were often used to make harpoon points and foreshafts. Now, ivory is used in artwork and much is sold to generate a cash income.

V. Polar Bears, nanuq

Polar bears are found throughout the Arctic and are hunted through much of their range. Polar bears remain on the pack ice for most of the year, and most hunting takes place during the winter on the pack ice. Polar bears are also taken opportunistically when they are encountered on land or in open water.

Polar bear hunting is considered one of the most dangerous hunting activities and successful hunters often enjoy high status in village communities. Traditionally, single hunters using spears, lances, or knives hunted polar bears. Boas (1964) and Nelson (1969) both described polar bear hunts before the introduction of rifles. In the Canadian and Greenlandic Arctic, it was common to release dogs to chase the bears and tire them. Once the bears stopped, they were approached on foot and killed with lances or spears. Dogs were not used commonly in Alaska, but were released if the bears were on young, unsafe ice. Spears and lances were quickly given up once rifles became available.

Hunting for polar bears is now nearly always done on the sea ice, and hunters often travel far offshore to find bears. Walking used to be the preferred method of transportation because it offered the advantages of a silent approach and the ability to hide quickly among the ice hummocks and ridges. Now, snowmobiles are preferred. With snowmobiles, hunters can pull sleds to transport the meat and hide back to the village, eliminating the need to drag the hide and then return with dogs to transport the meat.

Hunters usually find tracks rather than finding the animal itself. From the tracks hunters can tell the size of the animal, its direction and speed, and how long ago the bear passed. Tracks are followed until the bear is sighted. The hunter can then either move quickly to overtake the bear or move ahead to wait in ambush. In either case, it is important to get as close to the bear as possible to ensure a lethal shot. Wounded polar bears are dangerous and sometimes attack the hunter. If the bear is in a position that the hunter cannot reach, the hunter will sometimes try to lure the bear closer by mimicking a sleeping seal. Once the bear stalks close enough, the hunter picks up his rifle and shoots. Sometimes hunters leave seal blood or blubber on the ice and return to the area later to see if any bears have been lured by the smell. When bears venture close to villages or whaling camps they are almost always shot.

Polar bears are hunted for both their meat and their hides, which are divided among the village according to local tradition. In Greenland, the person who sights the bear becomes its "owner" regardless of whether they participate in the hunt. Any other people who shoot the bear or touch it before it is killed also receive shares of the bear. In Alaska and Canada, shares were traditionally distributed widely within the village. A young hunter's first bear was shared among all the people in the hunting party or was distributed to the elders in the village if he was hunting alone. Now, the shares are distributed less formally, but meat is usually shared with family members and others outside the family. The successful hunter usually keeps the hide.

Polar bear meat is prized by many people in the Arctic. Meat is always well cooked to prevent trichinosis, and the liver is never eaten due to high concentrations of vitamin A. In Alaska the sale of polar bear hides is prohibited by the Marine Mammals Protection Act of 1972. Hides are used for clothing such as boots, mittens, or trim for parkas and also for sleeping mats when camping on the ice. In Greenland, polar bear skins were used for warm hunting pants, but now all skins are sold to Greenland's trading department. Since 1994, polar bear hunters in Greenland have been able to sell bear meat to restaurants and hotels.

VI. Conclusion

Inuit and their ancestors have hunted marine mammals for thousands of years. The technology and techniques of hunting marine mammals evolved in a culture intimately associated with the sea and the creatures that inhabit it. In modern times, the technology and techniques of hunting marine mammals have changed, but many traditions and beliefs remain. Marine mammal hunting provides access to status within the community and a sense of self-worth for a generation of Inuit struggling to cope with the burdens of cultural assimilation. It is the traditions and beliefs that are necessary for marine mammal hunting to remain an important part of the Inuit people's subsistence and cultural lives.

Irrawaddy Dolphin

Orcaella brevirostris

PETER W. ARNOLD
Museum of Tropical Queensland, Townsville, Australia

The Irrawaddy dolphin *Orcaella brevirostris* (Owen in Gray, 1866) is a coastal Indo-west Pacific species that also occurs in major river systems of Southeast Asia. Until recently, it was known mainly through the classic monograph by Dr. John Anderson, Superintendent of the Indian Museum, Calcutta from 1865 to 1886.

I. Systematics

The Irrawaddy dolphin resembles the beluga *Delphinapterus leucas* (Pallas, 1776) in general appearance and certain anatomical features, such as the tympanoperiotic earbones. This led some specialists to consider it a tropical relative of the beluga, placing it in the variably defined family Monodontidae or Delphinapteridae. It has also been placed in a family of its own. Recent morphological and genetic studies consistently place it in the family Delphinidae. Genetic studies suggest that its closest relative may be the killer whale *Orcinus orca* (Linnaeus, 1758).

The common name refers to its occurrence in the Irrawaddy (Ayeyarwady) River, Burma (Myanmar). The freshwater population was originally described as a separate species *Orcaella fluminalis* (Anderson in Gray, 1871); however, studies provide little support for this distinction. Some morphological and genetic studies do suggest a potential taxonomic separation between animals found throughout Southeast Asia and those in Australia and Papua New Guinea.

II. Description

The head is broadly rounded, with no sign of a beak. There is an indentation behind the head, forming a distinct neck crease. The head is very mobile and can be deflexed almost 90° to the body axis. The dorsal fin, over halfway along the back, is small—hence the alternative name "snubfin dolphin" (Fig. 1). A midventral crease runs along the belly from level with the flippers to the genital slit. The flippers are broad and paddle-like; they are highly mobile and may be rotated forward through a wide angle.

The color pattern may vary regionally. Animals have been described as "dark gray" but Australian animals are lighter colored, with a subtle three-tone pattern (white belly, gray cape along the back, and lighter gray to brown along the sides).

Maximum recorded length of the Irrawaddy dolphin is 2.75 m, but it averages 2.1 m in length and 115–130 kg mass. Males appear to be about 15% longer than females.

There are 16–20 TEETH in each half of the upper jaw and 15–19 teeth in each lower row. In dolphins from the Mahakam River system, East Kalimantan, the teeth may not erupt from the gums.

III. Distribution

The species is widely distributed in coastal waters from the Madras coast of India as far north as Calcutta (22°N) to the northeast coast of Australia almost to the Queensland–New South Wales border (27°S). In between it is recorded from Bangladesh, Myanmar, Thailand, Kampuchea, Malaysia, Singapore, Brunei, Indonesia, the Philippines (unpublished records of Dr. A. A. Yaptinchay), Vietnam, and Papua New Guinea (Fig. 2).

It occurs to at least 1300 km upstream in the Irrawaddy River. There are also records of sightings throughout the Mekong River, from its mouth in Vietnam upstream to the border between Cambodia (Kampuchea) and Laos (Lao Peoples' Democratic Republic). Landlocked populations occur in the Lao PDR and in East Kalimantan, Indonesia.

Figure 1 *These animals clearly show the rounded head and small dorsal fin characteristic of the Irrawaddy dolphin. The squirting of water, which has been reinforced by training in these captive dolphins, occurs naturally in freshwater populations. The function is unknown. Courtesy of Isabel L. Beasley.*

IV. Ecology and Behavior

The Irrawaddy dolphin has a generalized diet, taking a wide variety of fishes as well as cephalopods (squid, cuttlefish, octopus) and shrimps. Food is taken both near the bottom and in open water. Captive animals were fed about 4–8% of their body weight daily, but this may exceed their metabolic needs. Phonations at about 60 kHz were recorded from Mahakam River dolphins held captive in Indonesia. These signals are apparently used for echolocation but vision also appears to be good. There is no basis for referring to this species as a "blind dolphin," as occurs in some of the general literature.

In the Northern Hemisphere, mating is reported from December to June. The gestation period has been estimated at 14 months. Newborn animals or near-term fetuses have been reported from April to June; births occurred in captive Indonesian animals from December to July. The newborn dolphin is about 1 m long and has a mass of 10–12 kg. Captive animals started taking fish at about 6 months and were fully weaned by 2 years of age. A small number of animals from northeastern Australia, aged using dentinal growth layer groups in teeth, reached near adult size at 4 to 6 years. Maximum life span was considered to be about 30 years.

Group size is usually 2 to 3, but may reach 10–15 animals. Surfacing is generally unobstrusive, with a low roll showing little of the back. Given this, and the small size of the dorsal fin, the Irrawaddy dolphin is often easy to miss in the field. However, it may raise the flukes above water and wave or slap the flippers, as well as spyhop or breach. The maximum dive time was recorded at 12 min but animals more usually submerge for about 2 to 3 min.

Although Anderson reported dolphins riding the bow of steamers in the Irrawaddy River, recent observations suggest lack of interest in or even avoidance of large power vessels. However, there are reports from Burma and Thailand, dating to the last century, of Irrawaddy dolphins driving fishes into fishermen's nets. Such cooperative fishing has been confirmed in the Irrawaddy River.

V. Conservation Status

Irrawaddy dolphins may be killed for their oil or captured for display in public aquaria. Both practices appear to be limited but may affect local populations. Legislation protecting dolphins is in place in most countries where Irrawaddy dolphins occur, but enforcement is a problem given the extensive (and poorly patrolled) range of the species. Dolphins may be killed in those areas where explosive fishing is still used. Of wider concern is accidental capture in fishing nets or nets used to control the number of sharks off popular swimming beaches. Concern has been raised especially about habitat reduction, with possible fragmentation of dolphin populations, and degradation. Suggested effects include reduced food supplies (from habitat degradation and overfishing), increased industrial and urban pollution of coastal sites, and disturbance from increased vessel traffic. Such potential threats are largely unquantified. There are few reliable population estimates from anywhere within the range of this species, and in most conservation plans it is listed as "insufficiently known." However, with the exception of northern Australia, the Irrawaddy dolphin has been reported in low numbers throughout its range, with suggestions of population declines in several Southeast Asian countries.

Japanese Whaling

TOSHIO KASUYA
Teikyo University of Science and Techology, Uenohara, Japan

Whaling is a fishing activity that targets whales, but the term does not often fit because of the ambiguity of *whale*, sometimes construed to exclude small cetaceans. This is also true in Japanese whaling. This article adopts the broadest meaning for the term Japanese whaling to include activities of hunting any cetaceans in Japanese territory, by Japanese companies, or by any companies known to be sponsored by them.

I. Subsistence Whaling

Numerous bones of gregarious dolphins in a site of the Jomon Era (10,000 B.P.–200 B.C.) on the Noto coasts, Sea of Japan, suggest the presence of a drive fishery. Other sites of similar antiquity on the Pacific coasts of central and northern Japan and on the coasts of northern Kyushu facing the Sea of Japan/East China Sea revealed remains of small cetaceans and detachable harpoon heads. The Okhotsk Sea culture of Hokkaido in the 5–14th centuries left skeletons, harpoons, and drawings depicting whale harpooning. Ainu people on Uchiura Bay, Pacific coast of southern Hokkaido, opportunistically hunted minke whales in the late 19th century using aconite-poisoned detachable harpoon heads and floats.

Skeletal remains from these sites represent at least 13 species of cetaceans, i.e., North Pacific right whale (*Eubalaena japonica*), common minke whale (*Balaenoptera acutorostrata*), sei whale (*B. borealis*), humpback whale (*Megaptera novaeangliae*), sperm whale (*Physeter macrocephalus*), false killer whale (*Pseudorca crassidens*), long-finned pilot whale (*Globicephala melas*), Pacific white-sided dolphin (*Lagenorhynchus obliquidens*), common dolphin (*Delphinus* sp.), common bottlenose dolphin (*Tursiops truncatus*), Dall's porpoise (*Phocoenoides dalli*), harbor porpoise (*Phocoena phocoena*), and unidentified beaked whales (Ziphiidae) (e.g., Kasuya, 1975). Differentiation of whales hunted from those stranded, however, is often difficult.

II. Traditional Commercial Whaling

On the coasts of Noto and northern Kyushu, whales were hunted until the end of the 19th century by placing small trap nets at whale passages. Recorded takes of harpooned whales in a harbor at Ine, Sea of Japan, included 167 humpback, 148 fin, and 40 right whales in 1656–1913. A village next to Ine took small cetaceans in the same way. A similar fishery was also recorded in the 14th century at villages on Tsushima Island, off northern Kyushu. A cooking recipe in 1489 recommended whale meat for noble guests.

Records of "harpoon whaling" started in the 1570s at Morosaki at the entrance of Mikawa Bay, a bay attached to Ise Bay that opens to the Pacific (Fig. 1). The whalers first used light harpoons with a detachable head and line. Harpoons with fixed head and lancing followed. The winter operation continued to the early 1800s and took gray (*Eschrichtius robustus*) and humpback whales for oil and meat.

This was soon transmitted eastward to Katsuyama (35°05′N) at the entrance of Tokyo Bay for Baird's beaked whales (*Berardius bairdii*) and survived until the late 19th century. It was also transmitted westward to the nearby Ise and Kii areas (before 1606), Shikoku (1624), northern Kyushu (1630s), and Nagato (around 1672).

Harpoon whaling on the Ise and Kii coasts mostly ceased before 1770. A whaling group at Taiji, Kii, was an exception. They modified old harpoon whaling learned from Morosaki in 1606 into new "net whaling" in 1677. During the whaling season (winter and spring), harpoon boats waited offshore for a signal from the spotters on cliffs. With signals of flags and smoke indicating species, number, and position of whales, they drove the whales toward shore where net boats waited, which placed nets in front of the whales to entangle them. Then the procedures of harpoon whaling followed, i.e., harpooners threw harpoons (of fixed head) and then lances followed. When a whale became weak, a harpooner swam to the whale to tie ropes through holes made near the blowholes and the back of the body to prevent the carcass from sinking (Fig. 2). Boats on each side of the whale towed it, using these ropes and additional ropes that surrounded the body, to the beach for flensing. This method was again transmitted to Shikoku (1681) and northern Kyushu (1684) (Fig. 1). The preference was to harpoon calves first and then their mothers to secure both with ease.

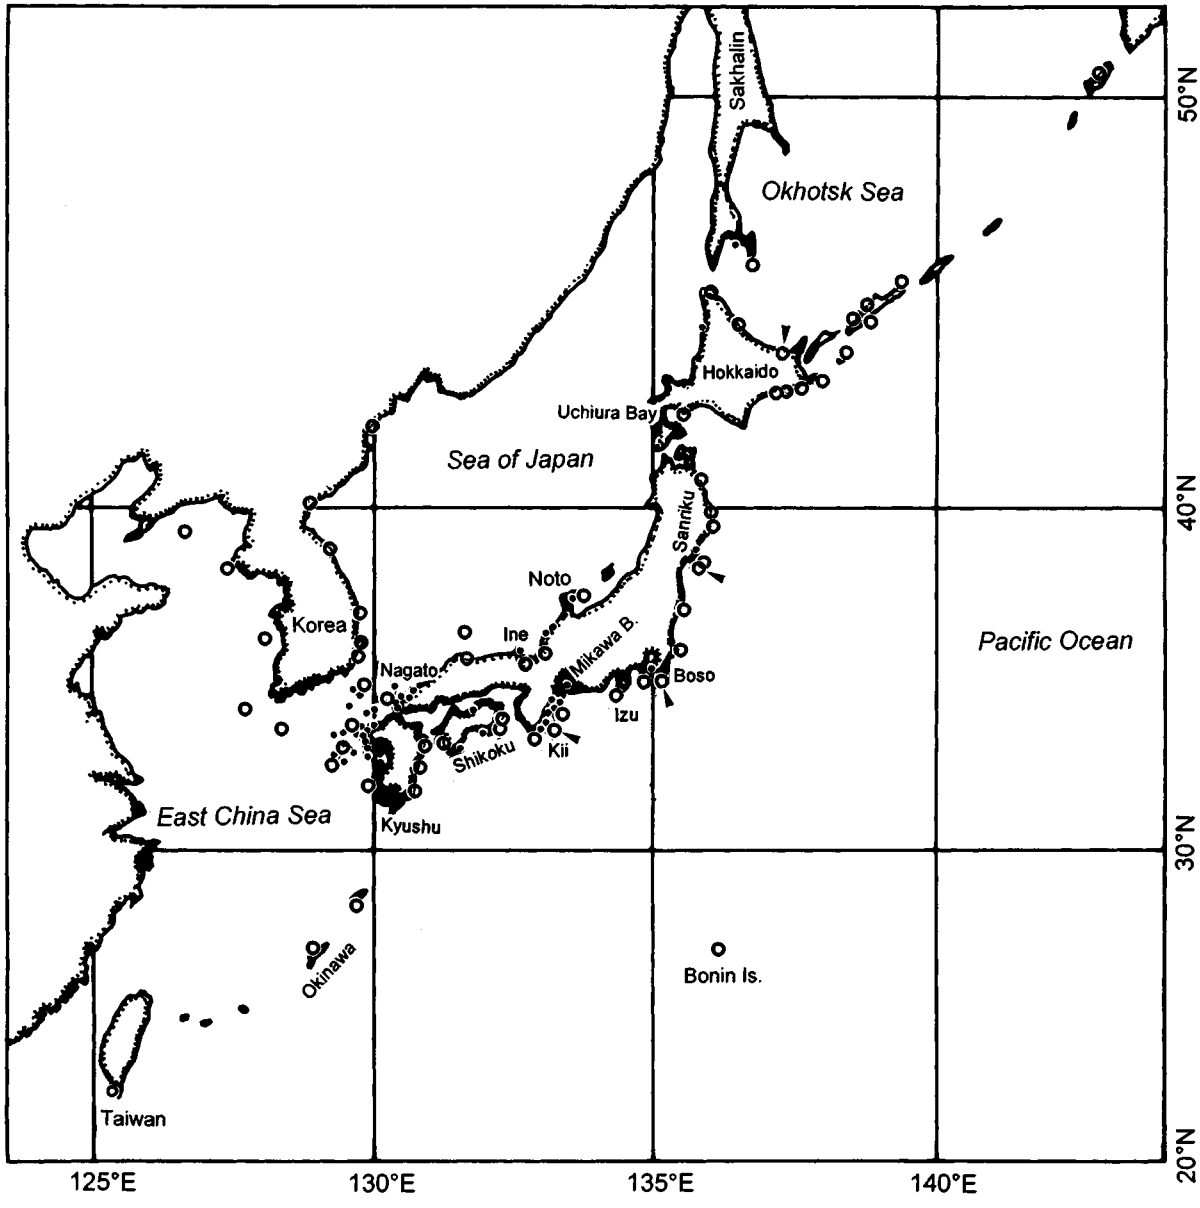

Figure 1 *Location of major land stations used by Japanese whaling. Closed circles represent harpoon or net whaling, open circles represent large-type whaling during pre- and postwar periods, and arrows indicate head land station currently in use by small-type whaling.*

Catches declined in the late 19th century, and some groups started modern Norwegian-type whaling, whereas others attempted to improve their traditional method. A few net whalers moved to new grounds in Hokkaido and southern Sakhalin and took gray whales.

Meat and most of the blubber were sold for human consumption fresh or salted. Oil was extracted from chopped bones and some BLUBBER and was used for light, for human consumption, and as a pesticide in rice paddies nationwide in Japan.

A Tsuro group in Shikoku in the late 1890s used 15 harpoon boats, 2 whale towers, and 14 net boats. The total full-time workers was 356, including 10 whale spotters, 12 flensers, 2 carpenters, 1 cooper, and 2 blacksmiths. Another group off northern Kyushu recorded 587 workers in the early 1800s. Each group took low tens of whales yearly (Table I). Annual expenditures of 12,423–15,864 yen made a profit of 987–25,640 yen (mean 9778) for a group at Kawajiri, Nagato, during 1884–1893.

III. Modern Coastal Whaling

A Russian, A. Dydymov, started modern Norwegian-type whaling in the western North Pacific in 1889 using a land station east of Vladivostok, Russia. In 1891, the Pacific Whaling Company was established at Vladivostok and operated from the

Figure 2 *A scene of net whaling (from Oyamada, 1832). A harpooner is climbing on a humpback whale to attach a line to the animal. Boats are ready to kill the animals with lances.*

Korean to Sakhalin coasts. Large amounts of whale meat sold by Russians at Nagasaki stimulated the Japanese to begin similar operations. After several attempts that caught the first whales in 1898 and survived only for a short period, Nihon Enyo Gyogyo (Japan Far Seas Fishery), founded in 1899 at Senzaki, Nagato, established modern whaling in Japan using Norwegian gunners. The company expanded the business and renamed themselves Toyo Gyogyo (Oriental Fishery) in 1904, absorbing other whaling companies. In 1908 a total of 12 modern whaling companies operated using 28 catcher boats. Toyo Gyogyo and five others merged in 1909 to form new Toyo Hogei (Oriental Whaling), which owned 20 land stations (3 in Korea) and 21 whale catcher boats. Six others remained independent. Data on whales taken by them are not available by species, but comparison with later records throws some light on the species and cetacean fauna during earlier whaling (Table II).

[b]Bryde's whales.
[c]Mostly Bryde's whales.
[d]Mostly sei whales.

In November 1909 the Japanese government placed hunting of sperm and baleen whales other than minke whales under its control and limited catcher boats to 30. This was further decreased to 25 (1934–1963) and to 7 (1977–) in several steps. On June 8, 1938, Japan enacted the protection of certain whales, i.e., cows accompanied by calves and whales below minimum size limits. However, it allowed the taking of right and gray whales, and the size limits, particularly for blue whales (*B. musculus*), were smaller than those existing in international agreements. In November 1945, Japan adopted international regulations of the time and joined the International Convention for the Regulation of Whaling of 1946 in April 1951 (before the peace treaty).

Postwar coastal whaling started in September 1945 and continued until March 1988 by five major companies using a maximum of 20 land stations (Fig. 2). This whaling was called large-type whaling to distinguish it from small-type whaling established in December 1947. The fishing season and land stations used changed over time. The last season of the fishery (1987/1988) used a land station at Bonin Islands for 317 Bryde's whales (*B. edeni*), and four stations at Yamada and Ayukawa (both in Sanriku), Wadaura (Boso), and Taiji (Kii) took 188 sperm whales.

Japan started a national sperm whale quota in 1959. The quota by North Pacific whaling counties (Canada, Japan, USA, USSR) replaced this starting in 1971. The four countries set quotas for fin (*B. physalus*), sei, and Bryde's whales in 1969; these were replaced by quotas of the International Whaling Commission (IWC) in 1972. The IWC prohibitions by species and dates of enforcement were blue (1965), humpback (1966), and fin and sei whales (1976).

Maximum annual catches by species since 1911 and their dates are 300 blue (1911); 1043 fin, 160 humpback, and 155 gray whales (1914); 14 right whales (1932); 1035 sei whales (1959); 504 Bryde's whales (1962); and 3747 sperm whales (1968). Whaling companies manipulated coastal statistics, particularly for sperm whales (Kasuya, 1999) and Bryde's whales.

IV. Pelagic Whaling in the Antarctic

A. Before World War II

In 1934, Nihon Hogei ("Japan Whaling," renamed from "Toyo Hogei" in 1934, which merged with Nihon Suisan in 1937) purchased the Norwegian factory ship *Antarctic* (9600 tons) and five catcher boats for £55,000 (¥900,000), which was three times the profit from one Japanese Antarctic fleet in

1937/1938. On the way to Japan the *Antarctic* and three catcher boats operated from December 1934 and took 213 whales. This was the first Japanese Antarctic operation. This company built a second fleet in 1936/1937 and a third one in 1937/1938.

Hayashikane Shoten, the antecedent of Taiyo Gyogyo (Ocean Fisheries), sent the *Nisshinmaru* fleet in the 1936/1937 season and had a second fleet in 1937/1938. Kyokuyo Hogei (Polar Sea Whaling) sent the *Kyokuyomaru* fleet in the 1938/1939 season. Thus the total Japanese Antarctic operation increased to six factory ships in 5 years.

The Japanese government enacted regulations of pelagic whaling on June 8, 1938, including (1) a fishing season from November 1 to March 15; (2) protection of gray whales and right whales (*Eubalaena* spp.), except for the North Pacific north of 20°N; (3) cows accompanied by calves; (4) minimum size limits; (5) processing within 36 hr; and (6) full utilization of the catch. This differed from international agreements of the time in a season about 6 weeks longer and the blue whale size limit about 1.4 m shorter, allowing taking blue whales that migrated earlier in the season. Implementation of international agreements in the industry had to wait new regulations in September 1946.

The main product of these operations was whale oil for export. The government strictly limited the importation of Antarctic whale meat until the 1939/1940 season to protect coastal whaling. Some of the whale oil of the last two seasons (1939/1940 and 1940/1941) was landed in northern Korea and was exported to Germany via Siberia.

B. Postwar Operations

In order to feed the starving Japanese population, the General Headquarters of the Allied Forces (GHQ) issued a permit for Antarctic whaling in August 1946. Taiyo Gyogyo converted an oil tanker into *Nisshinmaru No. 1* and Nihon Suisan another vessel to *Hashidatemaru*. These fleets caught 932 BWU, or 6% of the world catch of the 1946/1947 season, and produced 12,260 tons of whale oil and 22,167 tons of other edible products. The total was 36.9 tons/BWU, almost double the maximum prewar production of 19.0 ton/BWU. Whale meat became an important product of Japanese whaling. Kyoknyo Hogei sent the *Baikarumaru* fleet for sperm whales only in 1951/1952, before it returned to the Antarctic in 1956/1957.

While world Antarctic fleets recorded an increase from 9 (1946/1947) to 21 (1960/1961–1961/1962) and a subsequent decline, the decline of Japanese fleets was slightly slower, i.e., from a peak of 7 fleets in 1960/1961–1964/1965 to 1 in 1977/1978–1986/1987. In 1956, Japan purchased a foreign fleet to expand its operation. The objective of purchases changed in 1962, when Japan got a quota allocation of 41% and a further increase was permitted with fleet purchase. Out of 9 fleets purchased by Japan in the postwar period, 4 were for their quotas.

The total Japanese fleet and number of workers involved varied by quota and species hunted. The *Nisshinmaru No. 1* fleet in the 1950/1951 season, when it processed 631 blue and 1014 fin whales, had 348 persons on the factory ship, 604 on three freezing and salting vessels, and 197 on nine catcher boats. The total was 1149.

Takes of significant numbers of sei whales started in 1949/1950 and reached a maximum of 11,310 in 1965/1966, and that of minke whales (*B. acutorostrata* subsp. and *B. bonaerensis*) started in 1971/1972 and reached 3950 in 1976/1977.

Three Antarctic whaling companies split off their whaling sections to merge them into a new company, Nihon Kyodo Hogei (Japan Union Whaling), in 1976. The new company sent two fleets to the Antarctic in 1976/1977 and one in 1977/1978–1986/1987. The last two seasons were operated under objection to the IWC moratorium on commercial whaling.

Southern humpback whales were completely protected as of 1963/1964, "true" blue whales as of 1963/1964, all southern blue whales as of 1964/1965, fin whales as of 1976/1977, sei whales as of 1978/1979, and sperm whales as of 1981/1982.

V. Pelagic Whaling in the North Pacific

A. Before World War II

The *Tonanmaru* fleet was sent out in the 1940 and 1941 seasons by Hokuyo Hogei (Northern Sea Whaling), established jointly by three whaling companies, and caught 74 blue, 659 fin, 114 humpback, 9 sei, 333 sperm, 58 gray, and 4 North Pacific right whales in the two seasons off southern Kamchatka and in the Bering and Chukchi Seas.

B. Postwar, off the Bonin Islands (Ogasawara Islands)

Whaling had been operated in 1927–1944 using land stations on the Bonin Islands for humpback, Bryde's, and sperm whales, but the 1945 permit of the GHQ to whale off Bonin Islands prohibited the use of land stations. Therefore, Taiyo Gyogyo converted a navy vessel to a factory ship and whaled in March–April 1946. The number of fleets and companies involved subsequently varied by season; the last fleet was sent out in 1951. In 1952, pelagic whaling started in the northern North Pacific, and operations off the Bonin Islands ceased.

In the six seasons they took 923 Bryde's, 606 sperm, and 29 other whales. Only 20 humpback whales were taken because of offshore operations.

Subsequent whaling by Nitto Hogei, Nihon Hogei, and Sanyo Hogei was operated for Bryde's whales from a land station on Hahajima Island, Bonin Islands, in 1981–1987.

C. Northern North Pacific

The Peace Treaty came into effect in April 1952, and Japan sent out the *Baikarumaru* fleet to the North Pacific. The fleets increased to two in 1954 and three in 1962, and then decreased to the fleet of Kyodo Hogei (1976–1979). The operation was a joint venture of most of the Japanese whaling companies; Kyokuyo Hogei, Nihon Suisan, and Taiyo Gyogyo were the major ones. Factory ships and quotas changed frequently. The IWC ban on pelagic whaling for species other than minke whales came into effect in the 1979/1980 Antarctic and 1980 northern summer season.

The *Miwamaru*, a whale catcher–factory ship, operated in the 1973–1975 seasons for 279 minke and 6 Baird's beaked whales.

The first national quota of 350 BWU was for a 1-year test operation by one of the two fleets in 1954. This was followed

by a blue whale quota of 70 (1955–1961) or 60 (1962–1965) and quotas of about 800 BWU (1957–1964) and 1001 BWU (1965–1968) for species other than blue whales. Sperm whale quotas were from 1500 to 1800 (1957–1961), 2460 to 2700 (1962–1965), and 3000 (1965–1968).

The North Pacific whaling countries set quotas by species in 1969, which were followed by quotas of the IWC (as of 1971 for baleen whales and 1972 for all large whales). The IWC has protected blue and humpback whales since 1966 and fin and sei whales since 1976.

VI. Whaling under Foreign Jurisdiction

Since 1957, Japanese whaling has expanded into foreign territories, presumably for new whale stocks, efficient vessel allocation, unregulated operation, or for new business opportunities.

A. Taiwan, 1957–1959

Taiwan was outside the ICRW. Kyokuyo Hogei whaled for two seasons jointly with a local company using a land station in southern Taiwan but took only 29 humpbacks and a sperm whale. The Taiwanese partner operated for a few additional years.

B. Okinawa, 1958–1965

Under supervision of the U.S. military, the Ryukyu government governed the Ryukyu Islands from the end of World War II to 1972 when the islands were returned to Japan. Hand harpoon fishermen at Okinawa Island, the Ryukyu Islands, took humpback whales using harpoon guns beginning around 1950. In 1958 the Ryukyu government introduced IWC regulations. Only Nago whalers and two local companies got the new licenses. Two Japanese whaling companies, Taiyo Gyogyo and Nitto Hogei, offered crew and catcher boats to them. The land stations were at Nago, Sashiki, and Itoman.

In addition to catches of 52 humpback whales by the Nago group (1950–1957), the three groups took 788 humpback, 31 sperm, and 1 Bryde's whale in 1958–1965.

C. Brazil, 1959–1984

Two groups whaled off Brazil, each inviting a Brazilian partner. The Taiyo group whaled in 1960–1963 from a land station at Cabo Frio, and the Nichirei group in 1959–1984 from Costina. Catches were mostly sei whales in 1959–1964 (3214 whales in the six seasons) and then shifted to minke whales with a maximum recorded catch of 1036 in 1975. Sperm, fin, and blue whales were also taken (in decreasing order). Some of the supposed sei whales were Bryde's whales.

D. Canada, 1962–1972

Japanese whalers operated jointly with Canadian partners off Newfoundland and Vancouver Island. The Taiyo group operated in 1962–1967 using a land station at Coal Harbor, Vancouver Island, and caught mostly sei (2153), sperm (1108), and fin (837) whales, but some blue and humpback whales were also taken.

Off Newfoundland, the Kyokuyo group operated in 1966–1972 using a land station at Dilldo, and the Taiyo group in 1967–1972 using a Williams Port station. Their catch was mostly fin whales (1168) and a few humpback, sei, and sperm whales. The Canadian government closed commercial whaling in 1973.

E. South Georgia, 1963/1964–1965/1966

Two Japanese expeditions operated using South Georgian land stations leased from the United Kingdom. Their total catches were 1273 fin, 919 sei, and 218 sperm whales. Under international pressure, the United Kingdom agreed at the 1966 IWC conference to voluntarily retain the South Georgian catches at or below the level of the 1964/1965 seasons. This terminated Japanese expeditions.

F. Chile, 1964–1968

Chile, Peru, and Ecuador jointly regulated whaling in their territorial waters until 1979, when Chile and Peru joined the ICRW.

Nitto Whaling and its local partner whaled using one or two land stations and took 516 blue, 582 fin, 1061 sei, and 1221 sperm whales. The catch of blue whales occurred only in 1965 and 1966. Some of the supposed sei whales were probably Bryde's whales.

G. Peru, 1967–1985

A local company sponsored by Nihon Kinkai Hogei (Japan Coastal Whaling) whaled using a station at Paita. The operation ended in March 1985. The fishing season lasted almost 12 months of the year, with occasional interruption of 1 or 2 months in winter. The total catch was 291 fin (1968–1977), 3408 Bryde's (1973–1983), 232 sei (1973–1978), 2304 Bryde's or sei (1968–1972), and 14,331 sperm whales (1968–1981) (Valdivia *et al.*, 1984).

H. Philippines, 1983–1984

A local company whaled for two seasons using the *Faith No. 1*, the renamed *Miwamaru* catcher–factory ship of Japan. One of the Japanese sponsors had taken part in an earlier *Miwamaru* operation in Japan. A take of 9 Bryde's whales in 1983 and 47 Bryde's whales was reported with production of 277 tons of meat in 1984. The operation ended due to Japanese rejection of meat import and new regulation for her nationals concerning participation in foreign whaling. The local company operated in 1985 and took 40 Bryde's whales.

VII. Small-Type Whaling

This is defined as a whaling activity that takes minke whales and toothed whales other than sperm whales using a vessel and whaling cannon below a certain size limit. This fishery started around the start of the 20th century, e.g., the Baird's beaked whale fishery off the Boso coast introduced Greener's harpoon guns in 1892 and Taiji fishermen 20-mm five-barrel harpoon guns for pilot whales in 1904. The fishery was placed under control of the Minister of Agriculture and Forestry in December 1947. Before this the operation was unregulated except for the Boso coast where the Baird's beaked whale fishery required a license from Chiba Prefecture.

About 20 vessels operated the fishery off northern Kyushu, Kii, Boso, and Sanriku before World War II. The number increased to 53 in 1942 and 80 in 1950 and then it declined rapidly to 9 in 1970, 4 in 1988, and 5 since 1992. Conversion

from several small vessels to one larger vessel contributed to the earlier decline. During the war the vessel size was 5–20 tons. The size limit was 30 tons in 1947, 40 tons in 1963, and is now 50 tons. The maximum caliber of harpoon gun changed from 40 mm (1947) to 50 mm (1952–present) (Fig. 3). Other regulations included the prohibition of killing cows accompanied by calves and a fishing season of 6 months. The vessels usually leave port in the morning and return in the evening.

This fishery had no quota until 1977 and took minke, Baird's beaked, pilot, and killer whales (*Orcinus orca*). Dolphins and porpoises were also taken. IWC set a quota for minke whales for the seasons 1978–1987. The government of Japan set a national quota for Baird's beaked whales at 40 (1983–1987), 60 (1988), 54 (1989–1998), and 62 (1999–present).

The Japanese government maintains that target species of this fishery other than minke whale are outside the IWC competence, thus the decision of IWC to cease commercial whaling does not prohibit take of these species. Currently five catcher boats operate using four land stations: Abashiri on the Okhotsk Sea coast of Hokkaido, Ayukawa on the Sanriku coast, Wadaura on the Boso coast, and Taiji on the Kii coast. Their quota is 62 Baird's beaked whales, 100 short-finned pilot whales (*Globicephala macrorhynchus*) (50 for each of the two populations), and 30 Risso's dolphins (*Grampus griseus*).

VIII. Dolphin and Porpoise Fisheries

In Japan, dolphins and porpoises are taken by drives, hand harpoon, and small-type whaling.

At least 52 villages have operated dolphin drive fisheries since the 14th century on the Sea of Japan and Pacific coasts, but the number declined throughout the 19th and 20th centuries. When it was placed under the license system of the prefecture governments in 1982, only four groups acquired license. Currently, two groups, at Futo on the Izu coasts and Taiji on the Kii coasts, operate drive fisheries with quotas of about 3000 dolphins of six species.

The fishermen drive schools of gregarious dolphins into harbor using several fast boats. Other equipment used is a cone-shaped steel disk welded to one end of a 2-m-long steel pipe. The cone is placed underwater and the other end of the pipe in the air is hammered to scare dolphins acoustically.

Harpoon fisheries started in prehistoric time (see earlier discussion), but large-scale commercial hunts began possibly in 1920s when motor-driven vessels became common in coastal fisheries. Dolphins and porpoises are harpooned when they come to bow ride. An electric shocker is usually connected to the hand harpoon with a detachable head.

This fishery came under the control of regional fishery coordination committees in 1989. Currently, about 400 vessels of Hokkaido, Sanriku, Boso, Kii, and Okinawa operate with a quota of about 18,000 dolphins and porpoises. Okinawa hunters use crossbows; their efficiency is superior to hand harpoons for pilot whale hunts. The fishing season is variable among locations.

Quotas for drive and harpoon fisheries are 400 short-finned pilot whales of southern form, 50 false killer whales, 1280 Risso's dolphins, 1100 bottlenose dolphins, 950 pantropical spotted dolphins (*Stenella attenuata*), 725 striped dolphins (*Stenella coeruleoalba*), and 17,700 Dall's porpoises (two populations).

IX. Research Whaling

During 1956–1979, Japan issued several permits to take whales for research purpose based on Article 8 of the ICWR. The hunt accompanied the operation of ordinary commercial whaling. It killed a relatively small number of whales or lasted for only a few seasons. These features are different from the research whaling of the later period.

The ban on commercial whaling by the IWC came in effect in the 1985/1986 Antarctic season and 1986 coastal season. Japan withdrew its objection to this IWC decision on July 1, 1986, taking effect from May 1, 1987 (pelagic), October 1, 1987 (coastal minke and Bryde's whales), and April 1, 1988 (coastal sperm whales). In November 1987, Nihon Kyodo Hogei

Figure 3 *A small-type whaling vessel in search of pilot whales off the Sanriku coast, October 1985.*

dissolved. Half of the staff formed Nihon Kyodo Senpaku (Japan Union Shipping) to operate vessels acquired from Nihon Kyodo Hogei, and some others and Geirui Kenkyusho (Whales Research Institute) merged to establish Nihon Geirui Kenkyusho [(Japan) Institute of Cetacean Research (ICR)].

ICR started to take whales for scientific purposes in the 1987/1988 Antarctic season and 1994 North Pacific season. In the 1998 and 1999 seasons it took about 400 Southern Hemisphere and 100 North Pacific minke whales using a factory ship and catcher boats chartered from Nihon Kyodo Senpaku. Proceeds of products from these operations, about 4 billion yen/year (US$=100–110 yen), and subsistence and contract of about 1 billion yen from the Japanese government are used to finance activities of the institute. ICR expanded the project to Bryde's and sperm whales in the North Pacific in 2000.

Kentriodontidae

SUSAN D. DAWSON
University of Prince Edward Island, Charlottetown, Canada

Kentriodontidae is the most diverse family of archaic delphinoids in terms of morphology, geographic range, and temporal range. Unfortunately, while they are the best-studied archaic delphinoids, there are still many unanswered questions about this group, including the very basic question of whether kentriodontids are monophyletic (Muizon, 1988). The grade-level family Kentriodontidae has essentially been defined based on its members holding an intermediate position between primitive odontocetes and modern delphinoids. Additionally, no computer-aided cladistic analysis has described the relationships of taxa attributed to the Kentriodontidae.

I. History

Kentriodontids have a long history in the science of paleontology. The specimen now known as *Lophocetus calvertensis* was first described by Harlan in 1842 as *Delphinus calvertensis* (this is an early example of a fossil odontocete being taxonomically lumped with a modern genus). The family takes its name from *Kentriodon pernix*, described by Kellogg in 1927. Slijper named the subfamily Kentriodontinae in 1936 and considered it to be within the family Delphinidae. Barnes (1978) articulated the modern concept and classification of the family Kentriodontidae as distinct from but related to modern delphinoids. Subsequent studies (Muizon, 1988; Dawson, 1996) have been based on that classification.

II. Morphology

Archaic delphinoids resemble modern delphinoid species in general body morphology. Hindlimbs are absent, forelimbs are modified to form paddle-like flippers, and the rostrum is elongated to form a pronounced snout or beak in most species. Differences between archaic and modern delphinoids are apparent in features such as SKULL proportions and morphology, development of basicranial sinuses, tooth number and morphology, and vertebral number and proportions. Each of these features has primitive and derived character states, which are distributed among archaic and modern delphinoids.

Among modern delphinoids, there is a range of variation of flipper shapes, from the narrow flippers of the common dolphins (*Delphinus* spp.), to the wider flippers of the beluga whale (*Delphinapterus leucas*), to the wide ovoid flippers of the killer whale (*Orcinus orca*). Forelimb bones are known from only a few species of archaic delphinoids, making prediction of fossil flipper morphology tenuous. The humerus, radius, and ulna are known from *Hadrodelphis*, and the articular surfaces of these bones suggest that the flipper was wide, although without the bones of the manus it is impossible to predict the exact width.

Morphology of the cervical vertebrae is known from a few species (such as *Hadrodelphis calvertense*) and indicates that the cervical vertebrae of archaic delphinoids are less compressed along the cranio-caudal axis than the cervical vertebrae of modern delphinids and phocoenids. In these modern species, the cervical vertebral bodies are extremely thin and may be fused together, making the neck relatively rigid and very short. The increased length of the cervical vertebral bodies in archaic forms suggests that the neck was more elongate and mobile in these species, perhaps comparable to modern beluga whales. Different kentriodontid taxa also exhibit a range of vertebral centrum proportions in other regions of the vertebral column. While no species has lumbar vertebral centra elongated to the extreme extent found in some archaeocetes, some species such as *Kentriodon pernix* do have more elongated vertebral bodies than species of *Atocetus*. Differences in vertebral centrum proportions may have functional significance, a concept which has been explored by Buchholtz (1998). Individuals with relatively long vertebral centra may have had more flexible vertebral columns and may have been slower, more maneuverable swimmers, such as the modern beluga whale. Individuals with shorter, more compressed vertebral centra may have more rigid vertebral columns and may be faster swimmers, such as the modern Dall's porpoise.

Kentriodontids have been traditionally divided into three groups (Table I). Kentriodontines include the genera *Kentriodon*, *Delphinodon*, and *Macrokentriodon*. These genera have a cranial vertex morphology which is relatively flat and tabular. There is broad exposure of the nasal and frontal bones at the

 Family Monodontidae Gray, 1821 [Late Miocene–Recent; eastern North Pacific (Late Miocene–Pliocene), circumpolar Arctic]
 Family Delphinidae Gray, 1821 (Late Miocene–Recent; all oceans)
 Family Phocoenidae (Gray, 1825) (Late Miocene–Recent; all oceans)

[a]Kentriodontid genera of uncertain affinity are not included in this classification.

vertex, but the nasal bones are not enlarged or inflated, nor is the vertex significantly elevated. Lophocetines include the genera *Lophocetus, Liolithax,* and *Hadrodelphis* and have nasal bones that are more elongate and the cranial vertex slightly to significantly elevated. Pithanodelphines (including the genera *Pithanodelphis* and *Atocetus*) have large, inflated nasal bones. With the exception of some pithanodelphines, kentriodontids demonstrate the primitive condition of cranial symmetry; this feature is in contrast to modern delphinids, in which the cranial vertex is markedly asymmetrical and the left premaxilla does not contact the left nasal bone.

While primitive odontocetes retained heterodont teeth, archaic delphinoids (as well as other Oligocene–Miocene odontocetes such as eurhinodelphids) mark the transition to the polydont, homodont dentition found in modern delphinids (Fig. 1). There is variation in the number of TEETH in different species, but all kentriodontids have a tooth count that is increased beyond the generalized mammalian condition. Kentriodontids do not have the large, triangular, double-rooted cheek teeth of the Squalodontidae. Instead, all teeth are conical in shape and have a single root. Modern phocoenids also have a homodont dentition with single-rooted teeth, but the crowns of these teeth are spatulate rather than conical (Fig. 1A). There is no evidence of this tooth morphology in any kentriodontid, nor is it present in the earliest phocoenids. *Kentriodon* demonstrates an unusual morphology, with the most anterior premaxillary teeth elongate and procumbent, oriented in a horizontal rather than vertical plane (Fig. 1C). Some kentriodontid taxa, such as *Hadrodelphis* and *Kampholophos,* exhibit variation within the tooth row, such that more posterior teeth have a shelf-like projection on the lingual surface and a series of small cuspules (Fig. 1D). Anterior teeth are smooth and conical. This slightly heterodont condition is also found in modern Iniidae, the boto of the Amazon River (*Inia geoffrensis*), and is part of the evidence that led paleontologists to hypothesize relationships between archaic delphinoids and river dolphins. Further investigations of odontocete relationships, however, have focused on more diagnostic cranial characters than dentition and confirmed the relationship of kentriodontids with modern delphinoids.

Modern and archaic delphinoids exhibit wide variation in rostrum length (Fig. 1). Species such as the long-beaked *Hadrodelphis* have a rostrum that is approximately two-thirds the total length of the skull (Fig. 1D). Short-beaked species such as *Delphinodon dividum* have a rostrum that is only one-half the total skull length. Although there is also a range of variation between genera, monodontids and phocoenids tend to have shorter rostra than delphinids (Fig. 1B), and all three modern families tend to have shorter rostra than long-beaked kentriodontids. The short rostra of phocoenids (Fig. 1A) may be associated with paedomorphic modifications postulated for this group (Fordyce and Barnes, 1994). Longer rostra are found in the river dolphins, including platanistids, pontoporiids, lipotids, and iniids. No living odontocete possesses a rostrum as long as that of the bizarrely long-beaked eurhinodelphids, which had a rostrum four-fifths (or more) the total length of the skull.

III. Taxonomic, Temporal, and Geographic Diversity

The fossil record of modern delphinids, phocoenids, and monodontids extends to at least the Late Miocene (Table I). As a family, the modern Delphinidae are cosmopolitan in distribution, with individual genera having a more restricted range. The earliest fossil delphinids are reported from eastern North Pacific deposits of the Late Miocene. Barnes (1990) summarized the evolutionary history of the bottlenose dolphin, *Tursiops truncatus*. The genus is known from at least the early Pliocene, and possibly from the latest Miocene. Fossil species of *Tursiops* are widely distributed, having been reported from Atlantic, Pacific, and Mediterranean deposits.

Modern phocoenids are widely distributed in the Atlantic, Pacific, and Indian Oceans, but are not found in all regions of those oceans. The earliest Phocoenidae are known from the Late Miocene. Early phocoenid fossils are reported from the western coasts of North and South America, and this group may have originated in the Pacific basin.

Extant monodontids are restricted in DISTRIBUTION and diversity when compared to fossil members of this family. There

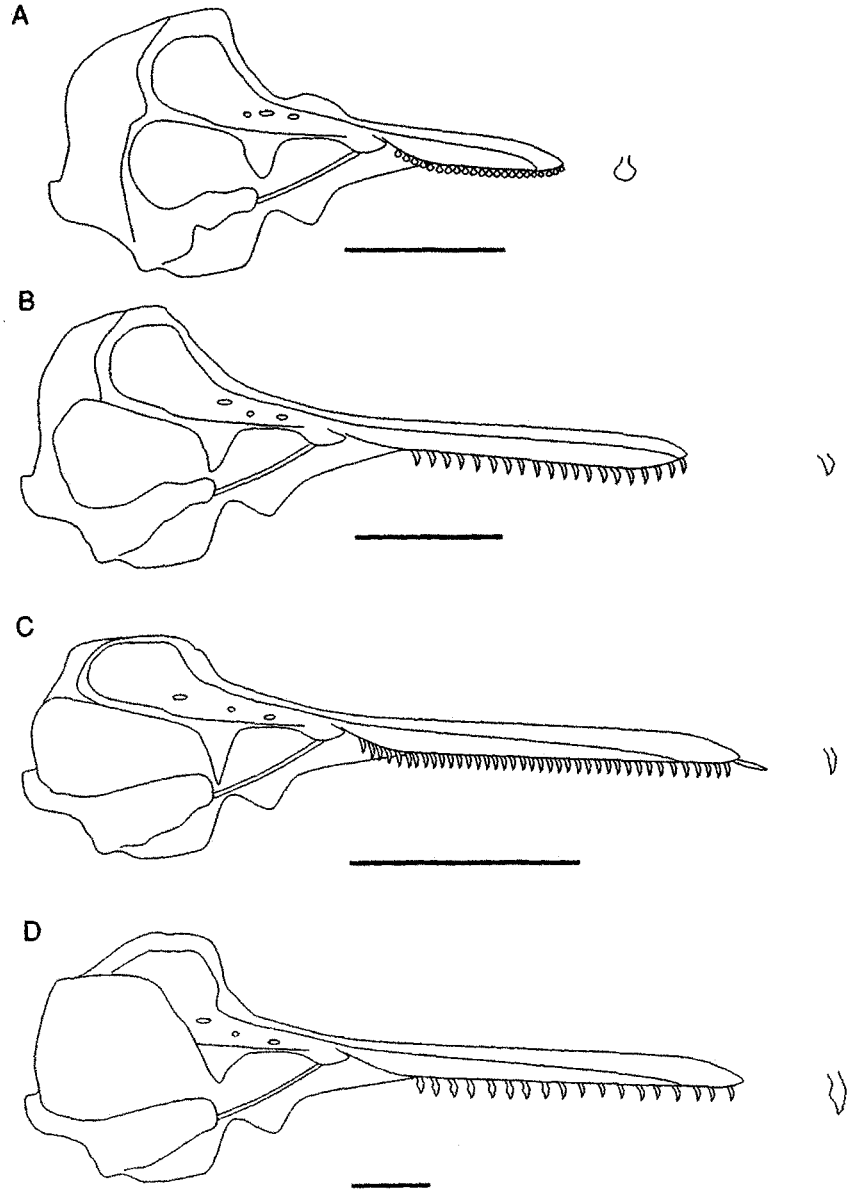

Figure 1 *Skull and tooth morphology of modern and fossil delphinoids. Scale bar: 10 cm. (A) Family Phocoenidae,* Phocoena phocoena; *(B) Family Delphinidae,* Tursiops truncatus; *(C) Family Kentriodontidae,* Kentriodon pernix *(fossil, reconstructed); and (D) Family Kentriodontidae,* Hadrodelphis calvertense *(fossil, reconstructed).*

are two living monodontids, the beluga (*Delphinapterus leucas*) and the narwhal (*Monodon monoceros*), both of which are found only in circumpolar waters of the Arctic. The earliest fossil monodontids are reported from the Late Miocene. Fossil monodontids showed greater taxonomic diversity and had a much different geographic distribution; they are reported from the Late Miocene and Pliocene of California and Baja Mexico.

The family Kentriodontidae is often described as cosmopolitan in geographic distribution, with a temporal range from the Late Oligocene to Late Miocene. However, because the group may not be monophyletic, the distribution of "Kentriodontidae" may be a spurious and irrelevant question. It is perhaps more meaningful to first examine the distribution of individual taxa and the taxonomic distribution of species within genera.

A. Interpreting the Fossil Record of Kentriodontids

All studies of fossil organisms are necessarily limited by the quality of available specimens. This problem is particularly acute with kentriodontids, as there is a lack of described specimens as well as a lack of specimens represented by diagnostic,

comparable material. While it is preferable for holotype specimens to consist of a skull and associated periotic, several kentriodontid taxa have been named based on isolated periotics or teeth. Analyzing the distribution of individual species of kentriodontids is particularly problematic due to the paucity of specimens. Most taxa are known only from the holotype material, making it difficult to account for individual variation; e.g., eight genera of kentriodontids are reported from North America, but only two of these genera are known from more than one skull (Dawson, 1996). There is little evidence of an individual species being known from more than one ocean basin or region. The sole published example of one species described from more than one basin or region are two specimens referred to as "aff. *Delphinodon dividum*" from the Middle Miocene of California and Japan; both of these specimens consist of isolated periotics, making this designation problematic.

B. Diversity of Kentriodontid Species

The distribution of genera both geographically and temporally is slightly less problematic. There are 16 genera included in the family; of these only 5 genera have more than one published species. The proper generic assignment of at least two of these species is questionable. There are two species formally assigned to the genus *Hadrodelphis: H. calvertense* and *H. poseidoni. Hadrodelphis poseidoni*, however, is questionable because it is based only on isolated teeth. The genus *Lophocetus* has also undergone considerable revision. There are currently two species formally assigned to the genus *Lophocetus*. Both species, *L. calvertensis* and *L. repenningi*, are represented by a skull with periotics. However, Muizon has questioned the generic assignment of *L. repenningi*, suggesting that it does not belong in that genus. Kellogg originally assigned *Liolithax pappus* to the genus *Lophocetus*, but Barnes' 1978 revision of the kentriodontids placed it in its currently accepted genus. The type species of the genus *Liolithax* is *L. kernensis* Kellogg 1931, which is described on the basis of isolated periotics. No cranial or postcranial material has been formally referred to *L. kernensis*.

The two species of the genus *Atocetus* offer a well-founded example of temporal and spatial diversity of a kentriodontid genus. *A. nasalis* is reported from the eastern North Pacific basin, whereas *A. iquensis* is reported from the eastern South Pacific. Both species are described from several diagnostic specimens.

The genus *Kentriodon* is the most diverse of the kentriodontids, with three named species and at least five undescribed species mentioned in the literature. It is the oldest described kentriodontid genus, reported from the Late Oligocene to the Middle Miocene; it is not reported from the Late Miocene (Ichishima *et al.*, 1994). *Kentriodon* also has the widest geographic range, reported from the eastern and western North Pacific, eastern and western South Pacific, western North Atlantic, and western South Atlantic. It has not been reported from the eastern North Atlantic, although most kentriodontids reported from this region are Late Miocene in age.

Kidney, Structure and Function

CAROL A. BEUCHAT
University of Arizona, Tucson

The marine environment presents mammals with unique physiological challenges. Most obviously, the ocean's high salt content and the inavailability of sources of fresh drinking water make it highly desiccating. The kidney is the sole osmoregulatory organ in mammals, so it must excrete excess minerals in urine while at the same time conserving water to prevent dehydration. Moreover, it must maintain osmotic homeostasis of the body fluids even while diving, when depressed cardiovascular function may compromise many physiological processes. To meet the special needs of mammals living in the sea, the kidneys differ in some significant and interesting ways from those of most terrestrial species.

I. General Structure of the Mammalian Kidney

In all mammals, the fundamental functional units are the millions of nephrons that transform plasma filtered from the blood into urine, which contains metabolic toxins and excess minerals that are then excreted from the body. Macroscopically, the kidney is organized into an outer tissue layer, the cortex, that surrounds an inner region, the medulla. In the simplest kidneys, such as those of rodents, the medulla forms a single cone-shaped papilla (unipapillary kidney). In other species, the kidney can

have multiple papillae, forming a "multipapillary" kidney. This type of kidney is also referred to as "multireniculate," with the reniculi corresponding to the medullary papillae and their associated cortical tissue (Sperber, 1944).

Multireniculate kidneys can be of two types (Oliver, 1968). In a "compound" multireniculate kidney, the cortex is continuous and encloses all of the papillae. The urine produced by each of the papillae is drained through the collecting ducts (the terminal segment of the nephron) into a funnel-like structure, the pelvis, that surrounds all of the papillae. This type of kidney is found in only a few species of mammals, including humans and beavers.

The "discrete" multireniculate kidney is actually a single organ composed of many miniature kidneys, the reniculi, enclosed in a sheet of connective tissue and peritoneum (the renal capsule) to form a contiguous renal mass (Fig. 1). Each of the reniculi typically resembles a simple unipapillary (or bipapillary) kidney, with its own blood supply and renal pelvis (Figs. 2 and 3). The microcirculatory organization and arrangement of the nephrons in each reniculus are essentially the same as those in a simple unipapillary kidney. Urine produced by each of the reniculi drains from the pelvis into ureteral tubules that connect to the main ureter, which carries the urine to the bladder. The reniculi can number in the hundreds or even thousands in each of the paired kidneys. Discrete multireniculate kidneys are found in almost all marine mammals, including cetaceans, pinnipeds, otters, and polar bears (*Ursus maritimus*), but in only a few nonmarine species.

II. Structure of the Kidneys of Marine Mammals

A. Cetaceans and Pinnipeds

The division of the multireniculate kidney into discrete, independent units is developed to the greatest degree in cetaceans and pinnipeds, which are considered here together because of their general similarities in renal morphology. There is no published information about the renal structure of the walrus (*Odobenus rosmarus*), although the regular harvesting of this animal historically and even in the present would seem to provide abundant opportunity for study.

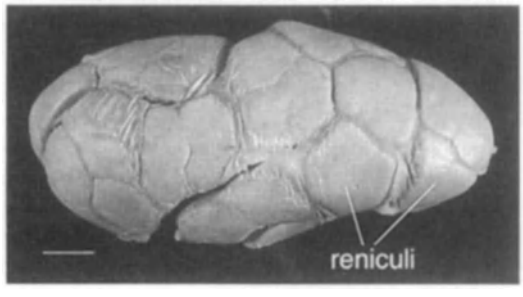

Figure 1 *The discrete multireniculate kidney of the Cape clawless otter* (Aonyx capensis) *with its covering of perirenal fascia. The outlines of the reniculi are evident on the surface of the kidney. Scale bar: 10 mm. Modified from Beuchat (1999).*

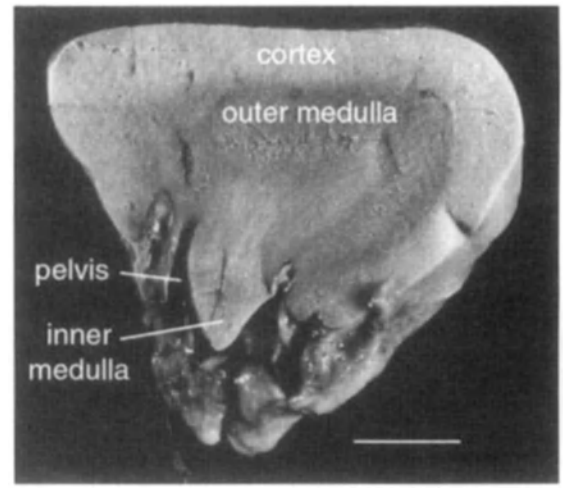

Figure 2 *A unipapillary reniculus from the kidney of the Cape clawless otter. Like the typical mammalian kidney, there is an outer covering of cortical tissue, and the medulla is divided into outer and inner regions. The inner medulla forms a conical papilla that contains the longest loops of Henle. Urine drains from the nephrons into the pelvis, and from there to the bladder via the ureter. Scale bar: 2.5 mm. Modified from Beuchat (1999).*

In cetaceans and pinnipeds, the renicular lobulation of the kidney is clearly evident as grooves on its surface. In some species, the reniculi are rather loosely packed within the renal capsule and are separated by considerable connective tissue (perirenal fascia), whereas in others the packing is tight and the reniculi are more hexagonal than round, minimizing the space between them. Especially in cetaceans, they can be arranged in grape-like clusters on branches of the ureter (Abdelbaki *et al.*, 1984).

Although most reniculi in cetaceans and pinnipeds are usually unipapillary, reniculi with two or three medullary pyramids are not uncommon, and reniculi with as many as seven pyramids have been noted in the North Atlantic right whale,

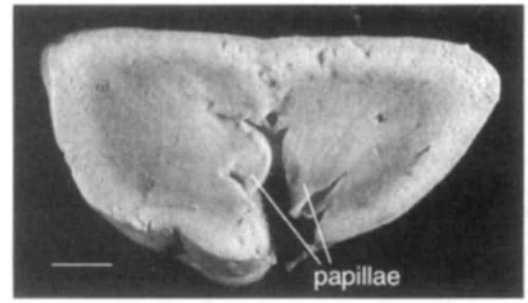

Figure 3 *A bipapillary reniculus from the kidney of the Cape clawless otter. The cortex is continuous, surrounding both medullae. The two medullary papillae are functionally separate, but the urine drains into a common pelvis. Scale bar: 3 mm. Modified from Beuchat (1999).*

Eubalaena glacialis (Maluf, 1989). In these multipapillary reniculi, which themselves resemble a compound multireniculate kidney, the medullary tissue forming each papilla appears to be functionally discrete, whereas the cortex can either have divisions corresponding to each papilla or can be continuous, forming a capsule that encloses all the papillae within the reniculus.

In the typical bean-shaped, unipapillary kidney of terrestrial mammals, the renal artery enters the kidney, and the renal vein and ureter exit, from the hilus, which is located at an indentation on the concave medial surface of the kidney. In cetaceans and pinnipeds, the comparable vessels (i.e., renicular artery and vein) are similarly arranged in the individual reniculus. In some pinnipeds, the entire multireniculate kidney is likewise bean shaped, with a hilus-like medial indentation where the renal artery enters and the renal vein and ureter exit. In other pinnipeds and most of the cetaceans, the renal mass is elongate, and the renal artery and vein enter toward the anterior end and the ureter exits more caudally.

A unique feature of the kidneys of cetaceans and pinnipeds is the presence of a conspicuous sporta perimedullaris, a fibromuscular sheet that separates the cortex and the medulla. First described in cetaceans, it was for a time thought to be unique to this group. Subsequently, however, it has been found to be well developed in both cetaceans and pinnipeds. Because it is present but poorly developed and inconspicuous in nonmarine mammals, it appears to be a feature of the kidney that is related to a marine existence.

The sporta perimedullaris lies at the corticomedullary junction and has perforations that allow penetration of tubular and vascular elements from the cortex into the medulla. In longitudinal cross section of the reniculus, the sporta perimedullaris usually appears as short ribbons of connective tissue and smooth muscle fibers. The function of the sporta perimedullaris remains unknown, but the presence of smooth muscle fibers suggests that, like the renal pelvis, it may be spontaneously contractile, perhaps assisting in expulsion of the urine from the kidney.

B. Otters

There are published accounts of renal structure for three species of otters (Sperber, 1944; Beuchat, 1996, 1999): the sea otter (*Enhydra lutris*), which is exclusively marine; the river otter (*Lutra lutra*), which occurs only in fresh water; and Africa's Cape clawless otter (*Aonyx capensis*), which like the manatee inhabits both freshwater and marine environments. Despite their very different osmoregulatory requirements, all three species have discrete multireniculate kidneys that most resemble those of pinnipeds. Lobulation of the kidney is readily apparent externally, and both unipapillary and bipapillary reniculi have been noted in the Cape clawless otter (Figs. 1–3).

C. Polar Bears

Nothing is known about the renal anatomy of the polar bear, the only ursid that can be considered truly at home in the sea. However, discrete multireniculate kidneys have been described in all other bear species examined (i.e., grizzley, *U. arctos;* sun bear, *U. malayanus;* and sloth bear, *Melursus ursinus;* Sperber, 1944). Studies of kidney function in polar bears are lacking.

D. Sirenians

The most exclusively marine of the recent sirenians is the extinct Steller's sea cow (*Hydrodamalis gigas*). The only descriptions of its kidney are from publications by Steller from the 1750s in which he notes that the kidney resembled "those of seal and sea otter," with numerous reniculi (Sperber, 1944; Maluf, 1989). From this the kidney would seem to be of the discrete multireniculate type. There were no studies of renal function in Steller's sea cow before its extinction.

The dugong (*Dugong dugon*) is also highly marine. Its kidney, however, is unlike that of any other marine mammals, bearing a greater resemblance to the crest-type kidney of the dog. It is elongated but lacks superficial grooves and internal division into reniculi. There is a continuous cortex and medial hilus. The medulla is divided into cranial and caudal regions, each forming a long crest with girdle-like dorsal and ventral extensions that are suggestive of transverse lobulation.

Manatees are found in a range of salinities from seawater to freshwater. The Amazonian manatee (*Trichechus inunguis*) is restricted to freshwater. The West Indian manatee (*Trichechus manatus*) and the West African manatee (*T. senegalensis*) are the only mammals besides the Cape clawless otter that naturally occur in both freshwater and marine environments. Sperber (1944) described the kidneys of *T. manatus* and *T. senegalensis* as appearing "to represent a transitional stage between kidneys with undivided cortex and divided medulla, and the renculi kidneys." In these species, the kidney seems to most closely resemble a compound multireniculate design, with 6–11 medullary papillae. Although a continuous cortex surrounds all of the medullae, there are folds of cortex (plicae corticales) and septa that separate adjacent medullary regions, producing the external appearance of lobulation in the adult (Maluf, 1989). The papillae are not conical, forming instead at their tips a concave surface that protrudes into a large, muscular renal pelvis. There is no inner medulla. The kidney is bean shaped, with the renal artery and vein and the ureter located together at the indentation of the hilus.

III. Size of the Kidney

The mass of the kidney increases with body size in mammals (Beuchat, 1996). In marine mammals that have discrete multireniculate kidneys, the number of reniculi in each kidney increases as well. In the harbor porpoise (*Phocoena phocoena*), for example, the kidneys of an adult (body length = 1.6 m) weigh 150–200 g and contain roughly 300 reniculi that range in weight from 0.15 to 0.6 g each. In an 11-m right whale, one of the kidneys can weigh 32 kg and contain 5400 reniculi, each with an average weight of 2.6 g.

In general, the kidneys of cetaceans and pinnipeds are larger than those of similarly sized terrestrial mammals (Beuchat, 1996). This may be a consequence of the division of the kidney into reniculi, with the connective tissue surrounding each reniculus accounting for at least part of the difference in mass.

IV. Urinary-Concentrating Ability

All marine mammals examined to date can produce urine that is at least as concentrated as seawater (1000 mosM), and

most can do substantially better than this. Measurements from cetaceans (six species) range from 1081 to 1737 mosM and those from pinnipeds (five species) and the sea otter are even higher, from 2000 to 2750 mosM (Beuchat, 1996). The highest value recorded from a manatee is 1100 mosM.

Although these osmolalities are far less than those achieved by some desert rodents, in which the urine can exceed 8000 mosM, they are surprisingly high considering the structure of the kidney in most marine mammals. The countercurrent multiplier theory predicts that the concentrating ability should increase with increasing length of the loop of Henle. In species with discrete multireniculate kidneys, the nephrons have very short loops of Henle because the individual reniculi are much smaller than an appropriately sized nonmultireniculate kidney would be for that species (Beuchat, 1996). How marine mammals produce such concentrated urine with such short loops of Henle remains a paradox.

Killer Whale

Orcinus orca

John K. B. Ford
Fisheries and Oceans Canada, Nanaimo, British Columbia, Canada

With its striking black and white markings and cosmopolitan range, the killer whale (*Orcinus orca*), or orca, is one of the most easily recognized and widely distributed of all cetaceans. Although the species has long been held in high regard by many aboriginal maritime cultures, other societies feared the killer whale as a reputedly ruthless and dangerous predator, and the animals were commonly vilified and persecuted. Attitudes toward killer whales have fortunately improved over the past few decades. The species has been an admired display species in aquaria for over 30 years and has been featured in numerous movies, documentaries, and other forms of popular media. It has become the focus of commercial whale-watching operations in several regions. Long-term field research using photo-identification of individuals from natural markings has resulted in certain populations of killer whales being among the best studied of any cetacean species (Fig. 1).

I. Characters and Taxonomic Relationships

The killer whale is one of the most distinctive of the odontocete cetaceans and is unlikely to be confused with any other species. It is a large dolphin, attaining maximum body lengths of 9.0 m in males and 7.7 m in females. Maximum measured weights are 3810 kg for a 6.7-m female and 5568 kg for a 6.75-m male (Dahlheim and Heyning, 1999). In addition to sexual dimorphism in size, mature males develop disproportionately larger appendages than females (Fig. 2). This includes the pectoral flippers, tail flukes (the tips of which curl downward in males), and dorsal fin, which is erect in shape and may attain a height of 1.8 m in males. At birth, neonate killer whales are approximately 2–2.5 m long and weigh approximately 200 kg.

The most distinguishing feature of the killer whale is its striking coloration. Killer whales are generally black dorsally and white ventrally. Above and behind the eye on each lateral side of the whale's head is a conspicuous, elliptically shaped white patch, referred to as the postocular patch. On the posterior lateral sides of the whale, the ventral white region continues dorsoposteriorly to form flank patches that extend almost half-way to the dorsal ridge. At the posterior base of the dorsal fin is a gray-pigmented area of variable shape termed the "saddle patch." In neonates, the normally white pigmented areas on

Figure 1 *Left side view of an adult male killer whale showing representative dorsal fin nick and saddle-patch scars that are used in photographic identification of individuals. Photo by G. Ellis.*

Figure 2 *Adult male killer whale breaching near San Juan Island, Washington. Note large pectoral flippers and tall dorsal fin typical of mature males. Photo by C. Emmons.*

the body have an orange hue, and the saddle patch is indistinct or absent for the first year of life. Considerable variation exists among killer whale populations and individuals in the size and shape of white and gray patches. In some populations, particularly in the Southern Hemisphere, killer whales have a faint gray pigmentation over much of their body and a black dorsal "cape" anterior to the dorsal fin.

The skull of the killer whale can be distinguished from other odontocetes by its shape, size, dental formula, and large teeth. Typically, 10–12 (up to 14) teeth are found per row, with teeth usually up to 10 cm in length. Upper and lower teeth interlock when the jaws are closed, which may result in considerable wear along their anterior and posterior facets. In some populations, extreme wear of the tooth crowns has been observed, even in young individuals, which may relate to diet.

Taxonomically, the killer whale is the largest species of the family Delphinidae. The genus *Orcinus* is considered monotypic, although two species, *O. nanus* and *O. glacialis*, were independently proposed for a population of purportedly small individuals in the Antarctic. These new species designations have not received general acceptance. The morphological and ecological features described in Antarctic killer whales likely represent the kinds of population-specific variations that may be typical of the species over much of its range (Hoelzel *et al.*, 1998; Barrett-Lennard, 2000).

II. Distribution and Abundance

The killer whale is second only to humans as the most widely distributed mammal in the world. They are found in all oceans and most seas, but are generally most commonly observed in coastal, temperate waters, especially in areas of high productivity. Notable concentrations occur in waters along the northwestern coast of North America, around Iceland, and along the coast of northern Norway. In the Antarctic, killer whales are commonly found up to the pack ice edge in many areas and may extend well into ice-covered waters. In the Canadian Arctic, killer whales are rarely seen in the vicinity of pack ice, but do visit the region during the open water season in later summer. Information on the species' distribution in most tropical and offshore waters is limited, but numerous scattered records attest to its widespread, if rare, occurrence.

Because of its general scarcity and sporadic occurrence in most regions, the killer whale is a difficult species to census. Photo-identification studies in nearshore waters of the northeastern Pacific Ocean, from the eastern Aleutian Islands to California, have yielded a total population count of approximately 1500 whales (Ford *et al.*, 2000). Similar studies off northern Norway have identified 445 whales (Similä, 1997). No reliable global population estimate is available for the species, although some rough estimates have been given for some ocean regions. Intensive vessel sighting surveys for cetaceans in the eastern tropical Pacific have resulted in an estimate of about 8500 killer whales in an area of 19 million km^2. Ship-board cetacean surveys in the Antarctic have yielded a rough estimate of 70,000 killer whales (Dahlheim and Heyning, 1999).

III. Ecology

The DIET of killer whales comprises an extremely diverse array of prey species, which can vary widely both within and among regions. It is the only cetacean that routinely preys upon marine mammals, with attacks or kills documented for over 35 different species (Jefferson *et al.*, 1991). Mammalian taxa that have been recorded as prey of killer whales include other cetaceans—both mysticetes and odontocetes—pinnipeds, sirenians, mustelids, and, on rare occasions, ungulates. A variety of fish species are also important prey of killer whales, notably salmon (*Oncorhynchus* spp.), herring (*Clupea harengus*), cod (*Gadus* spp.), tuna (*Thunnus* spp.), and various sharks and other elasmobranchs (Dahlheim and Heyning, 1999; Saulitis *et al.*, 2000; Ford *et al.*, 1998; Visser, 1999). Other animals noted as killer whale prey include squid, octopus, sea turtles, and sea birds.

In the northeastern Pacific, there is remarkable dietary specialization in different sympatric populations of killer whales, and a growing body of evidence suggests that similar degrees of specialization may also exist in other regions. Long-term photo-identification studies in British Columbia, Washington, and Alaska have shown that two different populations inhabit the same coastal waters, yet maintain social isolation from each other (Bigg *et al.*, 1990). These populations differ in genetic structure, morphology, behavior, distribution patterns, and ecology. One population, referred to as residents, are fish specialists, whereas the other, termed transients, are primarily mammal hunters.

Residents show strong seasonal movements associated with the coastal migrations of salmon. Observational studies of residents and analyses of stomach contents from beach-cast carcasses have determined that salmon is their predominant prey for at least half the year and that preference is shown for the largest or fattiest available species [chinook (*Oncorhynchus tshawytscha*) in British Columbia and coho (*O. kisutch*) in

Prince William Sound, Alaska; Ford *et al.*, 1998; Saulitis *et al.* 2000] (Fig. 3). Squid (*Gonatopsis borealis*) and a variety of nonsalmonid fish species are also eaten by residents (Ford *et al.*, 1998). There is no evidence that marine mammals are consumed, although porpoises and seals are harassed and killed by residents on rare occasions. Foraging groups of residents typically ignore marine mammals in their vicinity and seldom elicit avoidance responses from those species (Jefferson *et al.*, 1991; Saulitis *et al.*, 2000). The distribution and diet of residents in winter and early spring are poorly known.

Transients show relatively little seasonal change in ABUNDANCE and DISTRIBUTION, most likely because their preferred prey species are present year-round in coastal waters. In British Columbia, harbor seals (*Phoca vitulina*) are the primary prey of transients, although Steller sea lions (*Eumetopias jubatus*), California sea lions (*Zalophus californianus*), harbor porpoises (*Phocoena phocoena*), Dall's porpoises (*Phocoenoides dalli*), and Pacific white-sided dolphins (*Lagenorhynchus obliquidens*) are also important (Ford *et al.*, 1998) (Fig. 4). Larger cetaceans are seldom attacked and killed by transients in coastal waters of British Columbia, although this is common off California. Transients have been observed to harass and occasionally eat a variety of species of seabirds in British Columbia and southeastern Alaska. In Prince William Sound, Alaska, transients feed mostly on harbor seals and Dall's porpoises, but seabird predation has not been recorded (Saulitis *et al.*, 2000). Transients have not been observed to eat any species of fish, and no fish remains have been found in the stomachs of stranded transients.

Such extreme dietary specialization in sympatric populations is without precedent in mammals. These specializations likely evolved gradually over a long period by means of increasingly refined and successful foraging strategies that were learned by individuals and passed across generations. Effective foraging for the very different types of prey of residents and transients may require such divergent skills and tactics that lifestyles dependent on one or the other prey type are mutually exclusive. Foraging specializations may have played a role in the historical separation of ancestral resident and transient groups, and over time the two populations became socially and eventually reproductively isolated. Residents and transients are highly distinct in both mitochondrial and nuclear DNA composition (Hoelzel *et al.*, 1998; Barrett-Lennard, 2000). A third sympatric population has been documented in coastal waters off British Columbia south to California (Ford *et al.*, 2000). Provisionally termed "offshores," these whales are seldom encountered in protected inshore waters and have not been observed mixing with either the resident or the transient population. They form a genetically distinct group, although they are more closely related to residents than to transients (Barrett-Lennard, 2000). The dietary habits of this population are so far unknown.

Figure 3 *Resident killer whale with freshly killed salmon in Haro Strait, Washington. Photo by K. Soloman.*

Figure 4 *Transient killer whale ramming a Steller sea lion during an attack in Blackfish Sound, British Columbia. Photo by J. Borrowman.*

Populations of killer whales in other regions may also be highly specialized in feeding habits. In the Antarctic, two sympatric populations have been reported that differ morphologically and ecologically, with one population preying primarily on marine mammals and the other on fish. Off the northern coast of Norway, a population of killer whales moves seasonally in relation to the migration pattern of its principal prey, herring (Similä, 1997). It is likely that populations with dietary specializations exist wherever sufficiently abundant and reliable prey resources are available to sustain them year-round. In other regions, more opportunistic foraging strategies may be expected. For example, in the sub-Antarctic Crozet Islands, killer whales feed seasonally on southern elephant seal (*Mirounga leonina*) pups, but also forage for fish. Groups of killer whales have been observed to attack and kill large baleen whales and sperm whales in various locations (Jefferson *et al.*, 1991), but it is not known whether these groups specialize on such prey items.

The killer whale has no natural predators other than humans.

IV. Life History

Most detailed information on reproduction, mortality, and other life history parameters of killer whales has been derived from long-term photo-identification studies of resident killer whales in British Columbia and Washington (Olesiuk *et al.*, 1990). The reliability and completeness of this information are due to the extremely stable social structure of residents, where emigration from the natal group does not take place and mortalities can be documented reliably (see next section for more detail). It is not known whether these life history parameters are typical of other populations or regions.

Studies of captive whales indicate that sexually mature females have periods of polyestrous cycling interspersed with noncycling intervals of 3–16 months. The gestation period is 15–18 months. In resident killer whales, births may take place in any month, although most are in October–March. Neonate mortality is high, with an estimated 43% dying in the first 6 months (Olesiuk *et al.*, 1990). Calves are nursed for at least a year, but may start taking solid food from the mother while still nursing. Typical age at weaning is not known, but is likely between 1 and 2 years of age.

Females give birth to their first viable calf at between 11 and 16 years of age (mean of 15 years) (Olesiuk *et al.*, 1990). Intervals between viable calves average about 5 years (range 2–14 years). Females have an average of 5.35 viable calves over a 25-year reproductive life span, which ends at approximately 40 years of age. Females then become reproductively senescent for an average period of 10 years, but this postreproductive period may extend to more than 30 years. Mean life expectancy for females (calculated at age 0.5 years, following the period of high neonate mortality) is estimated to be approximately 50 years, and maximum longevity is 80–90 years. Males attain sexual maturity at about 15 years of age, as indicated by a rapid growth of the dorsal fin. Males continue to grow until they reach physical maturity at about 21 years of age. Mean life expectancy for males (calculated at age 0.5 years) is estimated to be about 29 years, with maximum longevity about 50–60 years. Mortality curves for both males and females are U-shaped, although the male curve is narrower.

V. Social Organization

Killer whales are usually observed traveling alone or in groups of up to about 50 individuals. Reports of larger groups likely involve temporary aggregations of smaller, more stable social units. Long-term photo-identification studies have provided information on the social organization of the species in several regions of the world. The most detailed of these are studies in coastal British Columbia, Washington, and Alaska, particularly for the resident population (Bigg *et al.*, 1990; Matkin *et al.*, 1999; Ford *et al.*, 2000). Resident societies can be arranged into a number of groupings based on maternal genealogy, social association, and acoustical relationship. The basic social unit of residents is the matriline, which is a highly stable group of individuals linked by maternal descent. A typical matriline is composed of a female, her sons and daughters, and the offspring of her daughters. Because females may live to 80–90 years of age, and females have their first viable calf at about 15 years of age, a matriline may contain as many as four generations of maternally related individuals. Some matrilines contain only one generation, which can result if a female dies and leaves only sons or daughters that have no young of their own. The bonds among members of a matriline are extremely strong, and individuals are seldom seen apart from the group for more than a few hours. No permanent dispersal of individuals has been observed from a resident matriline.

The next level of social organization in resident killer whales is the pod, which is a group of related matrilines that shared a common maternal ancestor in the recent past. Matrilines within pods are thus more closely related to one another than to matrilines in other pods. Pods are less stable than matrilines, and member matrilines may travel apart for periods of weeks or months. However, these matrilines still tend to travel more often with others from their pod than with matrilines from other pods (Ford *et al.*, 2000). The majority of pods are composed of one to three matrilines. Resident pods in British Columbia, Washington, and Alaska contain a mean of 18 whales (range = 2–49).

Above the pod is the clan, which is a level of social structure defined by the acoustic behavior of pods. It is composed of pods that have similar vocal dialects (see Section VII). All pods within a clan have most likely descended from a common ancestral pod through a process of growth and fragmentation along matrilines. Thus, the related dialects of clan members seem to reflect the common matrilineal heritage of the pods. Those pods with very similar dialects are probably more closely related, and have split more recently, than those with more different features in their dialects. Clans are sympatric, and pods from different clans frequently travel together. Clan membership is occasionally—but usually not—reflected in patterns of association. It is not clear how clans are related to each other, as they have no acoustical features in common, nor is the origin of clans known.

The top level of structure in a resident society is the community, which is made up of pods that regularly associate with one another. The community is thus defined solely by association patterns rather than maternal genealogy or acoustic similarity. Pods from one community have not been seen to travel with those from another, although their ranges may partly overlap. Three communities of residents have been identified in coastal waters of British Columbia, Washington, and Alaska: southern (83 whales in 3 pods, 1 clan), northern (214 whales in 16 pods, 3 clans), and southern Alaskan (237 whales in 11 pods, 2 clans) (Matkin *et al.*, 1999; Ford *et al.*, 2000).

Social organization in mammal-eating transient killer whales is not as well known as in residents (Ford and Ellis, 1999). Like residents, the basic social unit is the matriline, but unlike residents, offspring may disperse from matrilines for extended periods or permanently, either as juveniles or as adults. As a result, transient matrilines tend to be smaller than those of residents, and lone individuals, particularly males, are often observed. Small group sizes of transients appear to reflect the marine-mammal foraging specialization of this population (Baird and Dill, 1996; Ford and Ellis, 1999). Association patterns of transient matrilines are very dynamic, and they do not form consistent groupings of matrilines equivalent to resident pods.

All transient groups in a community can be linked together via this network of associations. All members of a transient community share a related call repertoire, as in a resident clan. However, regional differences exist in the vocal repertoire of transients.

Social organization based on matrilineal descent may be typical of killer whales globally. In other regions where long-term photo-identification studies have been undertaken, close and prolonged associations of mothers and offspring are commonly seen (e.g., Norway, Crozet Islands, Argentina). Temporal persistence of these bonds may be a primary variable determining group sizes and structure.

VI. Activity States and Behavior

The activity states of killer whale groups are of four basic types: foraging, traveling, resting, and socializing (Ford, 1989; Saulitis *et al.*, 2000). Minor differences in definitions and classification criteria of activities by different researchers make detailed comparisons difficult, but general patterns are evident. Foraging and traveling are the predominant activity states noted in all populations, although the proportions of the activity budget dedicated to these activities vary. Mammal-eating transients in coastal waters of the northeastern Pacific spend the great majority of their time (approximately 90–95%) foraging and traveling, whereas fish-eating residents spend only about 60–70% of their time doing so, at least during summer when salmon is abundant. Residents spend considerably more time resting and socializing than transients. Fish-eating killer whales in northern Norway have activity budgets very similar to those of northeastern Pacific residents (Similä, 1997).

A. Foraging

BEHAVIOR patterns of foraging killer whales vary considerably among populations and prey types. Groups of salmon-hunting residents often disperse over large surface areas while foraging, with members moving at roughly the same speed (mean = 6.0 km/hr) and direction. Foraging episodes are typically 2–3 hr in duration, but may last up to 7 hr. Individual salmon are pursued, captured, and eaten by single animals or small subgroups, usually a mother and juvenile offspring. Norwegian killer whales feed on herring in a coordinated manner referred to as "carousel feeding" (Similä, 1997). Using percussive actions such as tail lobbing, releasing blasts of bubbles, and flashing the white ventral side of their bodies, the whales herd herring into a tight ball close to the surface. The whales then stun fish by striking the edges of the ball with their tail flukes and eat the debilitated prey.

Transient killer whales in the northeastern Pacific typically forage in smaller groups than fish-eating killer whales. Transient groups hunt harbor seals in groups averaging three to four individuals (Baird and Dill, 1996; Ford *et al.*, 1998; Saulitis *et al.*, 2000), usually close to shore and near seal haul-out sites. While foraging, transients remain acoustically very quiet apparently to avoid detection by potential prey and possibly to locate prey by passive listening (Barrett-Lennard *et al.*, 1996). Harbor seals are killed and shared among group members relatively quickly compared to Steller sea lions or California sea lions, which may take over 2 hr to kill and consume. Sea lions are usually rammed or butted with the whales' heads, and slapped repeatedly with tail flukes, until the animal is debilitated sufficiently to be taken underwater and drowned. When hunting porpoises or dolphins, transients forage in slightly larger groups averaging five members, which spread out in open water in a rough line abreast. The whales single out an individual porpoise, chase it until it tires, and then ram it or jump on it to complete the kill (Ford *et al.*, 1998). Larger schools of Pacific white-sided dolphins are often driven by transients into confined bays where individual dolphins are trapped against the shore and killed (Ford and Ellis, 1999).

A variety of specialized tactics have been described for killer whales hunting marine mammals in other regions. In Patagonia, Argentina, killer whales hunt southern sea lion (*Otaria flavescens*) and elephant seal (*Mirounga leonina*) pups in the shallows along sloping pebble beaches, and often intentionally strand themselves temporarily in the process (Fig. 5). The whales hunt cooperatively and share their prey after capture. Killer whales in the Crozet Islands hunt elephant seal pups in a manner similar to those in Patagonia, and adults appear to teach this technique to their offspring (Guinet and Bouvier, 1995). In the Antarctic, killer whales have been observed to locate seals hauled out on ice pans by spyhopping and then dislodging them from the pan with a wave created by the whale's fast approach. Attacks on baleen whales or sperm whales often involve groups of 10–20 killer whales, which work together in a coordinated manner to subdue the prey. Individuals will attempt to grasp the tail flukes or pectoral flippers to immobilize the larger whale, while others attack the head and blowhole area evidently to prevent the whale from breathing. Once killed, often just the tongue, lips, and BLUBBER are consumed (Jefferson *et al.*, 1991). Because most baleen whales sink upon death, killer whales may only be able to feed extensively on carcasses of whales killed in shallow waters (Guinet *et al.*, 2000).

Figure 5 *Female killer whale catching a southern sea lion pup in Patagonia, Argentina. Photo by J. Ford.*

B. Traveling

Traveling killer whales move in a single direction at a consistent, fast pace, with no evidence of foraging or FEEDING. Groups often travel in a line abreast, with synchronized dives and surfacings. Resident killer whales have been documented to travel at speeds of over 20 km/hr (mean = 10.4 km/hr; Ford, 1989).

C. Resting

When resting, resident killer whales usually form a line abreast, often with individuals grouped tightly together (Fig. 6). Group diving and surfacing become closely synchronized and regular, with longer dives of 2–5 min duration separated by three or four short, shallow dives. The rate of forward progression is slow compared to foraging and traveling, and resting groups may stop altogether and rest motionless at the surface for several minutes (Ford, 1989; Similä, 1997).

D. Socializing

Socializing activity includes a wide range of physical displays and social interactions. Aerial behaviors are frequent and may include spyhops, breaches, flipper slaps, tail lobs, and head stands. Juveniles often chase each other, roll and thrash at the surface, and engage in various other forms of play behavior, including playing with objects such as kelp or jellyfish. Sexual interactions involving penile erections are commonly observed, predominantly in all-male play groups. Some individuals may rest quietly at the surface while other pod members actively socialize. Beach rubbing is a common behavior observed during socializing in some populations. Residents belonging to the "northern" community in British Columbia visit certain beaches repeatedly to rub their bodies on smooth pebbles in shallow water (Ford, 1989). Interestingly, "southern" community residents do not share this behavioral tradition and have not been seen to rub at any location.

VII. Sound Production

Like most delphinids, killer whales are highly vocal. They produce a wide variety of clicks, whistles, and pulsed calls for ECHOLOCATION and social signaling. Studies of resident killer whales in British Columbia have documented vocal variations associated with activity state and group identity (Ford, 1989, 1991). Vocal exchanges among foraging resident whales are dominated by highly stereotyped, repetitive discrete calls from a repertoire averaging 12 call types (range 7–17 call types) per pod. Resting activity is usually associated with greatly reduced vocal activity, and occasional use of certain calls heard predominantly, but not exclusively, in such contexts. Socializing whales use mainly whistles and nonrepetitive, variable pulsed calls, and aberrant versions of discrete calls. Excitement or motivational levels of vocalizing individuals are reflected in minor variations in pitch and duration of discrete calls.

Call repertoires of resident killer whale pods have features that are distinct, forming systems of group-specific dialects. The entire call repertoire appears to be shared by all pod members. Some portions of a pod's call repertoire may be shared with certain other pods, whereas other portions may be unique. Levels of similarity in these group-specific dialects appear to reflect the degree of relatedness of different pods better than do patterns of travel association. Dialects most likely are learned by young whales by mimicking their mother and siblings, and are retained in the matriline due to the lack of individual dispersal. Divergent variations in dialects among related matrilines likely accompany the gradual fission that leads to pod formation. Dialects likely provide an acoustic means of maintaining group identity and cohesion, and may serve as indicators of relatedness that help in the avoidance of inbreeding between closely related whales (Ford, 1991; Barrett-Lennard, 2000). Dialects have also been documented within a community of pods of killer whales in northern Norway, and likely exist elsewhere.

Mammal-eating transient killer whales in British Columbia and Alaska have greatly reduced vocalization rates compared to residents. Transients are generally silent when foraging. This includes the use of echolocation, which in one study was heard 27 times less often from foraging transients than foraging residents (using an index adjusted for group size; Barrett-Lennard *et al.*, 1996). Transients are more likely than residents to use individual (or "cryptic") clicks rather than click trains, presumably to avoid alerting potential prey to their approach. When vocal, transients off the coasts of southeastern Alaska to California produce a number of calls that are shared among all groups in the community. Certain other calls seem exclusive to transient groups in different portions of this range. Group-specific dialects as seen in resident pods are not evident, presumably due to the reduced stability of social structure in transients (Ford and Ellis, 1999).

VIII. Conservation Status

Globally, the killer whale is listed by the IUCN as "lower risk: conservation dependent," meaning that the species, although presently not considered at risk, could become so should existing conservation programs be discontinued and exploitation expanded. Historically, killer whales in several regions have been the target of directed fisheries, culling, and persecution. An average of 43 whales per year were taken by Japanese whalers in their coastal waters during 1946–1981, mostly for human consumption. This fishery is no longer active. Norwegian whalers took an average of 56 whales per year during

1938–1981 in a government-subsidized hunt aimed at reducing killer whale numbers to reduce competition for other fisheries. The killer whale meat from this fishery was used only for animal consumption. A small number of killer whales were taken annually by Soviet whalers in the Antarctic, with the exception of a large take of 916 animals in the 1979/1980 season. No significant directed hunt for killer whales continues today.

Killer whales have long been feared as dangerous predators or vilified as perceived or real threats to fisheries in many regions, and were often harassed or shot opportunistically. Although much reduced, some such persecution continues today. Killer whales have been shot by fishermen in Alaska and possibly other regions to prevent the whales from taking fish from long-line fishing operations (Matkin *et al.*, 1999). There is evidence that populations in coastal waters of British Columbia and Washington state were already depressed from shootings when a live-capture fishery developed there in the mid-1960s. Killer whales became highly sought for public display in aquaria following the first successful capture and display of the species at Vancouver in 1964. During 1964–1977, 63 whales were taken in this fishery to supply aquaria in many parts of the world (Olesiuk *et al.*, 1990). During the late 1970s to mid-1980s, live captures shifted to the waters of Iceland, where over 50 whales were taken. The improved success of captive breeding during the past decade has reduced the need for capture from wild populations, although periodic live captures continue.

Other CONSERVATION concerns include direct effects of oil spills and other forms of toxic pollution of killer whale survival. The *Exxon Valdez* oil spill in Alaska was strongly correlated with the subsequent loss of 14 whales from a pod that was seen swimming through light oil slicks early in the spill, although it was not possible to directly attribute the deaths to this cause. Oil spills may also have indirect effects on killer whales by reducing prey abundance. Being at high trophic levels in the food web, killer whales are susceptible to bioaccumulation of organochlorine pollutants. Levels of PCBs in resident and, in particular, transient killer whales in British Columbia and Washington state have been shown to be among the highest observed in any cetacean and are higher than levels found to affect the health of European harbor seals. It is not known whether there is a direct impact of PCBs on health in these killer whales, although such effects as immunosuppression and reduced reproductive success are possible (Ross *et al.*, 2000).

Other potential impacts of human activities on killer whale status are reduced prey availability and disturbance caused by vessel traffic. As an example, many stocks of salmon, the principal prey of residents killer whales, have declined significantly in British Columbia and Washington State as a result of overfishing, degradation of spawning grounds, and reduced ocean survival. Vessel disturbance is of particular concern in areas of intensive whale watching, although many forms of boat traffic have the potential to affect whales. The physical presence of moving boats near killer whales can disrupt their activities, particularly resting. Underwater noise from vessels has the potential to interfere with social or echolocation signals, or to mask passive acoustic cues that may be important in finding prey.

It is possible that many of these potential impacts on killer whales are, when taken alone, insufficient to negatively affect killer whale survival. However, there is a potential for more serious cumulative effects that could displace killer whales from critical habitats or result in reduced survival.

Krill

Roger P. Hewitt and Jessica D. Lipsky
Southwest Fisheries Science Center, La Jolla, California

Euphausiids, or krill, have long been recognized as a critical element of the natural economy of the world's oceans (Sars, 1885; Brinton, 1962; Marr, 1962; Mauchline and Fisher, 1969; Mauchline, 1980). Early fishery biologists repeatedly stressed the importance of various species of euphausiids as food for exploited fish and whale stocks (Lebour, 1924; Hickling, 1927; Hjort and Rund, 1929). Norwegian whalers referred to the euphausiids found in large numbers in the stomachs of whales caught in the North Atlantic as *stor krill* (or large krill, referring to *Meganyctiphanes norvegica*) and *smaa krill* (or small krill, referring to *Thysanoëssa inermis*); the word "krill" is now used in reference to euphausiids in general (Mauchline and Fisher, 1969). Laws (1985) estimated that 190 million tons of Antarctic krill (*Euphausia superba*) were consumed annually by baleen whales in the Southern Ocean prior to their exploitation. It is estimated that the current populations of whales, birds, pinnipeds, fish, and squid consume 250 million tons of Antarctic krill annually (Miller and Hampton, 1989). Of the 85 species of krill, Mauchline and Fisher (1969) listed only nine of primary importance in terms of their distribution range, biomass, and dominance in the diets of vertebrate predators. They noted that these species constitute a large fraction of the plankton where they are found and that their biomasses are largest at high latitudes. In addition to their numbers, the habit of euphausiids to form large swarms makes them particularly important as prey to marine vertebrates (Fig. 1).

The krill species considered most important to the trophodynamics of marine ecosystems are *M. norvegica, T. raschii,* and *T. inermis* in the North Atlantic Ocean; *E. pacifica, T. inermis, T. raschii, T. longipes,* and *T. inspinata* in the North Pacific Ocean; and *E. superba, E. crystallorophias,* and *T. macrura* in the Southern Ocean. Mauchline and Fisher (1969) list another seven species of importance in more restricted geographical areas and/or seasons: *Nyctiphanes couchii* in the North Atlantic Ocean; *T. spinifera* and *E. similis* in the North Pacific Ocean; *N. capensis* near the southern part of Africa; *N. australis* and *Pseudoeuphausia latifrons* from Western Australia to New Zealand; and *E. vallentini* in the Southern Ocean. In addition, the following seven species are often cited in predator diet samples from restricted locales and time periods: *Nematocelis megalops* in the North Atlantic; *E. recurva, E. lucens, E. hemigibba, T. gregaria, E. spinifera,* and *N. megalops* from Western Australia to New Zealand; *E. recurva, E. lucens,* and *T. gregaria* near the southern part of Africa; and *N. simplex* along the western coast of North America (Fig. 2).

While many of these species are broadly dispersed, they exhibit their highest densities in areas of enhanced seasonal primary and secondary production. These areas include eastern boundary currents, coastal and oceanic upwelling regions, and sea ice edge zones, as well as estuaries, fjords, and small-scale eddies where physical mechanisms may enhance the aggregation of krill. It is not surprising therefore to find krill predators, including baleen whales and crabeater seals, concentrated in these areas as well (Fig. 3).

Krill species differ in their geographic distribution, body size (ranging from less than 1 cm to 14 cm), and longevity (ranging from less than 1 year to as many as 10 years) but share many other characteristics that contribute to their importance as prey for baleen whales. Furthermore, baleen whales have not shown strong species or size selectivity among krill when foraging in an area where more than one species and/or developmental stage is present. Krill are therefore described here in general terms with species-specific reference only where appropriate.

I. General Morphology and Life History

The body plan of krill (Fig. 4) is divided into two main regions: the cephalothorax and the abdomen. The cephalothorax,

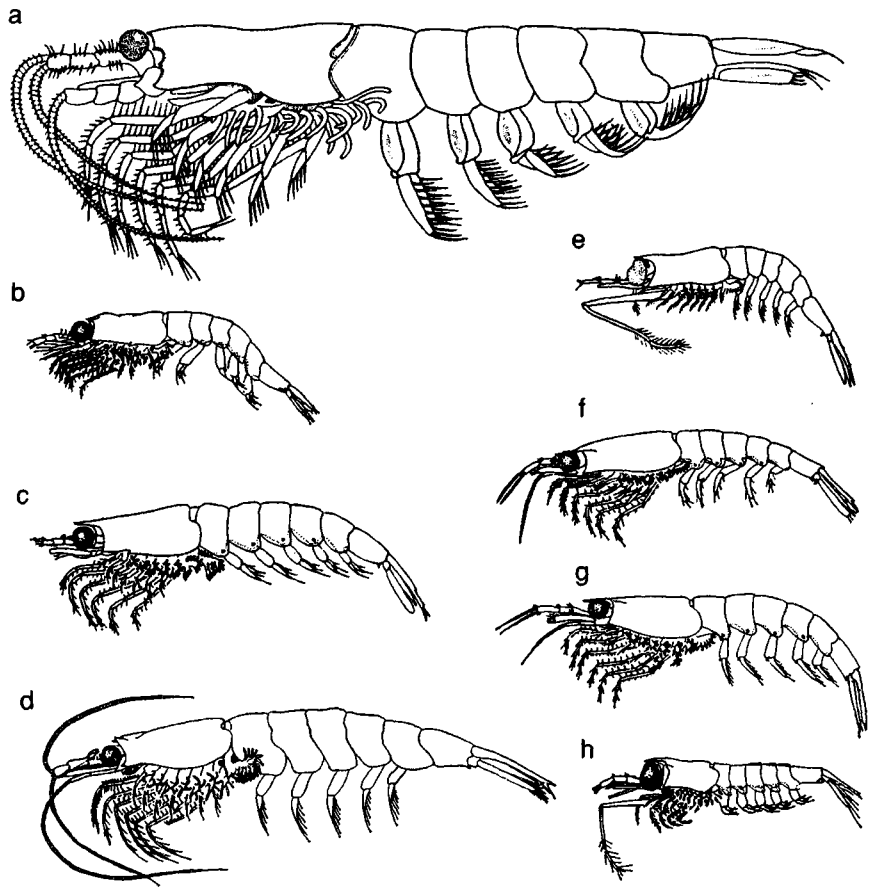

Figure 2 *Scale drawing of the eight most important krill species:* Euphausia superba *(a)*, E. Pacifica *(b)*, E. crystallorphias *(c)*, Meganyctiphanes norvegica *(d)*, Thysanoëssa macrura *(e)*, T. inermis *(f)*, T. raschii *(g)*, *and* T. longipes *(h)*. *From Mauchline and Fischer (1969).*

a fused head and thorax, contains the internal organs, including the digestive system, the heart, and gonads. It is about one-third of the body length and is covered by a thin shell or carapace. The muscled abdomen is made up of six segments ending with a telson and two pair of uropods, which together form a fan shape at the tail. At the head there are a pair of eyes and two pair of antennae with tactile and olfactory sensors; excretory organs open near the second set of antennas. The mouth is made up of several parts whose function is to filter, macerate, and manipulate food prior to ingestion. Six to eight pairs of limbs are connected to the thorax and are used to filter particles out of the water and pass them to the mouth. Unlike decapod crustaceans (crabs, lobsters, prawns, shrimps) the gills of krill are exposed, hanging below the carapace. The first five abdominal segments each have a single pair of limbs (pleopods) attached, which are used for swimming; the sixth abdominal segment has no appendages. On a mature adult male the first pair of pleopods is modified to form a petasma, which is used during copulation to clasp and transfer spermatophores to the female. The thelycum, or female copulatory organ, is located on the anterior underside of the thorax near the opening of the oviducts.

The exoskeletons of krill are translucent, allowing a view of the internal organs, including the heart, stomach, and hepatopancreas, which is often colored dark green or red. Krill are also luminescent with light-emitting photophores located at the bases of their pleopods, near the thelycum, close to the mouth and in the eye stalks. The photophores are a deep red color but emit electric blue light in the water. Many species are also pigmented with red chromatophores that expand when the animal is stimulated. As a result, swarms of krill often appear to be bright red, particularly when under attack by a predator. The guano of krill-eating birds is often pink in color, and the feces of krill-eating marine mammals are characteristically dark red.

As krill mature sexually, males elaborate packets of sperm called spermatophores and females develop clusters of eggs or broods. During spawning the male grasps the female with his petasmae and transfers spermatophores to her body where they adhere in the vicinity of her thelycum. Among the various species of krill, brood size ranges from tens of eggs to several thousand, and some species have been observed to spawn several broods during a single breeding season. When a female releases a brood of eggs, they are fertilized by spermatozoa now liberated from the spermatophores. For some species the

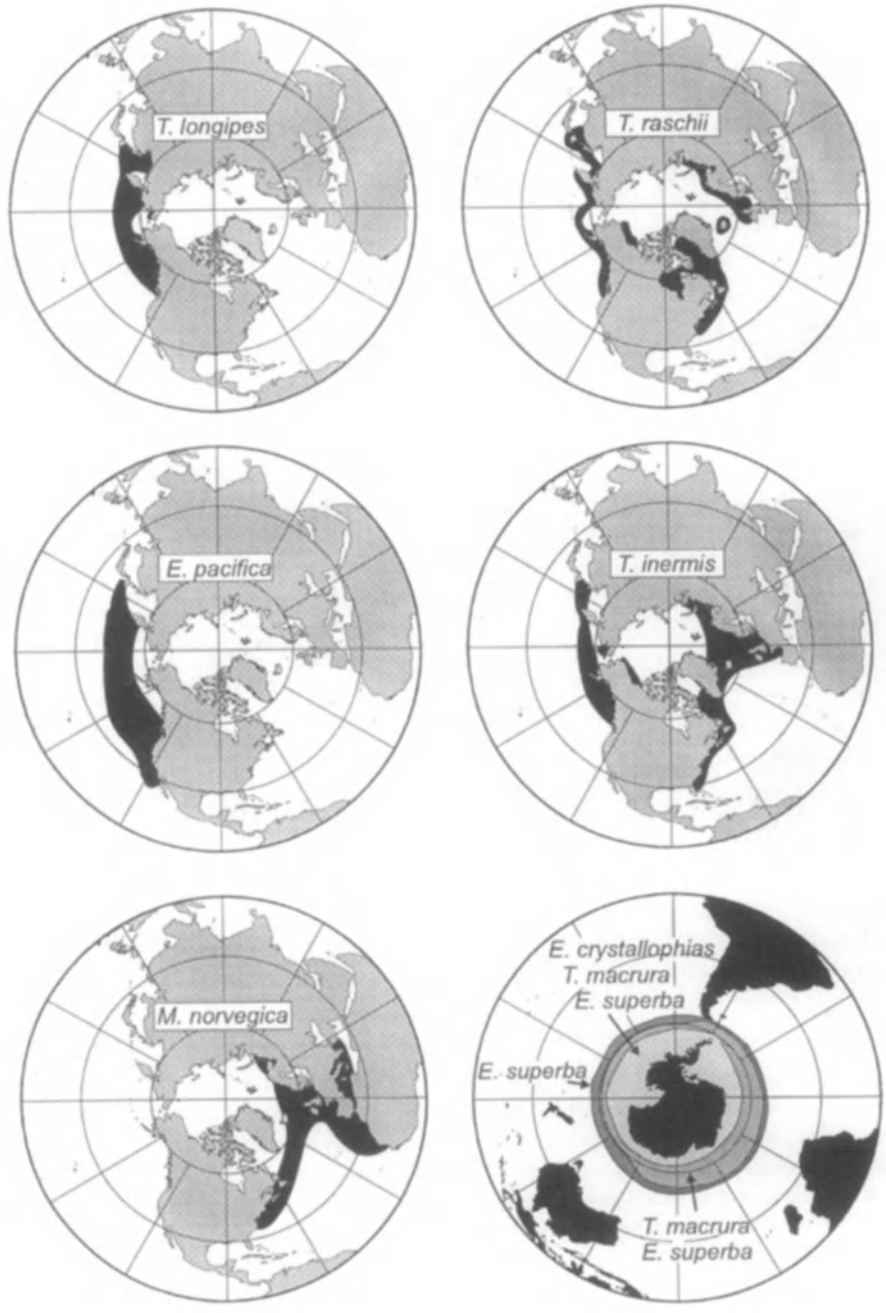

Figure 3 *Northern and Southern Hemisphere maps showing dispersion of important krill species. Redrawn from Mauchline and Fischer (1969).*

female carries the fertilized eggs in brood pouches until they hatch, thereby protecting them from predation. For most species, however, eggs are released into the open sea. In some cases the eggs are neutrally buoyant, but often they are heavier than water and sink before hatching into nauplius larvae, which in turn develop and molt through a series of larval stages, each resembling the adult morphology more than the previous stage. In the case of *E. superba*, a brood of 10,000 fertilized eggs may be released by a single female in a near-surface swarm of spawning adults; the eggs sink to depths of greater than 1000 m, incubate, and hatch. The nauplius has no swimming appendages and continues to sink as it grows, molts, and gives rise to more advanced larval forms. Once it can swim the larva begins its ascent into the surface waters, progressing through several more molts and ultimately emerging as a calyptosis larva. Calyptoses continue to eat, grow, and molt through additional stages in preparation for the winter when food is less available. Sometime in the late winter or early spring the larvae finally

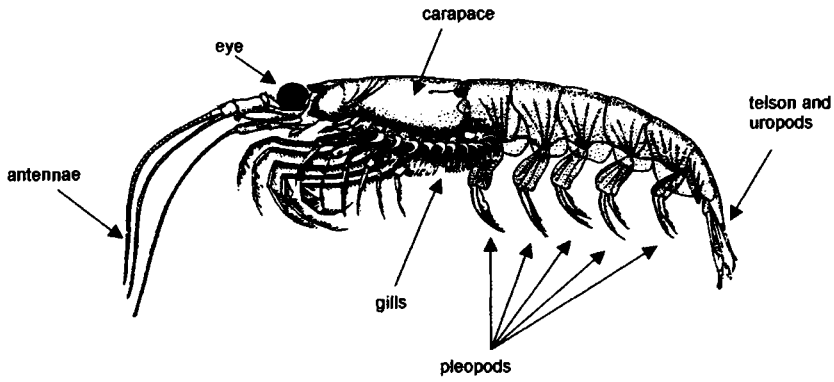

Figure 4 *General krill body plan.*

metamorphose into juvenile krill, but it may be as long as another year before they are ready to spawn themselves. In the case of *E. pacifica*, this process is compressed to a few months with spawning occurring during the spring and recruitment into the adult population occurring during the fall.

Except for rich fat stores invested in developing eggs, larval and postlarval krill do not elaborate high levels of fat reserves. Consequently, they must eat constantly in order to offset the energy costs of swimming, growth, and reproduction. In addition, krill periodically shed their exoskeletons throughout their life, adding substantially to their energy requirements. Krill are generally thought to be FILTER-FEEDING herbivores, grazing on phytoplankton in the surface layers of the ocean. Many species, however, are reported to be omnivorous, filtering and/or capturing copepods and other small zooplankton. *E. superba* has been observed in the cavities and cracks on the underside of winter sea ice, presumably feeding on interstitial ice algae. Krill growth and reproductive activity have been directly linked to available food supplies. Negative growth and regression of sexual characteristics have been observed in several species and related to lowered availability of food.

II. Swarming

Krill are heavier than water and must swim continually in order to maintain their position. They aggregate into dense swarms, which can take on a variety of shapes from discreet balls to extensive layers. The swarms may range from 1 m thick to several tens of meters and may extend horizontally tens of meters to several thousand meters. Individual animals appear to be in constant movement, and a sharp gradient in density is often observed at the periphery of a swarm. Within the swarm, volumetric densities may range up to several thousand animals per cubic meter. Near the shelf break surrounding islands in the southwest Atlantic sector of the Southern Ocean it is not uncommon to observe large swarms of *E. superba*, each estimated to contain several thousand tons of krill. Most krill species migrate vertically each day, moving into the upper waters at night and dispersing and moving downward just before dawn and aggregating into denser concentrations. It is generally thought that this behavior is the result of a trade-off between avoiding predation (dense swarms deep in the water during the day) and maximizing feeding efficiency (dispersed individuals in the more particle-rich surface water at night). Although this is a regular pattern, vertical migration behavior varies between species and within a species depending on location and season. Daytime surface swarms have been observed for several species and often contain reproductively mature individuals.

The highest densities of krill have been reported near areas of strong vertical mixing and enhanced primary production. These include coastal upwelling zones, ocean frontal boundaries, and topographic features that interrupt or modify currents such as continental shelf breaks, underwater canyons and escarpments, and seamounts. Krill swarms also tend to aggregate in areas of water flow discontinuity such as eddies and sheer zones between opposing currents.

III. Recruitment Variability

Recruitment of young animals into adult euphausiid population is highly variable in space and time. The production of spawn and the survival of larvae may vary widely within the distribution range of a species as well as between reproductive events. In his review of euphausiid life histories, Siegel (2000) noted that most species reduce their growth phase and extend their reproductive phase toward the center of their distribution ranges. Closer to their distribution limits, krill put more time into growth and less into reproduction.

There is no apparent relationship between stock size and the production of new recruits for most species studied. Relatively large adult stocks can produce few new recruits, and small adult stocks are capable of producing enough new recruits to increase the stock abundance severalfold. The intensity of spawning, survival of eggs and larvae, and the rate of growth have been shown to vary widely between years for several species, resulting in large year-to-year variability in abundances. Interannual variability in the abundances of *E. pacifica* and *N. simplex* off the west coast of North America has been estimated as 10-fold, 25-fold for *T. inermis* in the Barents Sea, and 5- to 60-fold for *M. norvegica* at different parts of its range in the North Atlantic.

Recruitment success is affected by exogenous factors, which act to enhance adult reproduction, survival of eggs, and growth of larvae. The best documented of these is the influence of

coastal upwelling, which enhances primary production and the subsequent growth and maturation of young krill. Temperature affects the incubation rate of eggs and the growth rate of larvae, exposing them to longer or shorter periods of predation. Fluctuations in currents may also transport animals into unfavorable areas. Near the Antarctic Peninsula, *E. superba* spawn earlier in the spring and for a longer period following winters of extensive sea ice development; their larvae enjoy a higher survival rate if sea ice is extensive during the following winter (Loeb *et al.*, 1997). Four to 5-year cycles are apparent in the seasonal extent of sea ice and the recruitment of krill in this region of the Southern Ocean. The postulated affect of seasonal sea ice is to provide a refuge, access to a wintertime food source (ice algae), and to inhibit rapid springtime population growth of a potential competitor to krill, *Salpa thompsoni* (Loeb *et al.*, 1997). *Salpa thompsoni* is a pelagic tunicate and obligate filter feeder, which requires open water access to springtime phytoplankton blooms in order to reproduce.

IV. Foraging Tactics of Baleen Whales and Crabeater Seals

The two characteristics of euphausiids described earlier—an immediate response, in terms of individual growth and reproductive output, to favorable conditions and highest densities in predictable locales—allow efficient exploitation of krill by baleen whales.

In general, baleen whales migrate between high-latitude summer feeding grounds and low-latitude winter breeding and calving grounds. Exceptions are bowhead whales (*Balaena mysticetus*), which are restricted to Arctic regions, and Bryde's whales (*B. edeni*), which usually range from subtropical to temperate waters. Blue, fin, and sei whales (*Balaenoptera musculus, B. physalus*, and *B. borealis*) tend to migrate in offshore waters while gray (*Eschrichtius robustus*), right (*Eubalaena* spp.), and humpback (*Megaptera novaeangliae*) whales tend to use a more coastal MIGRATION route. Adult whales are thought to feed less during migration than immature or undernourished animals. Off the western coast of North America, blue, fin, Bryde's, and humpback whales have been observed feeding on euphausiids aggregated along underwater escarpments and canyons during both winter and summer. The location and timing of whale foraging follow the appearance of high densities of euphausiids and tend to progress from south in the winter to north in the summer. In recent years, aggregations of euphausiids and foraging whales have been a predictable event in the Gulf of California during late winter, near underwater seamounts and canyons off northern California in the summer, and along the shelf break surrounding the Channel Islands in the fall.

Actively feeding whales have been observed to lunge through surface swarms of krill, engulfing large quantities of water and distending their bellies, before expelling the water and extruding as much as several hundred kilograms of krill (Fig. 5). Similar feeding behavior on subsurface swarms has been inferred from acoustic records of krill layers superimposed with dive tracks simultaneously recorded by instruments attached to foraging whales. There are many reports of humpback and fin whales herding and concentrating their prey before lunging through an aggregation of krill. Bryde's and minke whales (*B. acutorostrata* and *B. bonaerensis*) have also been observed gulping large quantities of aggregated euphausiids. Foraging by right and bowhead whales has been described as skimming a continuous stream of water rather than gulping; this behavior may be more efficient with dispersed prey (Nemoto, 1970). Sei and gray whales appear to use both methods.

Despite their name, crabeater seals (*Lobodon carcinophaga*) eat very little other than krill. They are found in the sea ice zone in the Southern Ocean and constitute 50% by number (75% by weight) of the world pinniped population. Crabeaters have lobed cusp TEETH with spaces between them. It is presumed from the shape of the mouth, tongue, an spacing between the teeth that crabeater seals engulf a portion of an aggregation of krill and then strain the water similar to a baleen whale. Crabeaters tend to feed at night when krill are in the upper layers and more dispersed than during the day.

V. Marine Mammal Diets and Euphausiid Consumption by Ocean Basin

A. North Pacific

Blue whales in the eastern North Pacific, foraging from British Columbia to the Californias, feed principally on three species of krill in the California Current; *E. pacifica* and *Thysanoëssa spinifera*, the more inshore species, which is replaced by *Nyctiphanes simplex* moving south (Fig. 6). Fin whales have been observed feeding from the Gulf of California to the northern parts of the Bering Sea from April to September, respectively. During the late winter and spring, fin whales feed on *N. simplex* in the southern portion of their foraging range; moving north in the summer they feed on *E. pacifica, T. raschii, T. longipes*, and *T. inermis*. Fin whales have also been observed to feed on copepods, with the change in prey type related to changes in local relative densities of prey. During the summer months, sei whales consume a variety of euphausiid species, including *T. gregaria, E. pacifica, E. recurva, E. diomedeae, E. tenera, T. inermis, T. spinifera, N. difficilis*, and *N. gracilis*.

Figure 6 *A blue whale swimming through a surface swarm of krill. Courtesy of John Calambokidis, Cascadia Research.*

South of Japan less than 2% of the sei whale diet has been reported to consist of fish, whereas prey species consumed near the Aleutian Islands include copepods, amphipods, decapod crustaceans, fishes, and squid. In comparison to blue whales and fin whales, sei whales appear to be more opportunistic feeders, willing to switch prey type more readily in response to local availability. Bryde's whales have been observed consuming *E. similis*, *N. difficilis*, and *T. gregaria* as well as amphipods, copepods, and fish in the western Pacific and both euphausiids and fish in the Gulf of California. Humpback whales have been observed foraging on euphausiids, including *E. pacifica*, *T. raschii*, *T. longipes*, and *T. spinifera*, from Southeast Alaska to Baja California, although a substantial part of their diet includes clupioid fish as well. Bowhead whales forage primarily on *T. raschii* and *T. inermis* in the Bering and Beaufort Seas during summer and fall, although copepods, mysids, and amphipods also form a part of their diet. Minke whales have been observed foraging on euphausiids, but appear to prefer fish throughout the North and northeastern Pacific. Gray whales are thought to consume primarily benthic amphipods in the Bering Sea during the summer months, although there are reports of gray whales consuming *T. raschii* in the Bering Sea and *E. pacifica* off northern California. Prey selectivity among ringed seals (*Pusa hispida*) appears to be dependent on seasonality and location. Ringed seals have been reported to eat *T. raschii*, *T. longipes*, and *T. inermis* in offshore waters in the Northern Hemisphere in spring and summer when krill abundance is greatest; in the winter they consume Arctic cod and other fish species in inshore waters.

B. South Pacific

Bryde's whales have been observed feeding on *E. diomedeae*, *E. recurva*, and *T. gregaria* and occasionally fish in the Coral Sea (western South Pacific) during the austral spring. In the eastern South Pacific, Bryde's whales consume euphausiids during the austral summer between 35° and 40° south latitude. Humpback whales have been observed off the east and west coasts of Australia feeding on euphausiids, including *E. hemmigibba*, *P. latifrons*, and *E. spinifera*.

C. North Atlantic

Fin whales feed primarily on *M. norvegica*, *T. inermis*, and *T. raschii* during the summer months, switching between prey species in response to local availability. Minke whales consume *T. inermis* and *M. norvegica* in the North Atlantic where euphausiids form a much larger portion of the diet than in the Pacific. North Atlantic right whales (*Eubalaena glacialis*) feed primarily on copepods, although consumption of euphausiids has been observed particularly when associated with copepods. Harp seals (*Pagophilus groenlandicus*) feed on a variety of prey, including decapods, amphipods, euphausiids, and pelagic fishes; however, newly weaned pups and young seals have been reported to feed mainly on *Thysanoëssa* species.

D. Indian Ocean

Fin and minke whales have been observed feeding on euphausiids in the southwest Indian Ocean during their spring and fall migrations to and from the Southern Ocean; prey species include *E. recurva*, *E. lucens*, *T. gregaria*, *E. spinifera*, *N. capensis*, and *E. diomedeae*. Bryde's whales forage on these euphausiids species as well in the southwest Indian Ocean. Near Durban, South Africa humpback whales have been observed feeding on *E. recurva* and *T. gregaria*, and a single pygmy blue whale (*B. musculus brevicauda*) was reported feeding on *E. recurva* and *E. diomedeae*. Sei whales were observed to consume euphausiids, as well as copepods, amphipods, pteropods, and fish.

E. Southern Ocean

Fin and minke whales consume several species of krill in the Southern Ocean throughout the austral summer. Species preference appears to be related to local availability with *T. macrura* and *E. vallentini* more prevalent in the diets of animals foraging in open waters and *E. frigida* and *E. crystallorophias* more prevalent near the continental shelf and ice edge regions. The numerically dominant euphausiid in the Southern Ocean, *E. superba*, is consumed in all areas. Southern right whales (*E. australis*) have been observed foraging on *E. superba* in the Atlantic sector of the Southern Ocean. Humpback whales have been frequently observed foraging on *E. superba* in bays and fjords along the Antarctic Peninsula. Crabeater seals consume *E. superba* and *E. crystallorophias* in the sea ice zone and in coastal fjords and bays; Antarctic silverfish have been reported as seasonal constituents of their diet but krill has been estimated to provide over 90% of their prey requirements. Much smaller portions of the diets of leopard (*Hydrurga leptonyx*), Ross (*Ommatophoca rossii*), Antarctic (*Arctocephalus gazella*), and subantarctic (*A. tropicalis*) fur seals have been reported to be composed of krill.

From these observations, some generalizations may be drawn: (1) blue and fin whales appear to have a higher preference for euphausiids than minke, humpback, or bowhead whales; (2) sei and Bryde's whales appear to be more opportunistic feeders; (3) gray whales and northern right whales prefer prey other than euphausiids but will consume them; (4) crabeater seals have a higher preference for euphausiids than other seals in the Southern Ocean; and (5) ringed and harp seals in the Northern Hemisphere include euphausiids in their diets during certain times of the year and life cycle.

Gross estimates of the consumption of euphausiids by marine mammals are summarized in Tables I and II. Estimates of stock

TABLE I
Consumption of Euphausiids by Whales

Ocean basin	*Whale species*	*Abundance*	*Average body weight (tons)*	*Summertime ingestion rate (10^3 kcal/day)*	*Feeding period (days)*	*% krill in diet*	*Krill consumed (10^3 tons)*
North Pacific	Blue whale	3,000–4,000	69.2	2136	180	100	1,240–1,654
	Fin whale	14,600–18,600	42.3	1452	180	80	3,282–4,182
	Sei whale	13,000–13,000	19.9	805	180	80	1,621–1,621
	Bryde's whale	34,500–45,500	13.2	584	180	40	1,559–2,056
	Minke whale	30,000–32,000	5.3	284	180	70	1,153–1,229
	Humpback whale	5,000–6,000	31.8	1161	180	60	674–809
	Bowhead whale	8,000–10,000	80.0	2392	180	80	2,963–3,704
	Gray whale	25,000–27,000	25.0	962	180	5	233–251
	Northern right whale	400–600	55.0	1784	180	25	35–52
						Total	12,760–15,559
North Atlantic	Blue whale	750–1,300	69.2	2136	180	100	310–538
	Fin whale	45,000–50,000	42.3	1452	180	80	10,117–11,241
	Sei whale	9,000–13,000	19.9	805	180	80	1,122–1,621
	Minke whale	120,000–182,000	5.3	284	180	70	4,610–6,992
	Humpback whale	10,000–11,000	31.8	1161	180	60	1,349–1,483
	Northern right whale	300–350	50.0	1656	180	25	24–28
						Total	17,532–21,903
South Hemisphere	Blue whale	600–800	83.0	3708	120	100	287–383
	Pygmy blue whale	2,000–6,000	68.9	3205	120	100	827–2,481
	Fin whale	10,000–20,000	48.0	2415	120	100	3,116–6,232
	Sei whale	35,000–45,000	17.5	1096	120	80	3,960–5,091
	Bryde's whale	78,000–108,000	13.2	879	120	40	3,538–4,899
	Minke whale (two species)	650,000–950,000	7.0	535	120	100	44,858–65,561
	Humpback whale	15,000–16,000	26.5	1517	120	100	2,936–3,131
	Southern right whale	6,500–7,500	55.0	2687	120	100	2,253–2,600
						Total	61,775–90,379

abundances were obtained from working papers and reports of the INTERNATIONAL WHALING COMMISSION, reports from the U.S. National Marine Fisheries Service, and the primary literature. In some cases, no reliable estimates are available and broad ranges were used. Daily ingestion rates for baleen whales during the feeding season were estimated from energetic requirements as a function of body weight following Sigurjónsson and Vikingsson (1997). A daily ingestion rate for seals was estimated as 7% of body weight. Average body weights, the percentages of euphausiids in the diets, and the caloric value of euphausiids (0.93 kcal/g) were taken from the primary literature. The duration of the feeding season was assumed to be 180 days for Northern Hemisphere baleen whales and seals, 120 days for Southern Hemisphere baleen whales and Antarctic and sub-Antarctic fur seals, and 335 days for crabeater, leopard, and Ross seals.

Although Tables I and II are based on several simplifying assumptions, some general conclusions may be drawn. Total consumption of euphausiids by marine mammals is on the order of 10–20 million tons per year in the North Pacific, 15–25 million tons per year in the North Atlantic, and 125–250 million tons per year in the Southern Hemisphere, with the bulk of the latter portion consumed in the Southern Ocean. In the North Atlantic, the largest portion is consumed by fin whales followed by minke whales. In the North Pacific, consumption is distributed more evenly, with fin and bowhead whales consuming the most, followed by blue, sei, Bryde's, and minke whales, all of which consume similar portions. In the Southern Hemisphere, comparable proportions of euphausiids are consumed by crabeater seals and baleen whales. Of the estimated total krill consumption by baleen whales in the Southern Ocean, minke whales (two species) consume approximately two-thirds. Crabeater seals consume more krill than any other marine mammal population in the world.

These crude calculations suggest that baleen whales consume a substantial amount of euphausiids; moreover, their food requirements must have been several times more prior to commercial whaling. Unfortunately, there is little information on which to judge whether krill production was higher prior to the onset of commercial whaling or whether other krill predators (e.g., crabeater seals) benefited as a result of the decline in baleen whale stocks.

What is more apparent is that krill abundance can vary dramatically over relatively short periods of time and that baleen whales have adapted to this variability. Their size and ability to accumulate substantial energy stores allow them to integrate over large distances and periods of time in their search for food.

TABLE II
Consumption of Euphausiids by Seals

Ocean basin	*Seal species*	*Abundance*	*Average body weight (tons)*	*Summertime ingestion rate (10^3 kcal/day)*	*Feeding period (days)*	*% krill in diet*	*Krill consumed (10^3 tons)*
Northern Hemisphere	Ringed seal	6,000,000–7,000,000	75	5.3	180	25	1418–1654
	Harp seal	100,000–400,000	130	9.1	180	25	41–176
						Total	1458–1830
Southern Hemisphere	Crabeater seal	15,000,000–30,000,000	220	15.4	335	94	72,742–145,484
	Leopard seal	300,000–500,000	275	19.3	335	37	716–1,193
	Antarctic fur seal	1,000,000–1,500,000	50	3.5	120	50	210–315
	Sub-antarctic fur seal	300,000–500,000	85	6.0	120	50	107–179
	Ross seal	125,000–225,000	175	12.3	335	10	51–92
						Total	73,826–147,263

Their longevity allows them to spread reproductive effort over several years. It is reasonable to expect, however, that the supply of euphausiids will not be sufficient in all years to meet total energy requirements and that reproductive success and population growth among krill-dependent baleen whales may vary from year to year in response to the availability of their prey.

VI. Anthropogenic Effects

The production of euphausiids can be very sensitive to environmental conditions. This raises two concerns with regard to the influence of human activities. The first is that highly productive euphausiid populations may be able to sustain large fisheries. The second is that climatic change (whether man-induced or not) may affect the frequency of environmental conditions that are favorable for reproductive success. Because these are relatively recent developments, we cite three studies as entries into a larger body of literature.

Fisheries on euphausiids have the potential of being the largest in the world. In their review of krill fisheries, Nicol and Endo (1999) described the harvest of *E. pacifica* off the coasts of Japan and western Canada, *T. inermis* off the coasts of Japan and eastern Canada, *E. nana* off the coast of Japan, *T. raschii* and *M. norvegica* off the coast of eastern Canada, and *E. superba* in the Southern Ocean. In recent years, the harvest of *E. pacifica* off Japan (ca. 60,000 tons per year) and *E. superba* in the Scotia Sea region of the Southern Ocean (ca. 80,000 tons per year) comprised over 90% of the world harvest of euphausiids. Nicol and Endo (1999) noted that these yields are well within their theoretical potentials, although expansion of the coastal fisheries is unlikely because of ecological, economic, and political considerations. They further note, however, that as conventional fisheries decline and demand for krill as aquaculture feed increases, fishing pressure is likely to shift to *E. superba* in the Southern Ocean where current harvests are far below current estimates of sustainable yields.

Evidence suggests that the production of euphausiids may be affected by long-term climatic change. Warming of the surface waters of the California Current since the mid-1970s has been accompanied by a reduction in the depth of the thermocline, reduced nutrient input via coastal upwelling, reduced primary production, and an overall decrease in macrozooplankton biomass by as much as 80% (Roemmich and McGowan, 1995). Euphausiids are the dominant taxa in the macrozooplankton fauna of the California Current and have shown decreased abundances during warm (El Niño) years and increased abundances during cold (La Niña) years. A 50-year warming trend in the Antarctic Peninsula region has been associated with a decrease in the annual production of sea ice. Loeb *et al.* (1997) correlated the reproductive success of *E. superba* with the wintertime extent of sea ice and suggested that the warming trend may cause a decrease in the frequency of strong year classes of Antarctic krill, a decrease in the mean population abundance of krill, and a change in the carrying capacity of vertebrate krill predators in the region.

Language Learning

LOUIS M. HERMAN
University of Hawaii, Honolulu

No single trait has been linked more closely with the human species than language. However, the definition of language and its uniqueness as a human trait continue to be areas of study and debate. Some, such as the linguist Noam Chomsky, take an evolutionary discontinuity position professing that language is a highly unique adaptation supported by special modifications of the brain that appear only in humans. Others, such as the anthropologist Barbara King, favor a continuity position, which suggests that language must have its roots in earlier hominoid adaptations for communication and that some of these adaptations may still be extant in modern ape species.

I. Human Language and Ape Language

The work on teaching various language-like systems to apes by Beatrice and Alan Gardner, David Premack, Duane Rumbaugh, and others, beginning in the mid-1960s and continuing throughout the decade of the 1970s, seemed to provide a genuine link between human and ape in fundamental language competency. This early work reported that chimpanzees were able to learn to use and understand not only words but also sentences. Sentences give human language its great communicative power through the infinite variety of meanings that can be constructed by the recombination of words. To understand a sentence the human listener must take account of both the meaning of the words and their grammatical relationships to one another, as governed by word order or other syntactic devices. This early work on teaching language to apes was thrown into disarray, however, by additional studies and criticisms from other researchers, such as Herbert Terrace and Carolyn Ristau. These researchers argued that the putative "sentences" produced by the apes were largely an artifact of context, imitation, or cueing. In particular, although sequences of symbols were indeed produced by the apes, the sequences had no syntactic structure that enhanced, explained, or modified meaning.

Until recently, the work with apes was focused on language production and paid scant attention to language comprehension. Investigators attempted to teach the apes to produce language—where words were represented by gestures, keyboard symbols, or other types of artificial symbols. These investigators assumed that if the ape produced a word, or series of words, that it therefore understood what the word or sequence represented. They also assumed that the ape could understand those same words or sequences when produced by the human partner. These assumptions, when finally tested, proved false. It was shown, instead, that comprehension did not automatically flow from language production. The preeminence of comprehension in language development, only recently appreciated in the ape language field, has long been emphasized among those studying child language. Language comprehension by young children develops earlier than language production, and even into adulthood comprehension vocabularies exceed speaking vocabularies.

Recent work with bonobo chimpanzees, pioneered by Sue Savage-Rumbaugh, has emphasized language comprehension and has progressed well beyond the earlier ape language studies. The bonobos have shown an ability to learn to understand instructions given in spoken English sentences. Together with some of her earlier work, Savage-Rumbaugh has shown that chimpanzees can learn to appreciate the symbols (words) of the language "referentially." The understanding that words *refer* to things or events in the real world is one of the key characteristics of human language. Among other things, referential understanding enables us to discuss things that are not immediately present or that happened at a different place or time.

II. Dolphins and Language

A. Natural Language?

Dolphins (including the common bottlenose dolphin *Tursiops truncatus*) produce various types of sounds, including clicks, burst-pulse emissions, and whistles. Clicks are used for ECHOLOCATION, the dolphin's form of sonar. Through echolocation, the

dolphin can examine its world through sound by listening to the echoes returning from objects struck by the clicks. Burst-pulse sounds may indicate the dolphin's emotional state, ranging from pleasure to anger. However, these type of vocalizations have been little studied and much remains to be learned about them. Whistles may be used for COMMUNICATION, but it is still an open question as to whether, or how much, whistle communication is intentional versus unintentional (e.g., rapidly repeated whistling may be elicited by stress, without any specific intention to convey that emotional state to others). During the 1960s, researchers attempted to determine whether the whistle vocalizations might be a form of language. Investigators recorded whistles from many dolphins in many different situations, but failed to demonstrate sufficient complexity in the vocalizations to support anything approaching a human language system. Some of the early work instead pointed to the stereotypy of the whistles from individual dolphins, leading David and Melba Caldwell to suggest that the whistle functioned principally as a "signature," with each individual dolphin producing a unique signature. Presumably, this enabled that individual to be identified by others. Other researchers have noted, however, that there can be a great deal of flexibility in the whistle. Douglas Richards, James Wolz, and Louis Herman, at the Kewalo Basin Marine Mammal Laboratory at the University of Hawaii, reported a study showing that a bottlenose dolphin could use its whistle mode to imitate a variety of sounds generated by a computer and broadcast underwater into the dolphin's habitat. Peter Tyack later reported that one dolphin could imitate another's whistle, thereby possibly referring to or calling that individual. As was noted earlier, referring symbolically to another individual, or to some other object or event in the environment, is one of the basic characteristics of a language. However, we still do not know to what extent the dolphin's whistles may be used to refer to things other than themselves or another dolphin. This is a fruitful area for additional study, however.

Although the evidence strongly suggests that dolphins do not possess a natural language, like the case for apes, it is still important and informative to study whether dolphins might nevertheless be able to learn some of the fundamental defining characteristics of human language. Any demonstration of language-learning competency by dolphins would bear on questions of the origins of human language, shifting the emphasis from the study of precursors in other hominoid species to common convergent characteristics in ape and dolphin that might lead to advanced communicative and cognitive capacities.

B. Early Attempts at Teaching Language to Dolphins

From the mid-1950s to the mid-1960s, John Lilly promoted the idea that bottlenose dolphins might possess a natural language. He based this supposition on this species' exceptionally large brain with its richly developed neocortex. He reasoned that the large brain must be a powerful information processor having capabilities for advanced levels of intellectual accomplishment, including the development of a natural language. He set about to uncover the supposed language. Failing in that quest, he then attempted, also without success, to teach human vocal language (English) to dolphins he maintained in his laboratories. Dolphins have a rich vocal repertoire, but not one suited to the production of English phonemes. The procedures used by Lilly and data he obtained were presented only sketchily, making any detailed analysis of his efforts at teaching language moot.

In the mid-1960s, Duane Batteau developed an automated system that translated spoken Hawaiian-like phonemes into dolphin-like whistle sounds that he projected underwater into a lagoon housing two bottlenose dolphins. He then attempted to use these sounds as a language for conveying instructions to the dolphins. A major flaw in his approach, however, was that individual sounds were not associated with individual semantic elements, such as objects or actions, but instead functioned as holophrases (complexes of elements). For example, a particular whistle sound instructed the dolphin to "hit the ball with your pectoral fin." Another sound instructed the dolphins to "swim through a hoop." Unlike a natural language, there was no unique sound to refer to *hit* or *ball*, or *hoop*, or *pectoral fin*, or any other unique semantic element. Hence, there was no way to recombine sounds (semantic elements) to create different instructions, such as "hit the hoop (rather than the ball) with your pectoral fin." After several years of effort, the dolphins were able to learn to follow reliably the holophrastic instructions conveyed by each of 12 or 13 different sounds. However, because of the noted flaw in the approach to construction of a language, the experiment failed as a valid test of dolphin linguistic capabilities.

C. Kewalo Basin Dolphin Language Studies

The work on dolphin language competencies by Louis Herman and colleagues at the Kewalo Basin Marine Mammal Laboratory in Honolulu was begun in the mid-1970s and emphasized language comprehension from the start. These researchers, working principally with a bottlenose dolphin named Akeakamai housed at the laboratory, constructed a sign language in which words were represented by the gestures of a person's arms and hands. The words referred to objects in the dolphin's habitat, to actions that could be taken to those objects, and to relationships that could be constructed between objects. There were also location words, *left* and *right*, expressed relative to the dolphin's locations, that were used to refer to a particular one of two objects having the same name, e.g., *left hoop* vs *right hoop*. Syntactic rules, based on word order, governed how sequences of words could be arranged into sentences to extend meaning. The vocabulary of some 30 to 40 words, together with the word-order rules, allowed for many thousands of unique sentences to be constructed. The simplest sentences were instructions to the dolphin to take named actions to named objects. For example, a sequence of two gestures glossed as *surfboard over* directs the dolphin to leap over the surfboard, and a sequence of three gestures glossed as *left Frisbee tail-touch* directs the dolphin to touch the Frisbee on her left with her tail. More complex sentences required the dolphin to construct a relationship between two objects, such as taking one named object to another named object or placing one named object in or on another named object. To interpret relational sentences correctly, the dolphin had to take

account of both word meaning and word order. For example, a sequence of three gestures glossed as *person surfboard fetch* tells the dolphin to bring the surfboard to the person (who is in the water), but *surfboard person fetch*, the same gestures rearranged, requires that the person be carried to the surfboard. By incorporating *left* and *right* into these relational sentences, highly complex instructions could be generated. For example, the sequence of five gestures glossed as *left basket right ball in* asks the dolphin to place the ball on her right into the basket on her left. In contrast, the rearranged sequence *right basket left ball in* means the opposite, "put the ball on the left into the basket on the right." The results, published by Louis Herman, Douglas Richards, and James Wolz, showed that the dolphin was proficient at interpreting these various types of sentences correctly, as evidenced by her ability to carry out the required instructions, including instructions new to her experience. These were the first published results showing convincingly an animal's ability to process both semantic and syntactic information in interpreting language-like instructions. Semantics and syntax are considered core attributes of any human language.

Ronald Schusterman and Kathy Krieger tested whether a California sea lion (*Zalophus californianus*) named Rocky might be able to learn to understand sentence forms similar to those understood by the dolphin Akeakamai. Rocky was able to carry out gestural instructions effectively for simpler types of sentences requiring an action to an object. The object was specified by its class membership (e.g., "ball") and, in some cases, also by its color (black or white) or size (large or small). In a later study, Schusterman and Robert Gisiner reported that Rocky was able to understand relational sentences requiring that one object be taken to another object. These reports suggested that the sea lion was capable of semantic processing of symbols and, to some degree, of syntactic processing. A shortcoming of the sea lion work, however, was the absence of contrasting terms for relational sentences, such as the distinction between "fetch" (take to) and "in" (place inside of or on top) demonstrated for the dolphin Akeakamai. Additionally, unlike the dolphin, the sea lion's string of gestures were given discretely, each gesture followed by a pause during which the sea lion looked about to locate specified objects before being given the next gesture in the string. In contrast, gestural strings given to the dolphin Akeakamai were without pause, analogous to the spoken sentence in human language. Further, Rocky did not show significant generalization across objects of the same class (e.g., different balls), but unlike the dolphin seemed to regard a gesture as referring to a particular exemplar of the class rather than to the entire class. Thus, although many of the responses of the sea lion resembled those of the dolphin, the processing strategies of the two seemed different, and the concepts developed by the sea lion appeared to be more limited than those developed by the dolphin.

D. Akeakamai's Knowledge of the Grammar of the Language

As a test of Akeakamai's grammatical knowledge of the language she had been taught, Louis Herman, Stan Kuczaj, and Mark Holder constructed *anomalous* gestural sentences. These were sentences that violated the syntactic rules of the language or the semantic relations among words. The researchers then studied the dolphin's spontaneous responses to these sentences. For example, the researchers compared the dolphin's responses to three similar gestural sequences: *person hoop fetch*, *person speaker fetch*, and *person speaker hoop fetch*. The first sequence is a proper instruction; it violates no semantic or syntactic rule of the learned language. It directs the dolphin to bring the hoop to the person, which the dolphin does easily. The second sequence is a syntactically correct sequence but is a semantic anomaly inasmuch as it directs the dolphin to take the underwater speaker, firmly attached to the tank wall, to the person. The dolphin typically rejects sequences like this by not initiating any action. The final sequence is a syntactic anomaly in that there is no sequential structure in the grammar of the language that provides for three object names within a sequence. However, embedded in the four-item anomaly are two semantically and syntactically correct three-item sequences: *person hoop fetch* and *speaker hoop fetch*. The dolphin in fact typically extracts one of these subsets and carries out the instruction implicit in that subset by taking the hoop to the person or to the underwater speaker.

These different types of responses revealed a rather remarkable and intelligent analysis of the sequences. Thus, the dolphin did not terminate her response when an anomalous initial sequence such as *person speaker* was first detected. Instead, she continued to process the entire sequence, apparently searching backward and forward for proper grammatical structures as well as proper semantic relationships, until she found something she could act on, or not. This analytic type of sequence processing is part and parcel of sentence processing by human listeners.

E. Understanding of Symbolic References to Absent Objects

Louis Herman and Paul Forestell tested the dolphin Akeakamai's understanding of symbolic references to objects that were not present in the dolphin's habitat at the time the reference was made. For this purpose, they constructed a new syntactic frame consisting of an object name followed by a gestural sign glossed as *"question."* For example, the two-item gestural sequence glossed as *basket question* asks whether a basket is present in the dolphin's habitat. The dolphin could respond *yes* by pressing a paddle to her right or *no* by pressing a paddle to her left. Over a series of such questions, with the particular objects present being changed over blocks of trials, the dolphin was as accurate at reporting that a named object was absent as she was at reporting that it was present. These results gave a clear indication that the gestures assigned to objects were understood referentially by the dolphin, i.e., that the gestures acted as symbolic references to those objects.

F. Interpreting Language Instructions Given through Television Displays

The television medium can display scenes that are representations of the real world, or sometimes of imagined worlds. As viewers, we understand this and often respond to the displayed content similarly to how we might respond to the real world. We of course understand that it is a representation and

not the real world. It appears, however, that an appreciation of television as a representation of the real world does not come easily to animals, even to apes. Sue Savage-Rumbaugh wrote in her book, "Ape Language," that chimpanzees show at most a fleeting interest in television, and that from their behavior it was not possible to infer that they were seeing anything more than changing patterns or forms. Her own language-trained chimpanzee subjects, Sherman and Austin, only learned to attend and to interpret television scenes after months of exposure in the presence of human companions who reacted to the scenes by exclaiming or vocalizing at appropriate times. Louis Herman, Palmer Morrel-Samuels, and Adam Pack tested whether the dolphin Akeakamai might respond appropriately to language instructions delivered by a trainer whose image was presented on a television screen. Akeakamai had never been exposed to television of any sort previously. Then, for the first time, the researchers simply placed a television monitor behind one of the underwater windows in the dolphin's habitat and directed Akeakamai to swim down to the window. On arriving there she saw an image of the trainer on the screen. The trainer than proceeded to give Akeakamai instructions through the familiar gestural language. The dolphin watched and then turned and carried out the first instruction correctly and also responded correctly to 11 of 13 additional gestural instructions given to her at that same testing session. In further tests, Akeakamai was able to respond accurately even to degraded images of the trainer, consisting, for example, of a pair of white hands moving about in black space. The overall results suggested that Akeakamai spontaneously processed the television displays as representations of the gestural language she had been exposed to live for many years previously.

III. Implications

The results of the language comprehension work with the bonobo chimpanzee and the dolphin Akeakamai show many similarities, especially in the receptivity of the animals to the language formats used and in their proficiency at responding to sequences of symbols. The dolphin has been tested in more formal procedures than the bonobo, leading to a fuller understanding of the dolphin's grammatical competencies than has been attained for the chimp. Findings with the bottlenose dolphin are in keeping with many other demonstrations of the cognitive abilities of this species. The advanced cognitive abilities of apes are also well documented. An early summary by Herman (1980, p. 421) still seems appropriate to accommodate the convergent cognitive and language-learning abilities of ape and dolphin: "The major link that cognitively connects the otherwise evolutionarily divergent (dolphins) . . . and primates may be social pressure—the requirement for integration into a social order having an extensive communication matrix for promoting the well-being and survival of individuals. . . . Effective functioning in such a society demands extensive socialization and learning. The extended maturational stages of the young primate or dolphin and the close attention given it by adults and peers . . . provide the time and tutoring necessary for meeting these demands. In general, high levels of parental care and high degrees of cortical encephalization go together. . . . It is not difficult to imagine that the extensive development of the brain in (dolphins) . . . and the resulting cognitive skills of some members of this group, have derived from the demands of social living, including both cooperation and competition among peers, expressed within the context of the protracted development of the young. These cognitive skills may in turn provide the behavioral flexibility that has allowed the diverse family of (dolphins) . . . to successfully invade so many different aquatic habitats and niches."

Leaping Behavior

Bernd Würsig
Texas A&M University, Galveston

Dolphins and whales leap above water in seemingly exuberant displays of sheer joy. While play may at times be a cause of leaping, there appear to be multiple leap types and reasons, not totally understood.

When large whales leap, the activity is generally termed breaching. Whales appear to breach to communicate to others, due to a high activity level (or state of alertness), or—at times—from apparent frustration or anger after a social interaction with one or more other whales (Whitehead, 1985). Breaching may also occur for the pure "joy" or "fun" of it, but these potential motivations are difficult for researchers to assess. Leaping by the smaller toothed whales may have similar general functions, as well as several of the more specific ones outlines here.

I. Basic Description

Leaping clear of the water is always an energetic and usually a highly acrobatic feat. First, to clear the water the cetacean needs to attain a rapid forward speed and momentum, near the limit of its SWIMMING capability. It generally bends its body abruptly to exit the water, then twists the body midair to reenter the water in some structured fashion. Even a noisy "belly flop" after a leap has been designed as such, as multiple similar leaps of the same animals demonstrate. Reentering the water can be head first, creating minimal splash and NOISE. It can consist of a side, back, or belly splash, resulting in a welter of white water and foam and a considerable percussive (splash) noise in-air and underwater. Finally, there is the "showy" acrobatic leap that consists of spins, somersaults, and various in-air twists. Frame-by-frame analysis of high-speed photographs shows that dolphins control these acrobatics to within split-second timing, affecting muscle movements that allow them to perform the same leap and reentry onto the water again and again. In human terms, a well-trained gymnast or pool diver comes to mind. Leaps tend to last for 1 to 2 sec, depending on the acrobatics being performed and the size of the leaping individual.

II. The Head-First Reentry Leap

There are three main variations of this leap that tend to create little water disturbance or noise upon reentry. One consists of a "stationary" leap, where the animal comes steeply from depth, usually greater than three body lengths. It leaps in-air, breathes, and tucks its body into a bend to reorient the head downward, then rapidly descends into depth at or very near the original exit point. This leap appears to be executed for the animal to leave whatever it is doing at depth for a minimal time, breathe, and use the in-air weight of its body to regain its position. The need for such an efficient mechanism to breathe becomes clear when we consider that dolphins feeding or mating at depth, for example, essentially need to interrupt these activities to obtain life-sustaining air. If they can do so rapidly, all the better. The stationary leap is performed singly by dolphins herding food fish below the surface (Würsig, 1979), but often in twos or threes during socializing (Norris *et al.*, 1994) (Fig. 1).

A second head-first reentry leap consists of rapid swimming just below the surface, a very abrupt bend of the body to exit the water, and then a long arcuate in-air leap that may propel the dolphin forward by up to three times its own body length. While the reentry is head first, there is nevertheless some splashing of water due to the rapidity of the action, kicked up by the body as it exits and again as it enters. This is the "running leap" of dolphins moving at speed, a form of high porpoising.

Figure 1 *A head-first reentry of a dusky dolphin.*

Dolphins propel themselves underwater with several powerful but rapid tail beats and then "sail" through the air, a medium 800 times less dense than water. There is considerable drag generated by crossing the air/water interface, but for an animal that needs to come to the surface to breathe anyway (such as penguins and dolphins), travel efficiency increases above a particular speed by leaping rather than swimming. For a 2.5-m-long dolphin, the crossover speed from swimming to leaping is about 4.6 m/sec, or 16.6 km/hr (Au and Weihs, 1980). Above about 4 m body length (and concomitant body weight), high porpoising is no longer as easy, although killer whales (*Orcinus orca*) moving very rapidly may leap in this manner for short periods of time (Fig. 2).

The third head-first reentry leap is designed to gain height. Dolphins, often in twos or threes, leap as high as three times their own body lengths above the surface of the water, usually but not always reentering the water head first. A 2.5-m male pantropical spotted dolphin (*Stenella attenuata*)—spotted dolphins are the champion high leapers—thus leaps about 7 m into the air, or the equivalent of over two apartment stories high. While these leaps may be performed largely for "fun," they may also serve the function of seeing to greater distance by gaining height. Dusky dolphins (*Lagenorhynchus obscurus*) leap in this fashion just before high porpoising toward feeding aggregations with flocking birds some kilometers away (Würsig and Würsig, 1980) (Fig. 3).

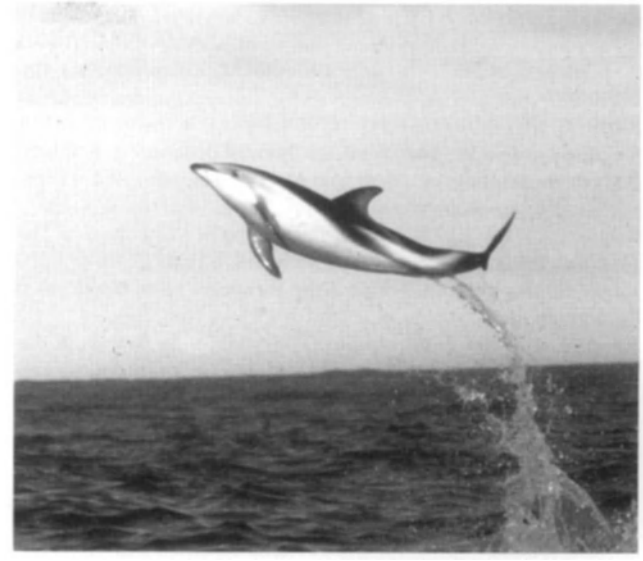

Figure 3 *A high leap of a dusky dolphin.*

III. The Noisy Leap

When dolphins or whales fall back onto the water with a broad side of the body, they invariably create a large splash and a percussive slap sound. Frame-by-frame analysis of high-speed photography shows that there are actually two splashes: one is created as the animal falls onto the water surface and initiates a crater of water underneath it and the other is the secondary splash (and slap sound) produced as the crater collapses upon itself. This cavitation is particularly dramatic for breaching whales, but is associated with almost all noisy leaps.

Dolphins that noisy-leap exit the water in similar fashion as in head-first reentry leaps, but twist the body to reenter with back, side, or belly first. Many noisy leaps end with the dolphin merely falling back onto the water surface. Others are particularly designed to have the animal reenter in a predetermined fashion, and high-speed photography shows subtle tail, flipper, head, or other body readjustments even split seconds before reentering and appearing to be structured to force the body onto the water with a maximal intensity of splash. These observations have led to speculation that noisy leaps are structured for omni-directional communication among dolphins and whales. Indeed, noisy leaps tend to occur more often in higher wind states (when near-surface ambient noise greatly increases), and this observation fits with the hypothesis of communication. Noisy leaps also occur around the periphery of near-surface schools, and in that case, the percussive slaps, as well as the underwater bubble clouds formed by dolphins reentering the water, may serve to frighten fish and cause them to school or aggregate more tightly. Dolphins may at times also stun or debilitate fish prey with the slaps of noisy leaps (as well as with tail slaps), but there is no detailed information on this possibility (Fig. 4).

Figure 2 *Dusky dolphins porpoising.*

IV. The Acrobatic Leap

Some dolphins are especially showy for at least some of their leaps, with spins, somersaults, combinations of flips, head twists, extra tail kicks in-air, and so on. These leaps are almost always associated with an obviously high level of social activity in a school or pod, as evidenced by social rubbing, sexual activity, and a cacophony of whistle and other sounds. Acrobatic leaps usually occur in bouts, with one dolphin (or whale) leaping at least several times. The more social the group, the more leaping dolphins and the longer the individual bouts. These leaps appear graceful to our human eyes and appear particularly structured to be enjoyed in the making and the viewing, like art. However, this may not be the case; we simply do not know.

Spinner dolphins (*Stenella longirostris*) spin by rotating their body rapidly around the long axis up to six times (usually

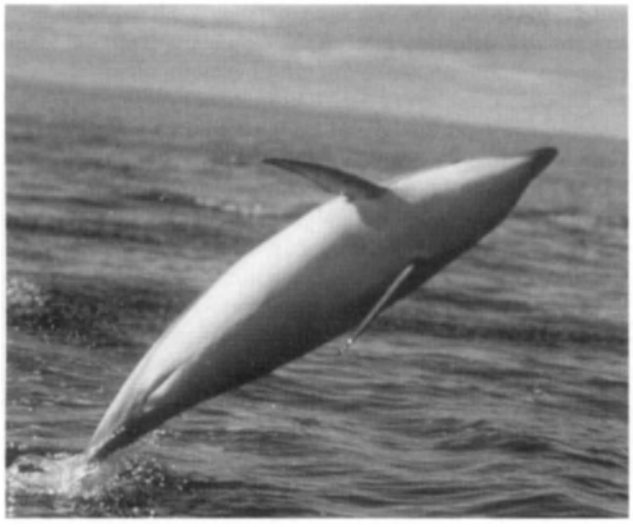

Figure 4 *A side slap of a dusky dolphin.*

Figure 5 *A spinner dolphin spinning.*

two to four times) before falling back into the water. They do so in both vertical spins and horizontal fashion (Norris and Dohl, 1980). Members of the genus *Lagenorhynchus*, such as Pacific white-sided (*L. obliquidens*) and dusky dolphins, are probably the most aerially acrobatic of all dolphins and whales, with somersaults, twists, and various inventive bends and contortions (Brownell and Cipriano, 1999). Individuals also have the longest bouts of any of the dolphins (some whale breach bouts are as long), with up to 36 somersaults having been counted in one dolphin in one about 5-min duration. Interestingly, *Lagenorhynchus* spp. individuals will "never" change leap type during a bout. If a dusky dolphin begins a backwards somersault with a half twist to the left and a tail kick just before reentering the water, it will continue this same leap, with absolutely no noticeable variation, during that leap bout. Toward the end of the bout, it will tire, muscle action will slow, and the leap will be slightly imperfect. It then quits and breathes while resting at the surface for several minutes. Later, in a different bout, the same individual will leap differently, demonstrating that it knows more than one leap type.

Acrobatic leaps tend to be noisy, but are not structured specifically to make noise. They are structured to be acrobatic, and it is difficult to imagine that they occur for anything but the "fun" (or the art) of it. A more scientifically acceptable explanation may be that acrobatic leaps are not merely an outgrowth of a high level of social activity, but are themselves a call for social activity. Acrobatic leap types may thus serve a social facilitation function that helps to coordinate members of a school or pod. Such facilitation may be especially useful to animals that coordinate finding and aggregating of food and that may need to establish and maintain delicate balances of social and sexual hierarchies. One argument against this stands out: dolphins leaping acrobatically are not being watched by others. They perform their show above the surface while, at any one time of a leap, most or all others are below. Acrobatic leaps may create somewhat different splash sounds from other more simple leaps, but this is not known (Figs. 5 and 6).

V. Conclusions

The descriptions in this article are not to be thought of as complete explanations of the various—and variable—leaps of cetaceans. There is much that we do not yet know, but it is certainly fair to say that surface-active cetaceans, being large-brained social mammals, may have many different reasons for their actions. One long-existing guess for leaping may have some truth to it as well. This is the suggestion that leaping, and the attendant splashing onto the water's surface, may be an attempt to dislodge parasites or other biological hitchhikers. Indeed, there is evidence for Hawaiian spinner dolphins, that individuals with remoras attached to their sides or bellies leap more than those that do not, and the author has seen remoras fly off spinning spinner dolphins, even before the dolphins hit the water. To get rid of potentially bothersome (and drag-inducing) freeloaders may be a partial explanation, but it cannot be the entire explanation. Leaping occurs for a variety of reasons, having to do with locomotion,

Figure 6 *A dusky dolphin somersaulting.*

rapid breathing, seeing in air, communicating, possibly scaring prey, social–sexual displaying and facilitation, removal of ectoparasites, and—most certainly—fun.

A discussion of leaping would be incomplete without mention of other than cetacean marine mammals. Indeed, otariid pinnipeds also high-porpoise (probably for the same hydrodynamic efficiency consideration as for dolphins), and especially fur seals and sea otters leap at the surface by rapidly rolling around their own axes. This activity serves to aerate the extremely fine, long, and dense pelage of these marine mammals that use air for insulation. Leaping in pinnipeds and sea otters at times may also consist of play activity, but there is no further information on this point

Leopard Seal

Hydrurga leptonyx

TRACEY L. ROGERS

University of Sydney, Australia

Leopard seals are large seals, displaying sexual dimorphism where the females are larger than the males. Females grow up to 3.8 m and weigh up to 500 kg, whereas males grow up to 3.3 m and weigh up to 300 kg.

I. Distribution

The main leopard seal population remains within the circumpolar Antarctic pack ice but the seals are regular, although not abundant, visitors to the sub-Antarctic islands of the southern oceans and to the southern continents. The most northerly leopard seal sightings are from the Cook Islands. Juveniles appear to be more mobile, moving further north during the winter. Because it does not need to return to pack ice to breed, the leopard seal can escape food shortages during winter by dispersing northwards. Every 4 to 5 years the number of leopard seals on the sub-Antarctic islands oscillates from a few to several hundred seals. The periodic dispersal could be related to oscillating current patterns or resource shortages in certain years.

The leopard seal population is estimated to be 222,000 to 440,000. During summer, leopard seals breed on the outer fringes of the pack ice where they are solitary and sparsely distributed. Their density is inversely related to the amount of pack ice available to the seals as haul-out platforms. Pack ice cover varies with the season, from a maximum between August and October to a minimum between February and March. Population densities are greatest in areas of abundant cake ice (ice floes of 2 to 20 m in diameter) and brash ice (ice floes greater than 2 m in diameter), whereas they are least in areas with larger floes. Densities range from 0.003 to 0.151 seals/km^2, and there is an age-related difference in their spatial behavior. Due to intraspecific aggression there is a greater degree of spatial separation among older seals.

II. Diet

Leopard seals take a diverse range of prey, including fish, cephalopods, sea birds, and seals. Different food sources are used when available or when opportunities to take other more sought after prey are few. Krill makes up the largest proportion of their diet, particularly during the winter months when other food types are not abundant. At this time the leopard seals must compete directly with krill-feeding specialists, such as the crabeater seal (*Lobodon carcinophaga*) and Adélie penguin. This is believed to be a time of potential food shortage and causes some juvenile leopard seals to move north from the pack ice during the austral winter. The leopard seal is responsible for more predation on warm-blooded prey than any other pinniped. Leopard seals capture and eat juvenile crabeater seals in particular, but also prey on Weddell (*Leptonychotes weddellii*), Ross (*Ommatophoca rossii*), southern elephant (*Mirounga leonina*), sub-Antarctic and Antarctic fur seals (*Arctocephalus tropicalis* and *A. gazella*) and southern sea lions (*Neophoca cinerea* and *Phocarctes hookeri*). Newly weaned crabeater seals are the most vulnerable and are taken from November to February. Crabeater seal survivors bear characteristic parallel paired scars from leopard seal attacks, and approximately 78% of adult crabeater seals display such marks. The teeth of the leopard seal have a dual role; the large recurved canines and incisors are designed for gripping and tearing prey, whereas the upper and lower tricuspid (three cusped) molars interlock to provide an efficient krill sieve.

III. Reproductive Biology

Male leopard seals are sexually mature by 4.5 years and females by 4 years of age. Females give birth to their pups and wean them on the ice floes of the Antarctic pack ice. Males do not remain with the females; only mother–pup groups are observed on ice floes. Length at birth is about 120 cm, with rapid growth through the first 6 months postpartum. Births are believed to occur from October to mid-November and mating

Figure 1 *Leopard seal in threatening posture.*

from December to early January, after the pups have weaned. Lactation is believed to last for up to 4 weeks. Mating in the wild has been observed rarely, but captive seals mount only when in the water. There is a period of delayed implantation from early January to mid-February. Implanted fetuses are found after mid-February when the corpus luteum (glandular structure in the ovary) has begun to increase in size and the corpus albicans (scar from ovarian glandular structure) from the previous pregnancy has continued to regress.

Acoustic behavior is important in the MATING SYSTEM of the leopard seal. Leopard seals become highly vocal prior to and during their breeding season (Fig. 1). Lone male leopard seals vocalize for long periods each day, from early November through January. Female leopard seals also use long-distance acoustic displays during the breeding season. However, female seals vocalize for a brief period only from the beginning of estrus until mating, presumably to advertise sexual receptivity. The calls of the leopard seal are at low-to-medium frequencies and so powerful that they can be heard through the air–water interface and felt through the ice.

Lobtailing

NATHALIE JAQUET
Texas A&M University, Galveston

Lobtailing is performed by the majority of cetacean species. It consists of slapping either the ventral or the dorsal side of the tail flukes against the water (Fig. 1) any number of times, from a single tail slap to over a hundred depending on the species and the context. It is a purposeful behavior, happening mainly in social and/or foraging contexts. As is the case with many social displays, lobtailing seems to be contagious and is often accompanied by breaches. The significance of lobtailing is still a mystery and may vary among species and contexts. Although its is probable that lobtailing is a form of communication, scientists are still far from having uncovered the exact functions of lobtailing.

I. Who Lobtails?

Although a large number of cetacean species have been observed lobtailing at least once, quantitative information on lobtailing rate is only available for a very few species. What is clear, however, is that there is a very high variability in the occurrence of lobtailing among species. Some species of large whales, such as sperm whales (*Physeter macrocephalus*), humpback whales (*Megaptera novaeangliae*), right whales (*Eubalaena australis, E. japonica* and *E. glacialis*), and gray whales (*Eschrichtius robustus*), are commonly seen lobtailing. However, lobtailing is much less common in minke (*Balaenoptera acutorostrata* and *B. bonaerensis*), sei (*B. borealis*), Bryde's (*B. edeni*), blue (*B. musculus*), and fin (*B. physalus*) whales. Large differences in the lobtailing rate also exist among species of small cetaceans: porpoises and river dolphins are seldom observed lobtailing whereas lobtailing is very common in most species of Delphinidae. For the least known species of cetaceans (e.g., many species of beaked whales and some poorly known species of dolphins), lobtailing frequencies are unknown.

However, despite the paucity of quantitative information available on lobtailing rates, it seems that, in general, species with complex social systems have a higher lobtailing rate than species that are more solitary. This is consistent with what has been found for some closely related behavior such as breaching.

II. How?

Lobtailing is performed differently by large and small cetaceans. Baleen whales and sperm whales lobtail when vertically in the water column with their tail flukes high above the water, the stock is then bent and the flukes are slapped forcefully on the water surface (Fig. 2). While lobtailing, these whales tend to stay almost stationary. However, small delphinidae usually lobtail while lying horizontally in the water, either on their belly or

Figure 1 *Lobtailing sperm whale. This is the first lobtail of a sequence of eight consecutive lobtails and thus the flukes tend to be still very high above the water.*

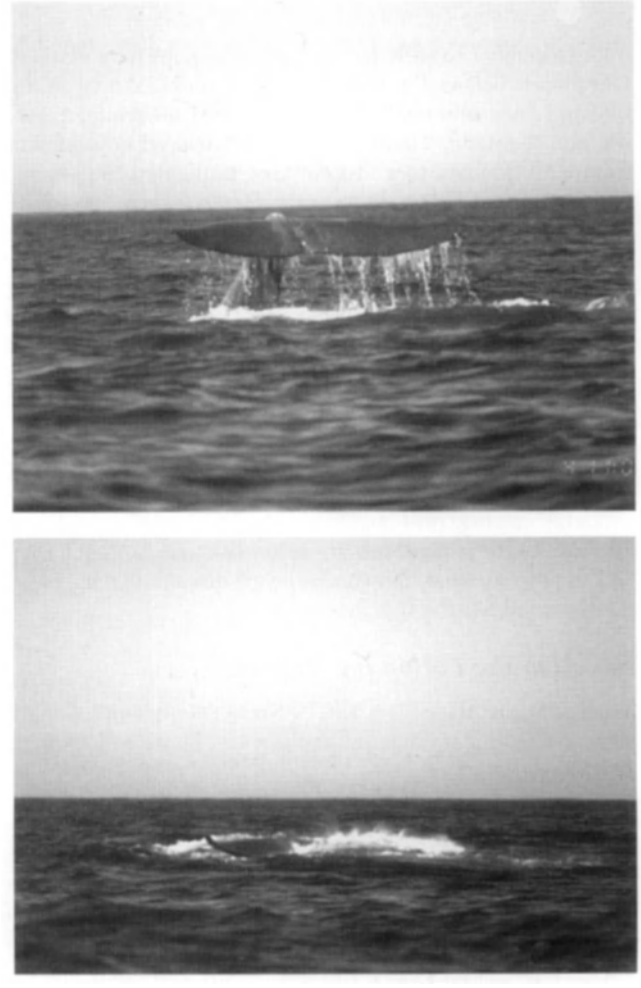

Figure 2 *Lobtailing sperm whale: (top) the stock is bent and (bottom) the flukes are slapped forcefully against the water surface.*

on their back, thus slapping either the ventral or the dorsal side of their flukes. Forward movement is sometimes associated with lobtailing. In both cases, lobtailing results in the production of a loud noise that propagates underwater for up to several hundred meters. Lobtails are often executed in sequences and a particular individual may lobtail over 100 times in a row.

III. When Does Lobtailing Occur?

Lobtailing occurs in a wide range of circumstances, and the circumstances may vary depending on the species. However, for all species, most lobtailing activities occur in either social and/or foraging contexts. Furthermore, for all species, it seems that lobtailing is very seldom performed by a lone animal, which would not be either in visual and/or in acoustic contact with at least another conspecific. It is also very seldom performed by resting animals. As it is difficult to generalize the occurrence of lobtailing for all species of cetaceans, a few specific examples are given.

In sperm whales, the occurrence of lobtailing seems to be strongly correlated with the complexity of the social situation. Sperm whales show a considerable sexual segregation in social organization: females and immatures form cohesive long-term family units of about 12 individuals, whereas bachelor and mature males form either loose aggregations or are found singly or in pairs. Females and young are often observed lobtailing, whereas this behavior occurs only very seldom in bachelor and mature males (Table I). Lobtailing occurs more often when a group of females and immatures is socializing than when it is foraging, and there is a good correlation between the occurrence of lobtailing and the occurrence of breaching. As it is generally a contagious phenomenon, it is rare to see only a single individual lobtailing.

Similarly, in humpback whales, lobtailing occurs more often when they are engaged in mating and calving (in winter) than when they are foraging (in summer), and there is also a strong correlation between lobtailing and breaching. However, in some populations of humpback whales, lobtailing is also associated with foraging activities. While surface feeding in the southern Gulf of Maine, humpbacks often lobtail one to three times before releasing a bubble cloud and ending the feeding event by lunging in the middle of the cloud.

In bowhead whales (*Balaena mysticetus*), lobtailing is associated with other socializing activities and mainly occurs in social–sexual groups, especially in the fall. Tail slapping is also used as an aggressive act toward conspecifics.

In dusky dolphins (*Lagenorhynchus obscurus*), lobtailing seems to be associated with surface feeding in large groups. Significantly more lobtails occur in the 15 min preceding a feeding bout and during a feeding bout than at any other time. In winter, when the dolphins tend to feed more individually, very little aerial BEHAVIOR is observed.

IV. Why Lobtail?

The function of lobtailing has been subject to much speculation and is not yet clearly understood. It is likely, however, that lobtailing has multiple functions, and therefore that this question does not have a single answer.

It has often been suggested that lobtails produce a loud percussive noise that can be heard underwater for long distances and thus that lobtailing may serve as a nonvocal acoustic signal. However, as the tail slap is produced at the surface, the underwater intensity of the noise is likely to be limited. Furthermore, measurements of received levels a few hundred meters from a lobtailing bowhead whale showed that the noises created by the tail slaps were much less intense than their calls.

As shown in the previous sections, lobtailing seems to occur mainly in species with a complex social organization and/or social contexts. Therefore, despite having limited underwater noise propagation, lobtailing is still likely to have some COMMUNICATION function. It could be an attention-getting signal, as suggested for

[a]Data from Waters and Whitehead (1990) and N. Jaquet, unpublished data.

Hector's dolphins, or communicate presence to a conspecific. It could also signal danger or precede synchronous dives as observed for spinner dolphins. In bowhead whales, it has been shown that tail slapping is at times used as an aggressive act toward conspecifics. In many species of dolphins and in humpback, bowhead, and southern right whales, it has also been suggested that lobtailing is a reaction to annoyance. In some species of dolphins, lobtailing may also inform nearby schoolmates that a school of fish has been found and thus act as a recruitment method.

Lobtailing also seems to play a role in foraging. In the case of humpback whales, it has been suggested that the lobtails associated with surface feeding were creating a frightening disturbance, causing near-surface fish to school more tightly. In dolphin schools (e.g., dusky dolphins), lobtailing and motorboating may be used in cooperative foraging to keep surface-herded fish from escaping laterally.

Any behavior that cannot be classified easily and for which the functions is unclear is often described as "play behavior." It is not possible to rule out that lobtailing also has a play function, but it seems unlikely that it is one of its major functions as, in most species, calves do no seem to lobtail more often than adults.

Locomotion, Terrestrial

ANDRÉ R. WYSS
University of California, Santa Barbara

Each of the major clades of marine mammals stems from different terrestrial origins—cetaceans sharing a common ancestry with ungulates, pinnipeds with carnivorans, and sirenians and desmostylians with paenungulates (elephants and kin). The degree to which these groups have become specialized for an aquatic existence varies dramatically, with some modern forms spending a considerable portion of their lives on land (pinnipeds), and others none (cetaceans and sirenians); their ability to locomote terrestrially varies accordingly. For those clades whose extant members are exclusively aquatic, the fossil record provides insights into the terrestrial locomotory capabilities of early transitional forms.

I. Pinnipedia and Kin

Being the geologically youngest group of marine mammals, pinnipeds evince the most obvious signs of their terrestrial ancestry. The limbs of pinnipeds are substantially shortened, reducing the terrestrial agility of these animals relative to their carnivoran allies. Even so, pinnipeds retain considerable mobility on land, but the way in which that mobility is achieved varies remarkably with the group. Pinnipeds can be categorized simple mindedly as "wrigglers" or "walkers." In phocids, during progression on land, the hind flippers remain outstretched posteriorly above the ground, with forward motion being achieved through lurching. Weight is borne not by the flippers but alternately by the abdomen and pelvic region. After the latter is drawn forward and planted, earthworm-like extension of the torso pitches the remainder of the animal forward (Tarasoff *et al.*, 1972). By contrast, in otariids and the walrus (*Odobenus rosmarus*), the hind legs are capable of being turned forward, with the soles and the palms contacting the ground in a more typically mammalian fashion. These drastically different modes of terrestrial locomotion influenced the now-refuted notion of multiple pinniped origins and were long argued to substantiate an exclusive grouping of otariids and walruses. Because use of the limbs in terrestrial locomotion is obviously a primitive feature, however, it bears neither on the question of a close otariid walrus relationship nor on the relationship of phocids to other pinnipeds.

Although typically playing little role in phocid terrestrial locomotion, the fore flippers are sometimes employed to a minor extent. In phocines the fore flippers can be used to help drag the body forward, whereas in elephant seals they provide balance. The crabeater seal (*Lobodon carcinophaga*) uses alternate strokes of its fore flippers and a sinuous flapping of its hindquarters to move rapidly on ice (O'Gorman, 1963).

In otariids, walking is accomplished with the abdomen held clear of the ground, with weight being borne equally by all four flippers (Beentjes, 1990). The elongated digits of the anterior limb point posterolaterally, with a sharp bend between the manus and the forearm occurring between the rows of carpals. The hindlimbs are bent forward at the ankle, with the toes pointing anterolaterally. As in all pinnipeds, the left and right knees are incorporated within the body wall, severely limiting the forward–backward excursion of the limbs (much as long, tight skirts do in humans). During a slow walk the fore flippers are moved alternately, whereas the hind flippers move in unison in some species and alternately in others. A gallop moves otariids more quickly, with the fore flippers being moved forward in unison and then the hind flippers. Walruses locomote in a similar manner, but most of the weight is carried by the

abdomen (which rests on the substrate), with forceful lunges propelling the animals forward (Gordon, 1981).

The early pinnipedimorph *Enaliarctos* (approximately 23 million years in age) is known from a beautifully preserved skeleton, including flipper-footed limbs (Berta *et al.*, 1989). Nothing of its postcranial anatomy suggests that *Enaliarctos* moved any differently on land than do modern otariids. Similarly, the extinct desmatophocids and allodesmids probably walked in the manner of otariids and the walrus.

II. Cetacea and Kin

Apart from sliding onto decks at marine theme parks, and snatching the occasional penguin or pinniped from water's edge, modern cetaceans are completely inept on land. Such was not always the case, however, as spectacular fossil finds have revealed whale progenitors retaining four fully formed appendages. While these early fossils—often termed "archaeocetes"—are nearly universally termed cetaceans, the latter name is not yet defined formally. Cetacea is probably best used, however, to designate the least inclusive clade encompassing mysticetes and odontocetes, in which case "archaeocetes" are not cetaceans by definition (despite being obviously closely related to cetaceans). The recently described *Ambulocetus* (meaning walking whale) from roughly 52-million-year-old river deposits in Pakistan is the most remarkable of these transitional animals (Thewissen *et al.*, 1994, 1996).

In contrast to cetaceans, the elbow, wrist, and digital joints remained fully functional in *Ambulocetus*. The hands sprawled laterally during terrestrial locomotion; movements of the forelimb were probably reminiscent of those seen in otariids. Contrasting again with modern forms, hindlimbs remained fully developed in *Ambulocetus*. On land, the short, stout femur was apparently rotated laterally, causing the enormous feet to be directed laterally. Hindlimb motion likely mimicked that of otariids, with propulsion stemming from extension of the lower back.

III. Desmostylia

Desmostylians inhabited coastal waters of mainly the northern Pacific during Oligocene and Miocene time. Inasmuch as desmostylians retain four stout but otherwise normally proportioned limbs, which are not modified into paddles, and their remains are found in near-shore marine sediments, the group is generally considered to have been amphibious, and therefore capable of locomoting terrestrially. The stance of these animals is highly peculiar, however, with strongly inturned fore and hind feet. Fusion of the radius and ulna severely curtailed rotation of the forelimb; details of foot posture in group remain somewhat controversial.

IV. Sirenia

Although sirenians do not venture onto land, there is no doubt that their forebears did. Eocene outgroups to Sirenia show limited but persuasive evidence that these animals retained functional hindlimbs, particularly the hip structure in *Protosiren* (Domning *et al.*, 1994). This stage in the ancestry of Sirenia thus records the quadrupedal (and likely amphibious) antecedents to fully aquatic members of the clade.

Lutrinae

WARREN FITCH
University of Calgary, Alberta, Canada

Otters (Lutrinae) are amphibious members of a group of mammals called the order Carnivora, family Mustelidae. This family also includes the weasels, badgers, and skunks. Technically, otters are defined according to the following suite of characters: (1) upper fourth premolar with a hypocone or hypoconal crest; (2) first lower molar with a strongly basined hypoconal crest; (3) entoconid reduced to a low crest or altogether absent; and (4) numerous aquatic adaptations, which are examined in more detail later.

I. Modern Diversity

Thirteen is currently agreed upon as the number of living species. There is less agreement on what to name these species of otters. Table I lists the 13 extant species recognized by Wozencraft (1989, 1993) and approximately where they are found.

Which genus name is used does not affect the number of species, just how they are hypothesized to be related. The BIOGEOGRAPHY is important in determining possible

TABLE I
Lutrinae

Genus species	*Common name*	*Location*
Aonyx capensis	Cape clawless otter	Central and southern Africa
A. cinerea	Oriental small-clawed otter	India to Indonesia, Southeast Asia, south China
A. congica	Congo otter (Zaire clawless otter)	Central Africa
Enhydra lutris	Sea otter	Coastal North Pacific
Lutra canadensis[a]	River otter	North America
L. felina[a]	Marine otter	West coast of most of South America
L. longicaudis[a]		Mexico, Central and northern two-thirds of South America
L. lutra	European otter	Widespread in Eurasia–Ireland to Japan, South to Sri Lanka
L. maculicollis	Spotted-neck otter	Most of sub-Saharan Africa
L. perspicillata[b]	Smooth-coated otter	South Asia–Afghanistan to Southeast Asia
L. provocax[a]	Southern river otter	Patagonian region of South America
L. sumatrana	Sumatran otter (hairy-nosed otter)	Southeast Asia and Indonesia
Pteronura brasiliensis	Giant river otter	Eastern and northern South America

[a]*Lontra* rather than *Lutra* appeared for these species in Wozencraft (1993). See Species List.
[b]*Lutrogale* rather than *Lutra* appeared in Wozencraft (1993).

relationships and evolutionary history. Fossils, though, have to be considered too.

II. Evolutionary History

The first mustelid fossil is from the late Eocene in Europe. Many different kinds of mustelids are known from the early Miocene (23 mya) of both Europe and North America. Lutrines (otters) are present by the late Miocene (16–18 mya) in the holarctic region. Forms considered to be probable lutrines are known from much earlier in the Miocene. The term "probable lutrines" means that we are not sure if they are otters because of a lack of information. Many early fossil specimens are known only from fragmentary data.

Because otters are placed in the Mustelidae, we can easily use the mink (*Mustela vison*) as a model of the possible morphology and ecology of the earliest proto-otter. An evolutionary scenario that leads us to the otters would read something like this: The ancestral lutrine probably lived in an area with a considerable amount of shallow water where many fish and invertebrates lived close to shore. It was terrestrial in habits but was able and willing to occasionally make use of the abundant food in the water. It had little specialized anatomy for aquatic locomotion or for food capture. Gradually, over the course of generations, this proto-otter tended to spend more time in the water, and slight alterations of the morphology began to appear. What are these alterations? They are the adaptations we now identify in modern otters. SWIMMING by the earliest otter-like form would have employed a terrestrial gait much like the mink still uses. Most likely, it started out hunting fish or other vertebrates in the shallows. Fish eating is considered primitive in lutrines (Berta and Morgan, 1986), and FEEDING on invertebrates evolved later. Piscivory (feeding on fish) involves using the mouth for capture of the prey. The portion of the brain of otters associated with facial sensitivity is larger in most otters compared with other mustelids. This would improve the capture success when using the head to capture prey. A few species of otter that feed on invertebrates such as crayfish show an enlarged area for tactile sensation in the forepaws, which is in line with their increased use in prey capture.

Body shape also changed. The mink shows no special shape adaptations. Gradually the proto-lutrine took on a more fusiform (streamlined) shape. The neck became shorter, the front legs also got shorter, and the hindlimb lengthened mostly through the elongation of the metatarsals and phalanges. These elongate digits on the hindlimb became encased in webbing. These changes went along with changes in the gait. Two types of locomotion developed to produce greater speed in the water. The limbs were used in a joint thrust and recovery stroke (simultaneously, both hind or both front legs would pump and then recover) and the tail was employed to add thrust. In some species, such as the giant river otter, the tail is used for high speed and the limbs just for maneuvering. The adaptations to life in the water reach their extreme in the sea otter. In essence, the sea otter embodies the story of otter evolution. In this species we see the completion of the evolutionary process that turned a land-dwelling mustelid into an animal quite at ease in its marine environment.

Male Reproductive Systems

SHANNON ATKINSON
University of Alaska, Seward

Studies of the reproductive biology of male marine mammals have not received the attention that has been focused on their female counterparts. In part this is due to the limited numbers of male marine mammals kept in captivity, but also to the difficulty of measuring the anatomical and physiological parameters of free-ranging males. This account focuses on the anatomy of male reproduction, with emphasis on features unique to the various marine mammal groups. Aspects of reproductive life history and behavior, such as mating systems, territoriality, and sociobiology, are covered elsewhere. The effects of environmental and pharmacological factors on reproduction are also briefly reviewed here.

I. Cetaceans

Genitalia are internal in whales, dolphins, and porpoises (Fig. 1); this contributes to hydrodynamic efficiency. There is no os penis (baculum). The penis is fibroelastic (Fig. 2), similar to that in artiodactyls, such as cows, pigs, and antelopes (Cetacea are included in the Artiodactyla, or Cetartiodactyla, by some taxonomists). It originates in two crura from the caudal part of the free pelvic bones or from the entire surface of these bones (Fig. 3). The two arms fuse into a long rope-like body, round or oval in cross section. In large rorquals it may be 2.5–3 m long and 25–30 cm in diameter. The distal part of the penis tapers smoothly to the tip and is covered with ordinary skin; this may be homologous with the glans penis of some terrestrial mammals. When retracted the penis rests in an S-shaped horizontal loop. Because enlargement through engorgement with blood is limited by the tough tunica albiginosa (modified skin covering) during arousal, this loop allows protrusion of the organ without its lengthening. A flat retractor penis muscle runs from its ligamental or rectal-wall origin to insert on the ventral surface of the penis; it serves to withdraw the penis back into the penile slit. The prostate is primitive among eutherian mammals, resembling that of marsupials and monotremes in consisting of diffuse urethral glands unlocalized to form a discrete prostrate gland.

The testes are intraabdominal (or cryptic) and mesial/ventral in position, a condition known as secondary testicondy. This feature is thought to be synapomorphic in Cetacea but is shared with some marsupials. The position varies among the cetacean taxa, from nearly renal in some odontocetes to ventral in baleen whales. In *Mesoplodon* spp., the organs are sunk in recesses of the abdominal cavity connected to the main cavity by short vagioperitoneal canals. The organs are long and cylindrical with a smooth shiny white surface. Relative testis size varies widely among the cetacean groups, being greater in those species thought to engage in sperm competition, such as right whales (*Eubalaena* spp.), than in polygynous species such as the sperm whale (*Physeter macrocephalus*). Odontocetes in general have testes 7 to 25 times larger than would be predicted for "average" mammals of their size, ranging to 8% of body weight in the dusky dolphin (*Lagenorhynchus obscurus*), as compared to 0.08% in humans. The largest mammalian testes known are found in right whales, weighing up to 900 kg in combination. Testicular activity (and size of some muscles associated with the penis) varies seasonally, and weight increases substantially with breeding season in at least some delphinid odontocetes, e.g., the spinner dolphin (*Stenella longirostris*). In many cetacean species, the spermatic tubules (vasa differentia) are more highly convoluted than in most terrestrial mammals. A distal spiral valve exists in the blue whale (*Balaenoptera musculus*), and mucosal folds have been described in the pygmy sperm whale (*Kogia breviceps*).

The scrotum functions in terrestrial mammals in part to lower ambient temperature to ensure viability of the sperm. Loss of the scrotum in Cetacea in the interest of hydrodynamic efficiency thus introduces a new thermoregulatory problem. This has been addressed by localized cooling through a cardiovascular countercurrent mechanism. Blood cooled in superficial veins of the dorsal fin and flukes feeds directly into a deep venous plexus closely juxtaposed to a similar arterial plexus that supplies the testis. Thus heat is drawn into the venous blood from the arterial blood before it reaches the testis, cooling the testis to below body core temperature.

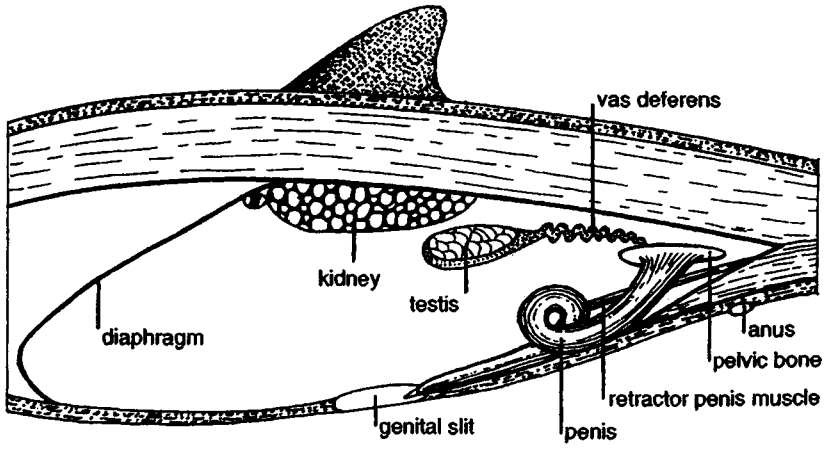

Figure 1 *Cetacean male reproductive system. From Berta and Sumich (1999), adapted from Slijper (1966).*

II. Pinnipeds and Other Carnivores

All pinnipeds, the polar bear (*Ursus maritimus*) and the sea otter (*Enhydra lutris*) possess a baculum, or penis bone, which is the ossified anterior end of the corpus cavernosum of the penis. The baculum is largest in the walrus (*Odobenus rosmarus*) and smallest in otariid pinnipeds, or eared seals and sea lions. The distal shape varies widely among species and is more complex in phocids (true or earless seals) than in otariids. As most of the phocids are aquatic copulators, relatively large bacula may function in preventing water damage to sperm after copulation or to facilitate sperm competition in species where the females mates with more than one male. Bacular size may also be adaptively constrained by a large body size in terrestrial copulators due to the risk of bacular fracture. The penis is vascular, as in terrestrial carnivores (Fig. 4). In phocids, the baculum is surmounted by a fleshy claviform glans. In otariids, it is covered by only a thin layer of epithelium. The prostate gland is bulky, weighing up to 760 g in the southern elephant seal (*Mirounga leonina*) and is similar in anatomy in all seals.

Phocid seals lack a scrotum; the testes are external to the abdominal muscles but covered by the posterior part of a superficial muscle. Otariid pinnipeds possess a scrotum, but in some species, e.g., the Antarctic fur seal (*Arctocephalus gazella*), the testes are usually withdrawn into the inguinal position and the scrotum is visible only as two areas of hairless skin; the testes descend into the scrotum only during the need to avoid hyperthermia. Seasonal changes in testis and epididymis size and function occur with breeding season in pinnipeds in which this has been examined (Fig. 5). The testes in the sea otter and polar bear are scrotal.

III. Sirenians

Sirenians do not possess a baculum. The penis is vascular and retracted when not engorged. The testes are abdominal. The prostate is lacking in the dugong (*Dugong dugon*) and is composed of erectile muscle tissue in the manatees (*Trichechus* spp.).

IV. Maturity and Seasonality

Testosterone is the main androgen in male mammals and stimulates spermatogenesis. Testosterone concentrations have been measured in many odontocetes and pinnipeds. In all species for which there are published data, testosterone concentrations

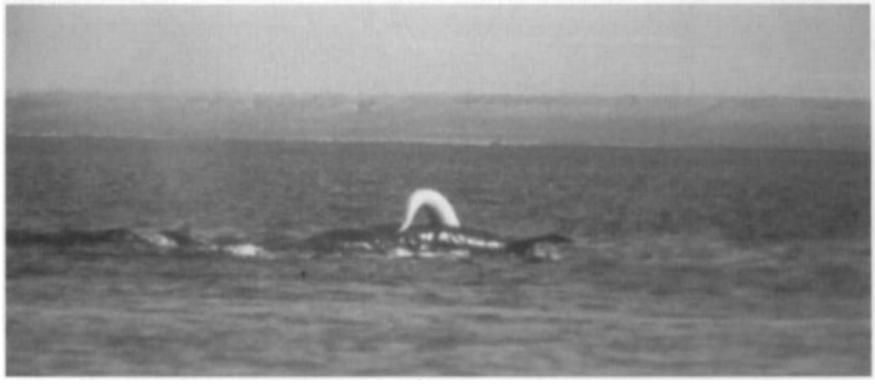

Figure 2 *The erect fibroelastic penis of the gray whale can often be seen on the breeding grounds in Baja California. Photograph by Steve Leatherwood*

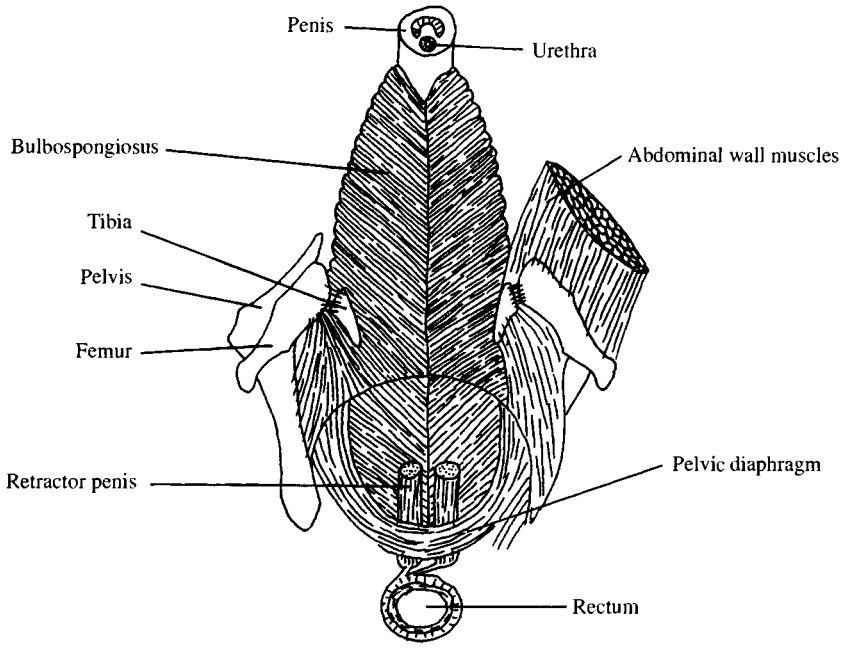

Figure 3 *Pelvis and male genitals of bowhead whale* (Balaena mysticetus) *in ventral view (top of drawing is anterior). This figure shows the close relation between the internal hindlimb bones (pelvis, femur, and tibia), the rectum, and the penis. Retractor penis and bulbospongiosus are penile muscles. (Modified after Struthers, 1893.)*

increase around the time of sexual maturity, making it a useful diagnostic tool. A seasonal pattern of circulating testosterone concentrations exists with elevated concentrations during the breeding season (typically in spring, but a few species are autumnal or multiseasonal breeders). In species with a short, tightly synchronized breeding season, testosterone concentrations are increased for 1 to 3 months at the start of the season but decline to baseline levels after breeding ends. Seasonality is also apparent in most male marine mammals in increased size of the testes and accessory reproductive glands (even muscles in some cetaceans) and increased spermatogenesis. Increased size of the testes is due to an increased diameter of the seminiferous tubules and epididymes, resulting in increases in the volume of sperm. Spermatogenesis usually lags behind testosterone production, as production of testosterone by testicular Leydig cells is necessary for germ cell differentiation in the seminiferous tubules.

A few marine mammals, such as dugongs and sea otters, lack a distinct breeding season. A few older male dugongs that

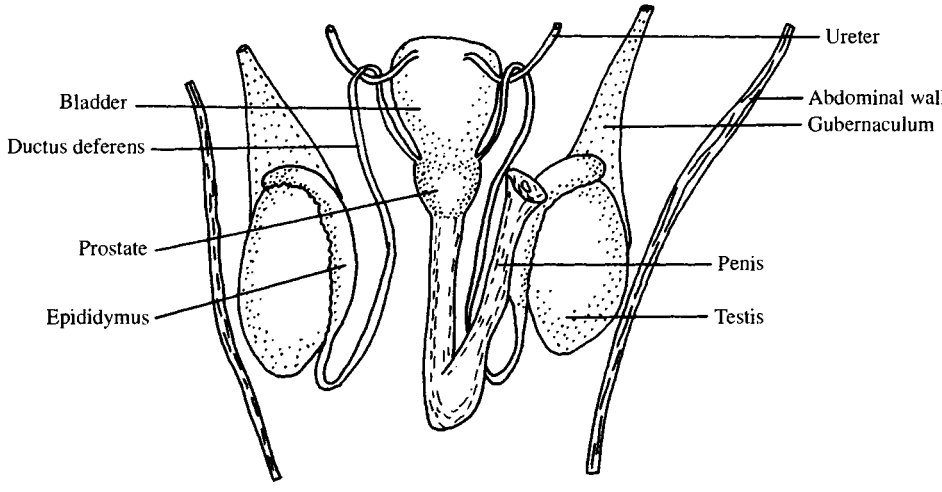

Figure 4 *Male reproductice tract of an otariid in ventral view (top is anterior). (Modified after Boyd* et al., *1999.)*

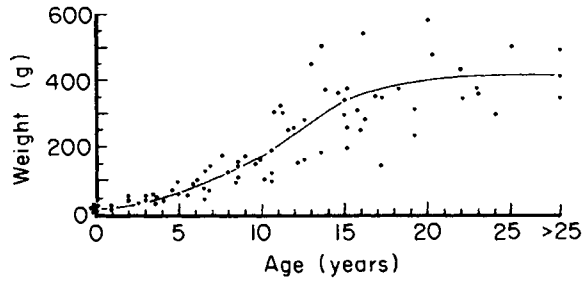

Figure 5 *Weight of nonspermiogenic testes of walrus in relation to age. (Modified from Fay, 1982.)*

were examined were found to be aspermic, suggesting long periods of sterility.

During seasonal quiescence, spermatogenesis ceases, although the testes retain relatively large seminiferous tubules with spermatocytes present. Shrinkage of anterior pituitary cells that produce gonadotrophins is thought to be ultimately responsible for the seasonal testicular regression.

V. Effects of Environmental Factors

Some environmental factors simply cue physiological events, whereas others have the potential to hasten or disrupt the system. The three most important are photoperiod, nutrition, and social factors.

Seasonal reproduction requires that males have adequate numbers of viable sperm when the females enter estrus. Hence the spermatogenic cycle must be initiated months before breeding. Photoperiod is the most commonly cited environmental cue for synchronizing reproductive processes in both males and females; it appears to function months before the breeding season begins. The pineal gland is responsible for the neuroendocrine communication of photoperiod to the rest of the body. Melatonin secretion, which is activated during short photoperiods, acts to relay photoperiodic cues to the target organs. In many species, melatonin is inhibitory to the gonadotrophic-releasing hormones (GnRH) that stimulate testosterone production and spermatogenesis. Thus reproductive processes in most species are stimulated during increasing daylength (i.e., spring). Conversely, increased melatonin concentrations due to a decreased photoperiod lead to inactivation of the testes.

Both sea otters and sirenians lack a defined breeding season, and the Australian sea lion (*Neophoca cinerea*) has a nonannual, nonseasonal reproductive pattern. Spermatogenesis in these species may be continuous. The lack of correlation between testicular activity and season in the dugong may relate to the absence of a pineal gland. No published studies have accounted for the lack of a defined breeding season in sea otters.

There is little published information of nutritional effects on the reproductive biology of male marine mammals. A high plane of nutrition is known to advance the onset of puberty in females and could be expected to have the same effect in males. It is also safe to assume that the plane of nutrition of an individual male will affect its position in a dominance hierarchy. For species in which there can be severe natural impacts on food resources, adult males may have lower blubber thickness during years of poor feeding, resulting in reduced stamina during the breeding season. Although the functional or mechanistic nature of the nutrition–reproduction relationship remains unclear, it can safely be concluded that the measurement of body condition and its effects on various reproductive events, especially during natural environmental perturbations, will continue to be important areas of marine mammal research.

Physiology and the environment influence the development of mating systems by affecting the relative distribution and availability of males and females, thereby altering the reproductive success of an individual male. After sexual maturation, serum testosterone concentrations may vary independent of testis weight, indicating that social factors play a role in reproductive processes. It is not uncommon to find captive situations with cetaceans that are of the same age but at very different reproductive states (i.e., one or more males remain sexually immature much longer than the others). Changing the social structure in an enclosure will often stimulate puberty in those lagging behind in sexual development.

VI. Effects of Pharmacological Agents

The most common reason for prescribing pharmacological agents is to reduce fertility. The three species for which this has been needed in captivity are the common bottlenose dolphin (*Tursiops truncatus*), the California sea lion (*Zalophus californianus*), and the harbor seal (*Phoca vitulina*). All of these can be prolific breeders in captivity, and the need regularly arises to control numbers in some facilities. Until recently, physical separation and contraception of females were the only practical methods. Now GnRH agonists and antiandrogens are being used, with varying success.

A second reason to prescribe pharmacological agents is to suppress aggression among males. The need to control behavior in the captive setting is obvious, especially with adult male bottlenose dolphins during the breeding season. It is less obvious but equally if not more important in the management of the Hawaiian monk seal (*Monachus schauinslandi*), a declining species in which males attempt mass matings, usually with a breeding-aged female, sometimes to the point of killing her.

GnRH agonists work by stimulating the anterior pituitary to release GnRH, which stimulates the testes to produce testosterone and initiate spermatogenesis. Paradoxically, the pituitary quickly becomes refractory and ceases its production of GnRH, which inhibits the testes. Injections of GnRH agonists have been used with some success with harbor seals and effectively decrease circulating testosterone concentrations to prepubertal levels in Hawaiian monk seals. Antiandrogens have been tried unsuccessfully with bottlenose dolphins.

Marine top predators are likely targets for xenobiotic compounds that act either as estrogens or antiandrogens. The most common of these are the polychlorinated biphenyls (PCBs) and dichlorodiphyenyltrichloroethanes (DDTs). These compounds bioaccumulate up the food chain, making marine mammals highly susceptible to their biological effects. Male marine mammals continue to accumulate organochlorines throughout their lives, whereas females tend to reduce their body burden via transplacental transfer and lactation. The range of PCB concentrations

reported for arctic marine mammals is highest in the walrus (*Odobenus rosmarus*), although the absolute concentrations are highest in polar bears. The effects of organochlorines on male reproductive physiology have not been well studied, as most research has focused on females. The known effects are pathologies related to structural changes and thickening of tubules in organs such as the kidneys, adrenals, and reproductive tract. The most striking possible example has been the occurrence of pseudohermaphroditic polar bears with a normal vaginal opening, a small penis with baculum, and no Y chromosome. The syndrome is hypothesized to be due to either excessive androgen secretion by the mother or endocrine disruption from environmental pollutants. The impacts of all the detected pathologies are unknown. However, there are widespread reports that xenobiotic compounds are also strongly immunosuppressive, rendering contaminated animals more vulnerable to bacterial and viral infections. Experimental studies using minks (mustelids such as the sea otter) indicate that the enzymatic pathways that metabolize steroids are disrupted, but the detailed biosynthetic pathways of the organismal response have not been elucidated.

Mammalia

J. G. M. Thewissen

Northeastern Ohio Universities College of Medicine, Rootstown

The animal kingdom is divided into approximately 15 phyla. These phyla represent large groupings of species descended from a single, ancient ancestor. Humans, as well as marine mammals, belong to the phylum Chordata and its largest subdivision, the Vertebrata. Vertebrates are animals with a segmented backbone consisting of a large series of similar bony elements, the vertebrae. Vertebrates are further divided into a number of classes, and mammals (Mammalia in Latin) is one of these (the others are amphibians, reptiles, birds, and several classes of fishes).

I. Mammalian Characteristics

All mammals are derived from a single ancestor that lived in the Late Triassic, approximately 220 million years ago. Scientists distinguish Mammalia from Mammaliformes (Rowe, 1988), but that distinction is not important for marine mammals and we can treat those terms as synonyms here. The first mammal was different from contemporary reptiles by having a lower jaw (half of the mandible) that consisted of a single bone holding both the teeth and the joint with the SKULL. In all nonmammals (e.g., birds and reptiles), the dentary does not take part in the mandibular joint, and instead a bone called the articular forms the joint with a skullbone called the quadrate. The articular and quadrate did not disappear when mammals evolved, instead they became part of the sound transmission mechanism of the ear and are called malleus (hammer) and incus (anvil) in mammals.

II. Marine Mammals

Many other features characterize modern mammals (Fig. 1), but for most of these there are exceptions, and marine mammals are commonly among the exceptions. Most modern mammals, for instance, can be characterized as air-breathing, endotherm (warm-blooded) vertebrates with hair that chew

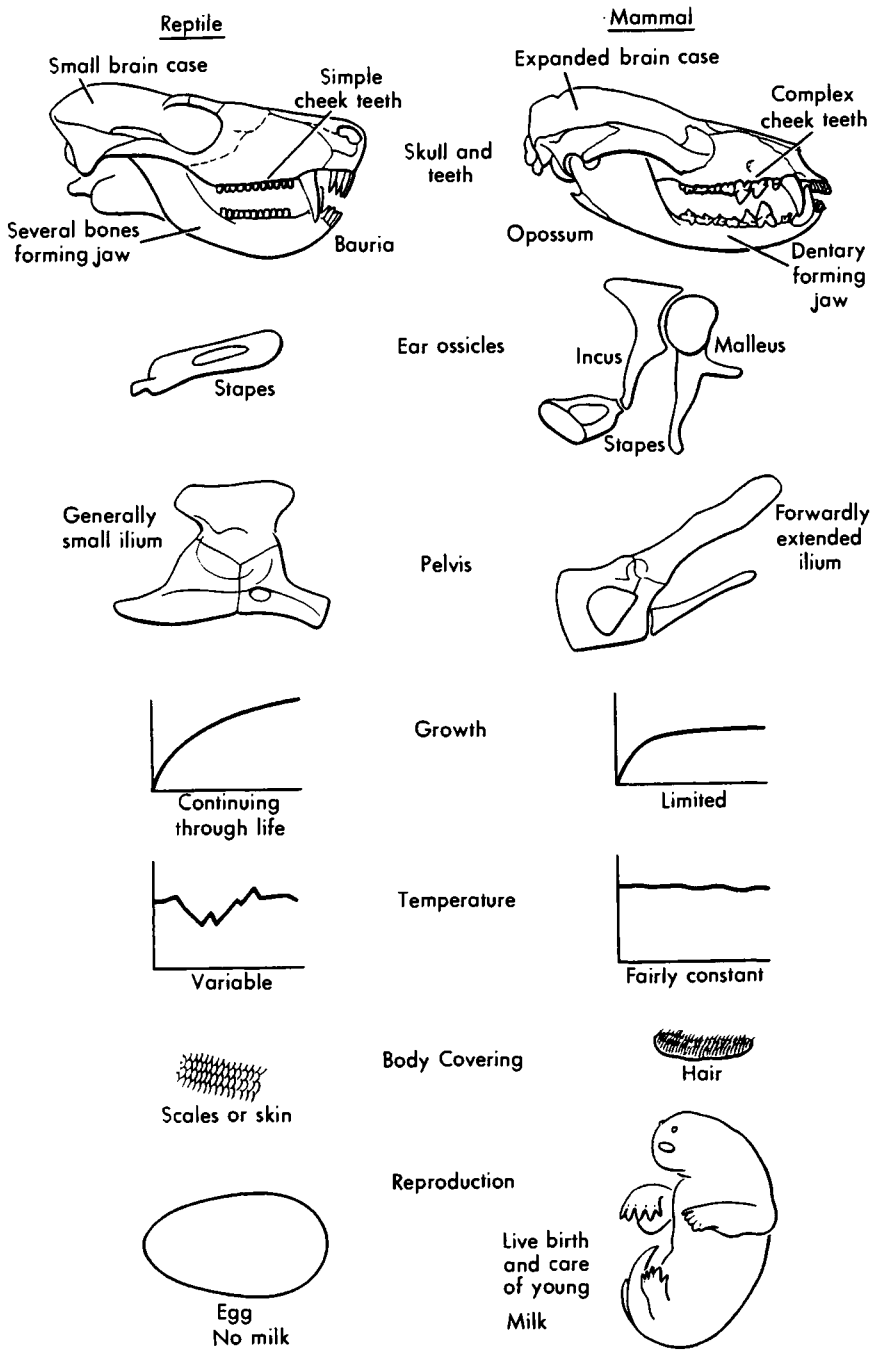

Figure 1 *Some of the characters that distinguish mammals from other vertebrates. From Colbert, E. H., and Morales, M. (1991). "Evolution of the Vertebrates," 4th Ed. Copyright © John Wiley & Sons, Inc. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.*

their food with complex TEETH and that feed their young milk produced by mammary glands of the female.

Most modern mammals have a battery of strongly varied teeth that occlude well and are used for chewing. Mysticete whales have no teeth and many modern odontocete whales and pinnipeds lack the complex morphology of the molars. Odontocetes do not chew their food and there is no fine occlusion. Most mammals have hair that covers the entire body, but not whales and sirenians. There are commonly two generations of teeth (deciduous and adult) in an individual mammal, but modern toothed whales only have a single generation. The skull articulates with the vertebral column by means of two convex joints called oc-

cipital condyles, which are present in all marine mammals. Nearly all mammals have seven neck vertebrae, but the manatees only have six. Mammals commonly have two pairs of limbs, each with five digits; modern whales and sirenians lack external hindlimbs and digits are commonly not visible externally.

Management

JAY BARLOW
Southwest Fisheries Science Center, La Jolla, California

Management refers to those regulations, laws, treaties, and policies that govern human interactions with marine mammals. Marine mammal management may promote a wide variety of human objectives: conservation of marine mammal populations for their intrinsic value, maintenance of marine mammal populations for human exploitation, protection of human health interests, humane treatment of captive animals, reduction of direct or competitive interference with commercial fisheries, and so on. This article concentrates on the general approaches used for marine mammal management.

I. Management Units

"Management unit" refers to the group of animals that is the target of some management action. It may refer to a colony, subpopulation, population, or species. The term "stock" has traditionally been used instead of "management unit," but this term has evolved to be synonymous with both "population" and "management unit," so, to avoid confusion, "management unit" is preferred. The appropriate definition of a management unit depends on the management objective. Laws to prevent the extinction of a species might have a species or subspecies as a management unit; however, the likelihood of achieving this management objective may be increased by managing on the basis of populations. Laws may not always explicitly define management units, but the stated goals of that law may give some clues as to how the term should be interpreted. For example, if the goal is to maintain marine mammal populations as functional elements of their ecosystems (one of the goals of the U.S. Marine Mammal Protection Act, MMPA), management units might necessarily be smaller than the entire population to ensure than range contractions would not prevent the attainment of this goal (Taylor, 1997). Knowledge of population structure is critical to defining management units. Population structure has been studied using tagging, radio and satellite tracking, allozymes, DNA fingerprinting, DNA sequencing, photo-identification, morphometrics, and chemical markers. Most of these methods are limited: they can only show that two samples differ and thus that population structure is present, but they cannot be used to demonstrate that population structure is absent. There is almost always some uncertainty in deciding how finely to divide management units, and one of the current challenges in marine mammal management is dealing with this uncertainty.

II. Methods of Marine Mammal Management

A. Traditions, Taboos, and Practices

Prior to modern times, management took the form of culturally enforced practices. Ancient Greeks, natives in the Amazon Basin, and many sea-going cultures held dolphins in especially high regard and had proscriptions against killing or eating dolphins. Monk seals (*Monachus monachus*) were considered by the early Greeks to have prophetic powers and to be protected by Poseiden; however, the popular views toward this species included antipathy and hostility. The societies that did harvest whales and seals (including Inuit and Aleut cultures) often had elaborate rules that determined who could hunt these animals and when they could be hunted. It is not known whether traditions and taboos were important in conserving marine mammals, but there is no evidence of marine mammal EXTINCTIONS caused by humans prior to that of the Steller's sea cow (*Hydrodamalis gigas*) in the 1700s. Traditions based on superstitions have been increasingly ignored as human populations have increased (Johnson and Levigne, 1999).

B. Harvest Bans

The most common method of protecting marine mammals from overexploitation has been a complete ban on harvesting. Most often, this has been practiced after a catastrophic decline has already occurred. Gray whales (*Eschrichtius robustus*), northern elephant seals (*Mirounga angustirostris*), and Guadalupe fur seals (*Arctocephalus townsendi*) were protected by Mexico after their near extinction. A complete ban on whaling for gray whales and right whales (*Eubalaena* spp.) was instituted early in the history of international whale management. Australia, Mexico, New Zealand, South Africa, and the United States have banned the commercial harvest of all marine mammal species in their waters. The European Union members of ASCOBANS (Agreement on the Conservation of Small Cetaceans of the Baltic and North Seas) have agreed to ban the intentional harvest of all small cetaceans. Exceptions to harvest bans are commonly made for aboriginal or subsistence harvests and for incidental mortality pursuant to other commercial enterprises.

C. Age/Sex Limitations on Harvests

Age and/or sex limitations on harvest are commonly employed in the management of terrestrial species. The U.S. North Pacific Fur Seal Act of 1910 outlawed the harvest of northern fur seal (*Callorhinus ursinus*) females and pups. This, together with the

provisions of the North Pacific Fur Seal Treaty of 1911, effectively reversed the marked declines of the populations that breed on islands in the Bering Sea. Because many marine mammals do not exhibit marked sexual dimorphism (as do fur seals), similar regulations are not practical for all species. The 1931 Convention for Regulation of Whaling and later regulations of the INTERNATIONAL WHALING COMMISSION (IWC) prohibited the commercial harvest of dependent calves and their mothers. Because most whales have a 2- or 3-year reproductive cycle and are nursing for only 6–12 months, females were not protected for the majority of time. Minimum size limits were also established for various whale species. These and other regulations were not effective in preventing the depletion of most of the world's whale populations.

D. Seasonal Area Closures

The seasonal closure of certain areas or all areas is another common practice in wildlife management. The 1931 Convention for the Regulation of Whaling established a closed season for factory ships in Antarctic waters from April 7 to December 8. Seasonal area closures have also been used to reduce the number of gill net entanglements of Hector's dolphins (*Cephalorhynchus hectori*) in New Zealand and harbor porpoises (*Phocoena phocoena*) in the U.S. Gulf of Maine.

E. Restrictions on Methods and Fishing Gear

Regulations may limit the methods by which marine mammals are killed. The Fur Seal Treaty of 1911 eliminated the at-sea pelagic harvest of northern fur seals (*Callorhinus ursinsus*), which were commonly considered to be wasteful (many carcasses could not be recovered) and which were more difficult to monitor. Methodological restrictions are not limited to direct, intentional harvests. Many gear restrictions have been applied to reduce marine mammal bycatch in commercial fishing operations. Finer mesh panels (Medina panels) were added to tuna purse seine nets in the eastern tropical Pacific to reduce dolphin ENTANGLEMENT. The use of acoustic warning devices (pingers) is mandated to reduce cetacean bycatch in several U.S. fisheries, and additional experiments with pingers are currently being conducted worldwide. Regulations may also address how a particular gear is used; the adoption of a "backdown" procedure greatly reduced the mortality of dolphins in tuna purse seines. In addressing marine mammal bycatch problems, restrictions sometimes take the form of a complete ban on a particular gear type. In 1989 the states and territories of the South Pacific banned the use of large-scale (> 2.5 km), drift gill nets in their exclusive economic zones, and in 1992 the United Nations General Assembly extended this ban to all international waters. There have been several attempts to ban drift gill nets in the Mediterranean. In the United States, Florida, Louisiana, Texas, and California have banned gill nets in all or part of their waters in response to marine mammal and other bycatch issues.

F. Quota-Based Restrictions

The most direct method to manage removals from a wild population is to set a limit on the number of animals that can be taken in a given time period (usually 1 year). Quota-based management was first applied to the directed harvest of marine mammals and was later adapted to regulation of bycatch. This method requires some method for estimating annual mortality, such as from a mandatory program placing observers on whaling or fishing vessels. Whaling on the high seas has been regulated with quotas since 1931, but early quotas were designed only to limit oil production and were based on a "blue whale unit" [the oil equivalent of one blue whale (*Balaenoptera musculus*) being two fin whales (*B. physalus*), six sei whales (*B. borealis*), etc.]. The lack of species- or population-specific whale quotas lasted until 1972 and is widely blamed for the near extinction of most large whale populations. The failure of IWC to effectively manage whaling resulted in an international moratorium on commercial whaling that started in 1986 and continues today. Since 1986, the IWC has devised and adopted a revised management procedure that incorporates a new, well-tested catch limit algorithm (CLA) for setting population-specific quotas. Aboriginal subsistence whaling continues under population-specific quotas that are based on biological considerations and on "cultural and nutritional needs." Quotas were first used in 1976 to limit bycatch in the U.S. tuna purse seine fishery to 78,000 dolphins per year. The U.S. quotas gradually decreased to 20,500 by 1981, but, like the blue whale unit, still had not adequately addressed species- and population-specific conservation concerns. The gradual conversion of the tuna purse seine fishery from a U.S. industry in 1970 to a largely international fleet by 1990 further complicated conservation efforts. The Inter-American Tropical Tuna Commission (and several nongovernmental organizations) have negotiated with its signatory nations to impose vessel-specific quotas on total dolphin bycatch (1993) and stock-specific quotas (2000). Although management of dolphin mortality in the tuna fishery has remained a special case, the United States has adopted a more general approach to setting stock-specific quotas on the maximum allowable levels (potential biological removal, PBR) of human-caused mortality for marine mammal populations in its exclusive economic zone. The PBR approach is like the IWC's CLA in that it sets allowable removal rates that are conservative in the face of uncertainty but which can increase as uncertainties are resolved. New Zealand uses a similar approach to setting annual bycatch limits for Hooker's sea lions (*Phocarctos hookeri*) and has closed its squid trawl fishery when this limit was exceeded. Several countries, including the United Kingdom, are investigating similar approaches to setting limits on fishery bycatch.

G. Market Monitoring and Trade Restrictions

Enforcement of laws on the high seas is often difficult or impossible; therefore, market monitoring and international trade restrictions may be necessary to prevent the illegal harvest and marketing of protected marine mammal. The Convention on International Trade in Endangered Species (CITES) is the primary implement for international trade restrictions and currently bans all trade in whale products, including some species that are not considered "endangered" but whose meat might be confused with that from endangered species. Genetic methods now can distinguish between all species, and CITES is under pressure from pro-whaling countries to lift the "look-alike" ban on nonendangered whales. Surreptitious market surveys by nongovernmental organizations and subsequent genetic analyses have shown that Japanese and Korean markets contain a wide variety of cetacean products, many of which are

mislabeled and some of which may have been illegally imported (some cetaceans taken within EEZ waters of those countries and minke whales taken under "scientific whaling" can be legally marketed). Because marine mammal products can be extremely valuable, there will be a strong incentive to cheat. Some IWC member countries are insisting that a system of market monitoring precedes the resumption of commercial whaling, possibly by genetically "fingerprinting" every legally taken whale.

H. Treatment of Wild and Captive Animals

Marine mammals, especially cetaceans, are regarded by many cultures as deserving special treatment by humans. These attitudes may stem from their similarities to humans (large brain, play behavior, etc.), from their representation in popular media, or from the endangered status of some species. Whatever the reason, the special treatment is often evident in national laws that afford more protection for marine mammals than for similar terrestrial mammals. For example, the U.S. MMPA prohibits "harassment" of marine mammals (defined as any pursuit, torment, or annoyance that has the potential to disrupt the natural behavioral patterns of the animal) unless a specific permit is obtained. Virtually any research on marine mammals (except passive observation) has a potential for harassing the subject and therefore requires an MMPA permit. National laws are also frequently implemented to regulate the public display of marine mammals to ensure that adequate space and care are provided to those animals. Some laws and regulations are expressions of public concern for individual animals (rather than concern about species or populations) and are derived more from the animal rights movement than from a conservation ethic, but this distinction is not clear in many cases. Stranding programs that rehabilitate beached animals may aid individuals and, for endangered species, the survival of the species.

I. Marine Sanctuaries

There is a long-standing and growing interest in the use of protected areas or sanctuaries as a management tool for marine species. The first marine mammal refuge [for pinnipeds and sea otters (*Enhydra lutris*) on Afognak Island, Alaska] was established in 1892, but most have been established since 1975. Protected areas are a useful management tool because the concept is so simple (easy to understand and to enforce). For marine mammals, established sanctuaries and protected areas are taxonomically limited: the Indian Ocean and Southern Ocean whale sanctuaries (established by the IWC) protect only large whales, the Irish whale and dolphin sanctuary (established by Ireland) protects only cetaceans, and the Banks Peninsula sanctuary (established by New Zealand) was designed to protect only Hector's dolphins. The level of protection varies between sanctuaries; the Irish whale and dolphin sanctuary does not prevent porpoise and dolphin bycatch in commercial fisheries (although the existence of the sanctuary has focused efforts on reducing bycatch). The utility of protected areas as a management tool depends critically on characteristics of the animals they are designed to protect (residency patterns, home ranges, mating strategies) and on the size of the protected area. The enormous Southern Ocean whale sanctuary (generally, all waters south of 40° S but excluding the Indian Ocean sanctuary) is currently recognized as being too small to effectively protect its whales (which migrate out of this area during the southern winter). In contrast, small protected areas are quite effective in sheltering breeding colonies of pinnipeds or essential warm spring habitats of manatees. To conservation biologists, a "marine protected area" refers to an area of complete protection at all ecosystem levels. Existing marine protected areas are too small to afford much protection for marine mammal species, although they may protect some critical habitat.

J. Pinniped Control Programs

The recovery of many pinniped populations from a legacy of hunting and near extermination is one of the success stories in marine mammal management, but this recovery is hardly viewed as a success by fishermen and aquaculturists who share their waters. Even conservationists are faced with a dilemma in some situations, such as when California sea lions (*Zalophus californianus*) (protected, but now numbering approximately 200,000) are threatening the survival of a depleted stealhead run in Washington State. Laws protecting marine mammals can and have been modified to deal with such small-scale problems by authorizing the lethal or captive removal of specific problem animals. In some areas, the use of acoustic harassment devices (AHDs) has been authorized to deal with the economic loss to seals by aquaculture facilities or commercial fishermen. Although some of these "fixes" appear to be successful in the short term, their long-term utility is questionable and there is concern about the impact of AHDs on other elements of the ecosystem. Even more controversial are programs designed to reduce entire pinniped populations by culling. Government-sanctioned culling programs to improve fisheries have been practiced in many countries, including Norway and the United States. In Canada, the high annual quota on harp seals (*Pagophilus groenlandicus*) and hooded seals (*Cystophora cristata*) is justified, in part, as a means to reduce seal predation on depleted cod stocks. This approach has been criticized on theoretical grounds because it oversimplifies ecosystem interactions; pinnipeds may feed on a commercially important fish species, but may also feed on predators of that species. Management of culling programs would typically fall under national regulations, but the IUCN Marine Mammal Action Plan has established a protocol to evaluate culling proposals.

K. Ecosystem Management

Ecosystem management refers to approaches ranging from simply considering the impact of a management decision on other elements of the ecosystem to the simultaneous optimization of management strategies to meet management goals of all elements of an ecosystem. There are no examples of the latter approach, although Norway and the signatory nations of the Convention for the Conservation of Antarctic Marine Living Resources are pursuing this goal by promoting multispecies considerations in the management of marine mammal, fish, and seabird resources. Although it is unarguably true that improvements can be made in resource management by considering ecosystem interactions, it is also true that predicting the impli-

cations of even a simple ecosystem perturbation is far beyond our current capabilities. Significant progress in implementing ecosystem management may be left to future generations.

III. Trends in Marine Mammal Management

In recent years, there has been a movement toward management procedures that determine quotas for allowable harvests or incidental mortality based on rigid formulae. Both the IWC's CLA and the U.S. PBR approaches are based on formulae that estimate the allowable removals from a management unit based on measurable attributes (such as estimated population size, population growth rates, catch histories, and the precision of the various estimates that are used). The advantage is that all parties can reach a *priori* agreement on the management objectives and on the rules that will be used to reach those objectives without divisive arguments about the effect on anyone's quota. Biological data are inherently imprecise and full of other uncertainties. For both CLA and PBR approaches, computer simulation studies were used to "tune" the quota formulae to achieve their goals even in the presence of imprecision and bias in available data (Wade, 1998). With the increasing emphasis on rigid quota-based management, debates about management practices are changing. Instead of concentrating on which values of biological parameters and which analytical models should be used, managers are now more concerned with how management units should be defined.

Coincident with the movement toward rigid formula-based quota schemes is an increasing reliance on direct approaches to measuring population parameters and a decreasing reliance on industry statistics, such as catch per unit effort. Advances in survey methodology (line-transect and mark-recapture) have greatly improved our ability to estimate the size of cetacean populations. Photo-identification studies, combined with mark-recapture analysis, have refined our understanding of marine mammal life history. Observer programs have increased the reliability of bycatch and harvest estimates. Satellite tagging and the recent revolution in molecular biology have contributed to an explosion of new information on the structure of marine mammal populations. Although all these recent trends promote the potential for effective marine mammal management, the real impediment to effective management is now the lack of collective willpower to implement regulations and to enforce existing regulations.

There has been increasing interests in applying the "precautionary principle" in marine mammal management. In the face of uncertainty, management decisions should be made to minimize the damage caused by being wrong. In most resource protection issues, there are two types of damage: the damage caused to a regulated industry by providing more marine mammal protection than is needed and the damage done to the populations and the industry by providing too little protection. A look at the catastrophic history of marine mammal management illustrates the disastrous economic and ecological results of management approaches that are not precautionary. One way to add precaution is to reverse the legal burden of proof to ensure that any action will *not* adversely affect the population before that action is permitted. Clearly, the future challenge is how to make marine mammal management appropriately precautionary.

Manatees

Trichechus manatus, T. senegalensis, and *T. inunguis*

John E. Reynolds III
Eckerd College, St. Petersburg, Florida

James A. Powell
Florida Marine Research Institute, St. Petersburg

The manatees (order Sirenia; family Trichechidae; subfamily Trichechinae) represent one of the most derived groups of extant mammals. Although ancestral forms were terrestrial, descendant forms have occupied aquatic habitats since the Eocene Epoch, providing the group with a long period of time over which to evolve. Apart from their suite of unusual morphological attributes (adaptations) associated with their herbivory and aquatic habitat, manatees have many behavioral and life history traits that are similar to those of other mammals. For most aspects of species biology, the Florida manatee is the best-studied taxon, and without data to the contrary, scientists assume that other manatees may be similar to the Florida subspecies.

I. Scientific and Common Names

Trichechus inunguis, Natterer, 1883: Amazonian manatee
T. manatus, Linnaeus, 1758: West Indian manatee
T. m. manatus: Antillean manatee
T. m. latirostris: Florida manatee
T. senegalenis, Link, 1795: West African manatee

II. Conservation Status

The various manatee species are protected by laws specific to the countries they occupy, but enforcement of these laws is generally minimal. Several countries (e.g., United States, Mexico, Belize, Guatemala, Ivory Coast, Cameroon, and Nigeria) have created manatee reserves and sanctuaries, and others (Brazil and Peru) have "protected" areas that include important manatee habitat.

The following list provides examples of broader-scale protection efforts.

Trichechus inunguis: CITES: Appendix I
World Conservation Union (IUCN): listed as vulnerable
United States, Endangered Species Act (ESA): listed as endangered
T. manatus latirostris: CITES: Appendix I
World Conservation Union (IUCN): listed as vulnerable
United States, Endangered Species Act (ESA): listed as endangered
T. manatus manatus: CITES: Appendix I
World Conservation Union (IUCN): listed as vulnerable
United States, Endangered Species Act (ESA): listed as endangered
T. senegalensis: CITES: Appendix II
World Conservation Union (IUCN): listed as vulnerable
United States, Endangered Species Act (ESA): listed as threatened
Protected under Class A, African Convention for the Conservation of Nature and Natural Resources

III. Name Derivations

The generic name of the manatees, *Trichechus*, comes from the Greek words *trichos* (hair) and *ekhō* (to have), referring to the sparse body hairs and abundant facial hairs and bristles. *Inunguis* refers to the lack of nails on the pectoral flippers of the Amazonian manatee. At least two possible origins for *manatus* have been suggested: It could refer to the hand (*manus*), as manatees sometimes use their front, or pectoral, limbs to push food into their mouths. More likely, the term comes from the Carib Indian word *manati*, which means woman's breast, perhaps referring to the fact that the manatee's mammary glands are located in the axillary region in approximately the same anatomical location as the breasts of a human female; this particular anatomical feature contributed to the association of the manatee with the mythical mermaid. *Senegalensis* denotes that the West African species is found along the coast of Senegal, although it also occurs in waters of other west–central African countries.

Vernacular names for the manatees vary by region. In English-speaking areas, they are typically referred to as sea cows; similarly, in German, a manatee is referred to as a *seekuh* or *manati*, in Dutch as a *zeekoe*, in French as a *lamantin*, in Spanish as a *manati* or *vaca marina*, and in Portuguese as a *peixe-boi*, or ox fish. In some west African countries, a manatee is called a *"mammy wata,"* which refers to a water deity. Diverse indigenous names are also in use in Africa and South America.

IV. Diagnostic Characters

A. Diagnostic Characters of the Modern Trichechidae

Unlike some marine mammals (e.g., pinnipeds, polar bears, and sea otters), manatees and the other living member of the order Sirenia, the dugong (*Dugong dugon*), are totally aquatic. They inhabit shallow waterways and feed primarily on plants, a diet that makes the sirenians unique among modern marine mammals.

Although manatees do not dive to great depths or for prolonged periods as many cetaceans and pinnipeds do, they are anatomically well adapted to aquatic habitats (Fig. 1). They lack hind (pelvic) limbs; have reduced, paddle-like front (pectoral) limbs; have fusiform (streamlined, spindle-shaped) bodies with few external protuberances and thick, tough skin; and are very large (an adaptation that facilitates heat conservation). Their heads are somewhat streamlined, and the nostrils are located on the dorsal side of the muzzle. A dorsal fin is lacking. Internally, manatees have extremely thick, heavy (pachyosteosclerotic) bones and an unusual arrangement of the diaphragm and lungs that facilitates buoyancy control. Manatees, like other marine mammals, have sensory and other adaptations that enhance diving, osmoregulatory, and thermoregulatory abilities.

Unusual adaptations accommodate the manatee's herbivorous diet. These include (1) enlarged lips (especially the upper lip) equipped with prehensile as well as tactile vibrissae and moved by a muscular hydrostat; (2) the presence of supernumerary (polydont) molariform cheek teeth that are replaced via horizontal migration along the jaws throughout the lifetime of each manatee; and (3) a greatly expanded gastrointestinal tract (specialized for hindgut fermentation, as in horses and elephants) with several unusual gross and microscopic features.

Manatees differ sharply from their close relative, the dugong. Manatees have a rounded fluke, whereas dugongs have split flukes similar to those of cetaceans. Dugongs have tusks, which manatees lack, and the mode of tooth replacement in the two differs. The rostrum of the dugong is much more sharply deflected downward than the rostrum in any manatee species. In addition, dugong skin is smoother than is the case for West African and west Indian manatees.

B. Diagnostic Characters of the Individual Species

The West Indian manatee is the largest living sirenian, with individuals approaching 1500 kg in weight and 4 m in length. Females tend to be somewhat larger than males, but body size cannot be used to determine either the sex or the age of an individual. West Indian manatees are euryhaline (can tolerate both salt and freshwater) but may require periodic access to fresh water to drink. West African manatees are generally very similar to West Indian manatees in terms of their size, general body form, and habitat, but the West African manatee has a blunter snout, somewhat protruding eyes, and a slightly more slender body. The Amazonian manatee is the smallest trichechid, measuring about 3 m long or less and weighing less than 500 kg. Its "rubbery" skin is smoother than that of its con-

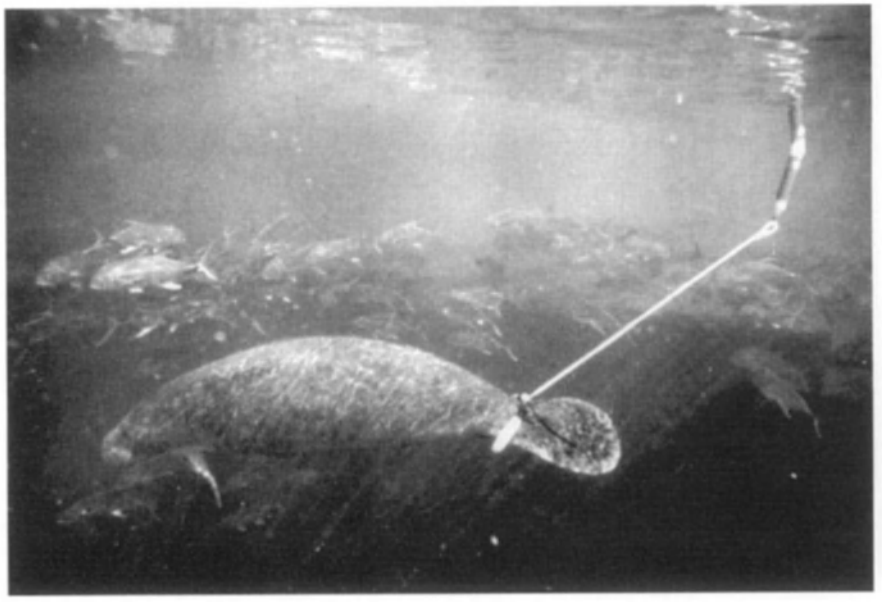

Figure 1 *Although manatees may not swim as fast or dive as deep as some cetaceans do, manatees have the fusiform bodies, the reduced or absent limbs, and the powerful locomotory fluke that cetaceans also have. This particular animal has been fitted with a belt attached to a floating canister containing telemetry equipment. Photograph by Patrick Rose.*

geners, and it lacks nails at the tips of the pectoral flippers, which are proportionately longer than in the other species. In addition, white or pink belly patches are common. The Amazonian manatee is confined to freshwater habitats.

Manatee species also vary in the degree of rostral deflection, corresponding to the predominate location in the water column of food plants in their natural habitats. West African manatees have the least deflected snouts, and Florida manatees the most deflected.

V. Distribution and Abundance

All extant manatees occupy subtropical and tropical waters (Figs. 2–5).

A. West Indian Manatee, *T. manatus*

This species occupies coastal and riverine habitats from the mid-Atlantic region of the United States, throughout the wider Caribbean Sea and Gulf of Mexico, and into coastal parts of northeastern and central–eastern South America. The Florida manatee, *T. m. latirostris*, occurs from eastern Texas to Virginia in the summer, but occupies waters of Florida and southeastern Georgia year-round (Fig. 2). Although its distribution is not continuous, the Antillean manatee, *T. m. manatus*, occupies the remainder of the species' range, from southwestern Texas to South America. It occupies the waters of 19 countries (Fig. 3). The range of the Antillean manatee may overlap with that of the Amazonian manatee around the mouth of the Amazon River (Fig. 4).

Scientists estimate that there may be 3300 or more Florida manatees. Some recent analyses of population trends of manatees occupying different regions of the species' range suggest that the population grew through the 1980s and early 1990s but leveled off in at least some locations during the mid-1990s. As the 20th century ended, other analyses suggested that the population may be relatively stable or may even be increasing slightly in some regions, but the statistical uncertainty associated with data and models leaves open the possibility that the overall population may be declining.

The number of Antillean manatees is unknown. During recent aerial surveys of Belizean waters and waters of southern Quintana Roo, Mexico, more than 400 manatees were counted. The corridor between Belize and southern Mexico is considered to be a last stronghold for the subspecies.

B. Amazonian Manatee, *T. inunguis*

This species occupies freshwater habitats throughout the drainage of the Amazon River and its tributaries, including rivers and lakes in Brazil, Peru, Ecuador, and Colombia (Fig. 4). There are no reliable population estimates.

C. West African Manatee, *T. senegalensis*

This species is found in the coastal and riverine waters of nearly two dozen countries in central and West Africa, from Senegal to Angola (Fig. 5). Manatees inhabit the upper reaches of the Niger River to Guinea and occur throughout the inland delta of Mali. Manatees in the upper Niger River are cut off from the sea by cataracts and a hydroelectric dam. Manatees inhabit two tributaries of Lake Chad, the Logone and Chari rivers, but are not found in the lake itself. The Logone and Chari rivers do not communicate with the sea; during times when water levels were higher, manatees in these rivers probably were able to mix with other manatees by moving through interconnecting

Figure 2 *Range of the Florida manatee,* T. m. latirostris *(map produced by Leslie Ward).*

lakes to the Benue River, a tributary of the Niger River. There are no reliable population estimates.

VI. Geographic Variation/Subspecies

The only species for which subspecies have been identified is the West Indian manatee. The two subspecies differ most obviously in their skeletal (especially skull) morphology.

However, Garcia-Rodriguez *et al.* (1998) examined mitochondrial DNA (mtDNA) control regions from 86 individual west Indian manatees from 8 different locations. They found 15 different haplotypes that could be clustered into three, rather than two, distinctive lineages for the species. These authors also noted for three presumed West Indian manatees from Guyana that their mtDNA haplotypes were more consistent with that of the Amazonian manatee.

Clearly, the systematics of manatees is a topic that requires additional study.

VII. Ecology

All manatees are herbivores, and as hindgut digesters (like horses and elephants), they can subsist on low-quality forage. Because they are such large mammals, manatees would be expected to have a low weight-specific metabolic rate, but their metabolism is 20 to 30% lower than one would expect. The best-studied species, the West Indian manatee, consumes more than 60 species of plants (almost exclusively angiosperms) and may ingest a mass of food that approximates up to 7% of its body weight each day. In some locations, 50 to 90% of the plant biomass may be eaten or uprooted by grazing animals, but the overall effects on local plant productivity of manatee feeding are not well understood. The dugong has been described as a cultivation grazer, and the manatee may serve the same role.

Although manatees subsist primarily on plants, they also consume flesh. They have been reported to consume fish entangled in nets and tunicates have been found in large numbers in some manatee stomachs. Of course, the plants manatees consume have epiphytic organisms growing on their leaves.

The DISTRIBUTION of the Florida manatee is influenced by temperature, and perhaps, by access to fresh water to drink. In cold weather, manatees tend to migrate south and/or seek refuge at natural and artificial warm-water refugia (Fig. 6). The distribution of other manatee species or subspecies appears to be governed to at least some extent by the availability of water and suitable habitat during the wet and dry seasons. Antillean manatees, for example, may move upstream in coastal rivers during the wet season, when water levels are high, and return to lower reaches of rivers during the dry season. Amazonian manatees occupy lakes during the dry season, when rivers and streams dry up. Because the lakes are murky and lack bottom vegetation, manatees may fast during the dry season for up to 200 days when water levels drop and shoreline vegetation is no longer available for them to eat.

The habitat requirements of West African manatees are similar to those of West Indian manatees. Although manatees along the coast of Africa tend to move up rivers and out of estuaries during the dry season, they can occasionally be found in any aquatic habitat. In the upper reaches of the Niger River and some other large rivers, West African manatees, like Amazonian manatees, may remain in lakes during the dry season, when water levels drop, and stay there until waters rise and they can move back into the rivers.

PREDATION on manatees has not been well documented, but it appears that they have few natural enemies and that preda-

Figure 3 *Range of the Antillean manatee,* T. m. manatus *(map produced by Leslie Ward).*

tion levels are very low. Anecdotal reports suggest that crocodilians and sharks may account for some manatee mortality in different parts of the world; in Florida, such reports are reinforced by the rare presence on living manatees of wounds caused by alligators or sharks. Especially, but not exclusively, when aggregated in lakes during the dry season, Amazonian manatees may also be preyed upon by jaguars.

Natural factors that have been documented to kill large numbers of Florida manatees include cold weather and red tides.

VIII. Behavior

Manatees feed on bottom vegetation, plants in the water column, and floating or shoreline vegetation. Their flexible pectoral flippers and prehensile lips, which are equipped with bristles, are used to push vegetation into the mouth. The most striking and well-documented migrations occur in Florida in response to cold weather. Aggregations of more than 300 manatees occur at each of several natural and artificial sources of warm water in winter (Fig. 6). On very cold mornings, the majority of Florida manatees may be found at a few warm-water refugia scattered along the coast. Florida manatees disperse widely in warm weather. Amazonian manatees also migrate seasonally, from rivers and streams in the wet season to deeper waters, such as lakes, in the dry season. In some areas, West African and Antillean manatees show movement patterns similar to those of Amazonian manatees in response to low water and lack of freshwater flow.

Mating herds, composed of a female in estrus and a consort of several (up to 22) males, may remain together for periods of up to a month, typically outside the winter season. The cow is receptive to mating for only a day or two during that time. Although "fighting" does not occur, the males vigorously push and shove one another to gain access to the female. Females mate with several males during the estrous period. The MATING SYSTEM is an example of scramble competition polygamy (specifically polyandry).

Cues males use to locate estrous females are not known, but it is possible that the males detect olfactory, gustatory, and acoustic signals produced by the females. Males tend to have larger home ranges than females do; thus, wandering males may routinely encounter a number of females. Females in estrus have a larger ranger of movement than nonestrous females.

Calves tend to stay close to their mothers for some time after birth. Weaning generally occurs when the calf is 1–2 years old, although calves up to 4 years old may still nurse. When traveling, calves swim parallel and close to their mothers, presumably in a position where they are easy to protect, where COMMUNICATION is facilitated, and where hydrodynamic drag is minimized. During the long period of maternal care, calves

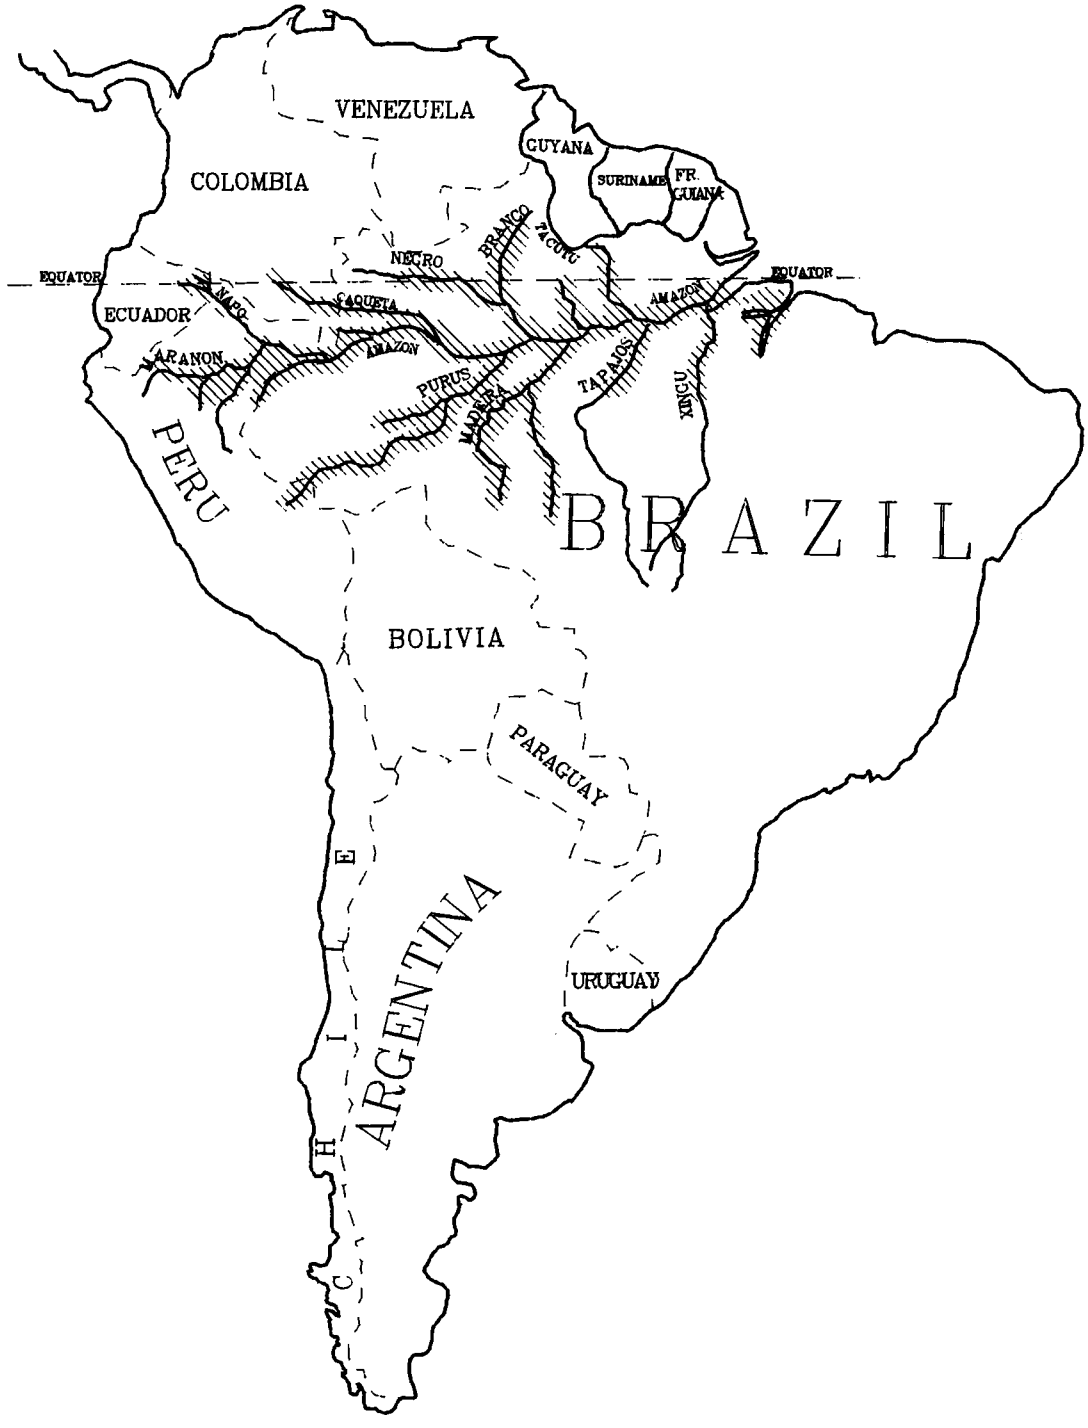

Figure 4 *Range of the Amazonian manatee,* T. inunguis *(map produced by Leslie Ward).*

apparently learn the locations of important resources such as warm-water discharges or fresh water. The learning process causes groups of manatees, including young animals that have recently become independent from their mothers, to use the same areas year after year.

Details of the social structure of manatees are lacking. Florida manatees appear to have a simple fission–fusion society in which individuals come together in a series of temporary groups. G. B. Rathbun has stated that although such societies may be relatively unstructured, the lack of social structure is not the same as a lack of social complexity.

Communication among manatees appears to involve acoustic signals (squeaks and squeals, mostly in the 3- to 5-kHz range), tactile cues (rubbing and "kissing"), visual cues, and

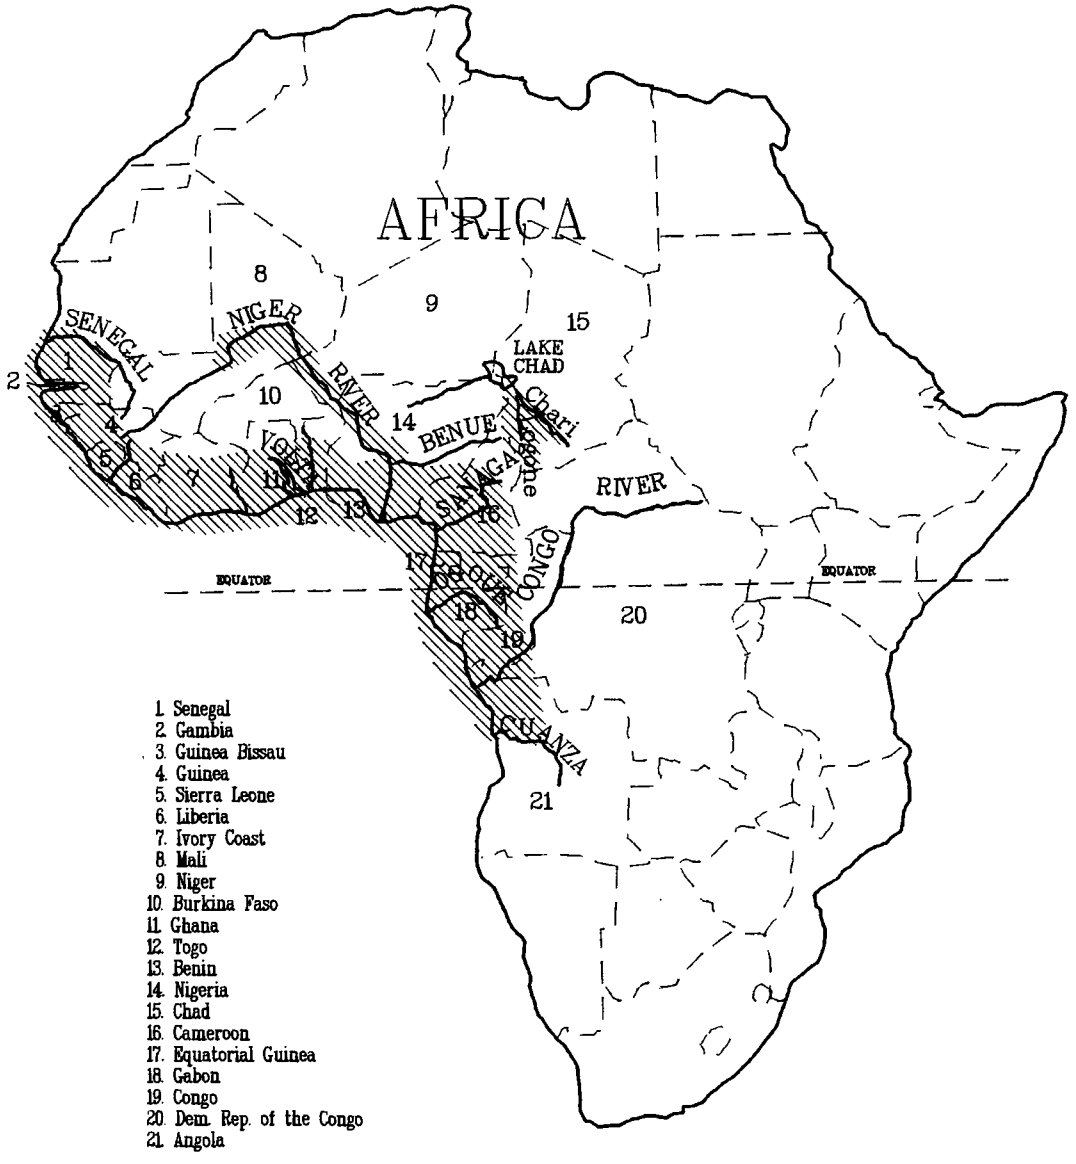

Figure 5 *Range of the West African manatee,* T. senegalensis *(map produced by Leslie Ward).*

possibly chemical cues (suggested by repeated use of "rubbing posts" and by individuals mouthing one another).

Manatees appear to play. Body surfing and follow the leader have been observed.

IX. Anatomy/Physiology/Life History

Manatees have a suite of unusual adaptations. We note here some features of a variety of organ systems.

The bones, especially the ribs, are dense and heavy (osteosclerotic), and the ribs and some other bones are swollen (pachyostotic). As in other marine mammals, the long bones are shortened and the phalanges in the pectoral appendage are more elongated than are those of "typical" terrestrial mammals. Hyperphalangy, however, does not occur. The first digit is reduced and the fifth digit is enlarged. Pelvic limbs are absent, although vestigial pelvic bones that are sexually dimorphic remain embedded in hypaxial musculature. Erythropoiesis (formation of red blood corpuscles) and granulopoiesis (formation of certain white blood cells) occur primarily in the vertebral bodies. The SKULL is elongated but not telescoped. Nares and nasal bones have migrated dorsally. The zygomatic arch, which abuts the periotic bone on each side of the skull, is relatively light and porous and is permeated with oil. However, compared to the bones of the zygomatic arches of most marine mammals, the bones of the manatee's arch are huge, reflecting their importance as an attachment for powerful chewing muscles.

The muscle color is of several shades, from almost white to red, apparently due to differences in myoglobin concentration in particular muscles or muscle groups. Axial muscles to the fluke are extremely powerful. The panniculus muscles are very

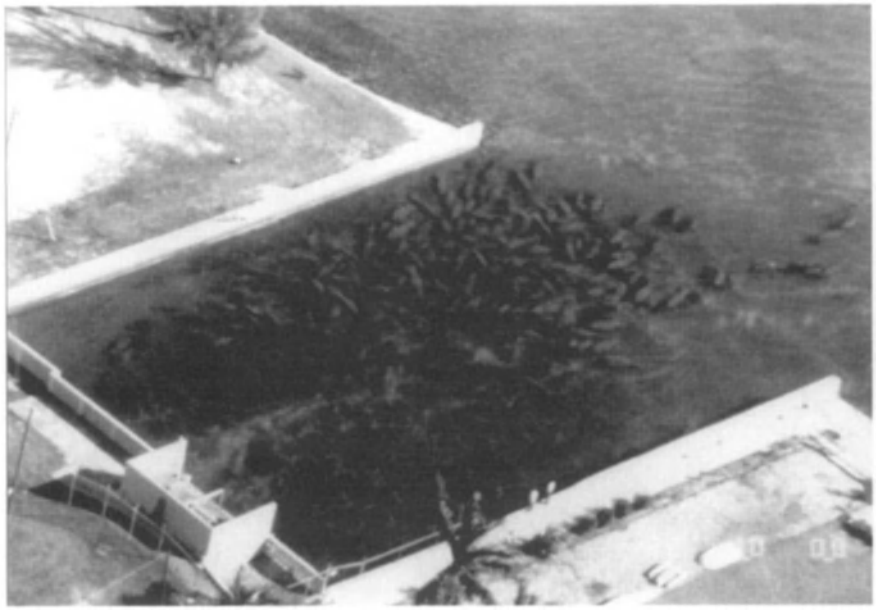

Figure 6 *Florida manatees aggregate in large numbers around natural and artificial sources of warm water in winter. In this photograph, approximately 230 manatees huddle in the discharge of the Riveria power plant. Photograph by John Reynolds and Florida Power & Light Company.*

well developed, as are muscles to the pectoral flipper (presumably to facilitate both dexterity and strength).

The skin is extremely heavy and thick and may provide some of the ballast needed for buoyancy control. Body hairs are sparse (approximately 1 every cm^2); sweat glands are lacking; and nerve plexuses associated with some hairs suggest that the hairs are important in detecting pressure or in tactile communication. Instead of having one layer of BLUBBER as many other marine mammals do, manatees have alternating layers of panniculus muscle and blubber (somewhat resembling bacon).

The lungs are long and unlobed and occupy virtually the entire dorsal region of the trunk. Manatees exchange about 90% of the air in their lungs in a single breath. The branching pattern of the bronchi is monopodial, and the terminal airways are reinforced with cartilage. The diaphragm is large and powerful, is located in a horizontal (coronal) plane, is constructed as two independent hemidiaphragms, and is instrumental in maintaining buoyancy control.

The large intestine is enormous (more than 20 m long in large animals), a feature that is not surprising in a hindgut fermenter. The stomach has a large accessory organ of digestion (the cardiac gland), and the capacious duodenum has two prominent diverticulae. The cecum is small and bicornuate. The life-long, horizontally oriented tooth replacement is a very unusual feature and may be an adaptation to facilitate the consumption of the gritty plant material that manatees consume. Histology of the various portions of the gastrointestinal tract shows some unusual cellular arrangements. The accessory organs of digestion (liver, pancreas, salivary glands) are unremarkable. Manatees have taste buds but no vomeronasal organ.

The heart is not unusual except for a persistent interventricular cleft, the presence of notable amounts of cardiac fat, and the large amount of pericardial fluid. Circulatory adaptations (retia, arteriovenous anastomoses, countercurrent heat exchangers) facilitate overall heat conservation, while also allowing for the cooling of the reproductive organs and the nervous tissues.

The brain is small (the encephalization quotient for *T. manatus* is 0.27), and the cerebral hemispheres lack extensive convolutions. Notably large trigeminal (cranial nerve V) and facial (cranial nerve VII) nerves are associated with the facial vibrissae.

The uterus is bicornuate. The ovaries are rather flattened and diffuse, and in mature individuals, the ovaries have numerous corpora. The penis and testes are located inside the body wall. The testes are relatively small, but the seminal vesicles are very large. The testes abut the kidneys along the caudal part of the diaphragm.

The kidneys are lobular, are located on the ventral surface of the caudal part of the diaphragm, and are often encapsulated in fat. Their microscopic structure suggests an ability by manatees to produce concentrated urine and therefore to go for prolonged periods without access to fresh water.

Manatees can remain submerged for more than 20 min but generally dive for much shorter periods of time (2–3 min or less). Because the plants manatees consume grow close to the surface where sunlight is available, dives are usually shallow.

Scientists have historically suggested that temperatures below about 19° C induce sufficient stress to cause at least some manatees to seek warm water as a refuge. Some recent evidence suggests that this temperature may be a little high and

that 17° C is perhaps a more realistic point at which stress occurs. Even though scientists may be uncertain of the precise point at which thermal stress occurs, it is clear that both chronic and acute exposure to low temperatures may cause death.

The extent to which manatees physiologically *need* fresh water is unclear. It is clear, however, that Florida manatees *like* fresh water to drink. Functional morphology suggests that the kidney should be able to produce hyperosmotic urine and be able to rid the body of excess salt following seawater ingestion.

Manatees, like other marine mammals, are *K* strategists when compared to most other animals. In some ways, however, manatees appear to be less *K* selected if the comparison group is just the marine mammals. Table I provides life history information on Florida manatees.

X. Evolution and Fossil Record

Sirenians probably arose in the Old World (Eurasia and/or Africa) not later than the early Eocene Epoch, 50–55 million years ago. The oldest fossils are from Jamaica. Within a few million years (i.e., in the middle Eocene, 45–50 million years ago), several genera of sirenians existed. Peak diversity of sirenians occurred during the Oligocene and Miocene Epochs (5–35 million years ago).

The first truly manatee-like (i.e., trichechine) sirenian was *Potomosiren*, fossils which are about 15 million years old (Miocene of Colombia). During the Pliocene Epoch (about 2–5 millions years ago), trichechids also inhabited the Amazon Basin and the Caribbean. The Amazonian trichechids gave rise to the Amazonian manatee, and the Caribbean trichechids are thought to have given rise to the West Indian and West African manatees, which are sister taxa.

Due at least in part to their dense bones, sirenians in general are well preserved in the fossil record, but true manatees are rare until the Pleistocene.

Various lines of evidence (e.g., genetic analyses, electrophoresis of serum proteins, and morphological studies) suggest that the order Sirenia (manatees and dugong) is most closely related to a group of mammalian orders called the Paenungulata. The extant paenungulates include the elephants (order Proboscidea) and hyraxes (order Hyracoidea). The sirenians appear to be most closely related to elephants and the extinct, HIPPOPOTAMUS-like desmostylians.

XI. Interactions with Humans

Humans have interacted with the various manatee species in a number of ways, most of them harmful to the manatees. The following information includes both well-documented and presumed interactions.

Manatees have historically been hunted throughout their ranges. In Florida, HUNTING pressure has virtually ceased within the past few decades, although animals are occasionally still taken illegally for meat. The best-documented and most extreme example of manatee hunting occurred in Brazil from 1935 to 1954, when between 80,000 and 140,000 Amazonian manatees were killed for their meat and hides. Primary products included *mixira* (fried manatee meat preserved in its own

TABLE I
Estimated Population Traits of the Florida Manatee Based on Long-Term Life History Research[a]

Trait	*Description*
Maximum life expectancy	60 years
Gestation period	11–13 months
Litter size	1
Percentage of twins	1.79% at Blue Spring; 1.4% at Crystal River
Sex ratio at birth	1:1
Calf survival to year 1	0.60 at Blue Spring; 0.67 at Crystal River
Annual adult survival	90% on Atlantic coast; 96% at Crystal River and Blue Spring
Earliest age of first reproduction: ♀	3–4 years
Mean age of first reproduction: ♀	5 years
Earliest onset of spermatogenesis	2 years
Proportion of adult ♀♀ pregnant	0.33 of salvaged carcasses; 0.41 of living animals at Blue Spring
Proportion of nursing first-year calves during winter season	0.36 (mean)
Mean period of calf dependency	1.2 years
Mean interbirth interval	2.5 years
Period of highest number of births	May–September
Period of highest frequency of mating herds	February–July

[a]From Lefebvre and O'Shea (1995), supplemented by some more recent data.

fat), uncooked meat, lard, and the tough hides, which could be used for a range of products, including whips, shields, and machine belts. Although the market for hides diminished after 1954, several thousand manatees were killed each year through the late 1950s, and probably beyond.

In certain countries such as Peru and Ecuador (Amazonian manatee) and possibly in some West African countries, military patrols hunt manatees, or hire local hunters to catch manatees, for food.

Manatees are also hunted for reasons other than the products they provide. In Sierra Leone, the Mende people hunt manatees, in part, to reduce the number of manatees and thereby to keep them from tearing fishing nets, destroying fish that have been netted, and plundering rice fields.

However, local traditions may work in favor of manatees and prevent their harvest in particular areas. In the Korup region of Cameroon, for example, villagers fear manatees and have no taste for the meat, so they generally do not hunt the animals.

An interesting presumed effect of manatee hunting in tropical America and West Africa is that some manatees have become nocturnal and/or crepuscular.

Manatees are captured accidentally in fishing gear (crab pot lines, trot lines, fishing nets) in the United States and other countries. The extent of serious injury or mortality is unknown.

Collisions with boats and barges account for about 25% of all manatee mortality in the United States (Fig. 7). The number rose at a rate of about 7.5% per year between 1976 and 1996, and currently more than 70 animals die annually in this way. The number of registered boats in Florida alone exceeds 750,000. Based on observations of scarred animals, collisions with boats appear to be occurring with increasing frequency in other parts of the world, but the extent to which those collisions kill manatees outside the United States is unknown. Also unknown is how seriously boat-inflicted injuries debilitate manatees and affect reproduction, without causing immediate death (Fig. 8).

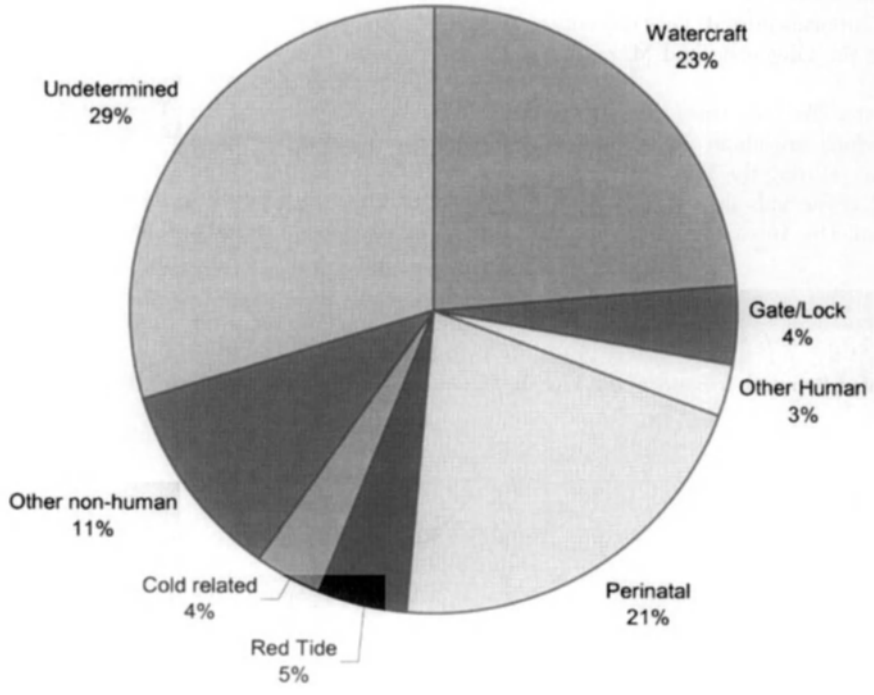

Figure 7 *Categories of manatee mortality in Florida. This pie chart shows manatee mortality categories based on 3501 carcasses recovered or reported to federal or state agencies from 1974 through 1998. The highest percentage of deaths remains undetermined* (n = *1043*) *and includes unrecovered* (n = *99*), *badly decomposed* (n = *588*), *and other carcasses* (n = *423*) *that were not badly decomposed but for which cause of death could not be assigned. Total human-related mortality is high* (n = *1065, 31% of total*) *and includes watercraft-related deaths* (n = *828*), *trauma or drowning caused by canal locks or flood gates* (n = *145*), *and other human-related factors such as entanglement* (n = *92*). *Non human-related causes of death* (n = *658, 19% of total*) *are related to cold exposure* (n = *124*), *red tide outbreaks* (n = *164*), *or other factors* (n = *92*). *Perinatal mortality* (n = *735*) *refers to the death of a small animal* (≤ *150 cm long*) *for which cause of death cannot be determined; perinatal mortality can be either human or nonhuman related. Watercraft-related mortality continues to rise annually and is the single highest known category of death. Produced by James Powell.*

Figure 8 *Although several dozen Florida manatees die each year because of collisions with watercraft, many animals survive such encounters, albeit with considerable pain and disfigurement. The extent to which reproduction and longevity of survivors are compromised is unknown. Photograph by Sirenia Project, U.S. Geological Survey.*

The propeller scars and increased turbidity caused by boats negatively affect the health and distribution of sea grasses and other vegetation eaten by manatees. Boats also make noise, which may affect manatee distribution, habitat use, and energetics. Boats can, therefore, affect manatees both indirectly, by contributing to diminished food resources, and directly, by disturbing, injuring, or killing them. In Florida, manatees sometimes become trapped in flood control structures and canal locks and die. About 4% of the manatees known to die between 1974 and 1996 were crushed and drowned in flood gates or canal locks. Increasingly, scientists and environmentalists at the national, state, and regional levels are concerned about the effects of POLLUTION both on the health of individual animals and on the status of populations. Levels of certain chemical pollutants have been assessed in some marine mammal tissues, but the effects of these chemicals are unclear. In only one case did scientists experimentally demonstrate a clear cause-and-effect relationship between a toxicant and reproductive impairment (in harbor seals). Based on toxicological studies of laboratory animals, scientists suspect that chemical pollution is harming the endocrine and immune systems of at least some stocks of marine mammals, but this has yet to be demonstrated.

Scientists have found elevated levels of copper in the tissues of Florida manatees from certain locations, but levels of other metals and of organochlorines have been unremarkable. No other toxicants have been examined, and the effects of elevated copper levels on manatees are unknown.

In Central America, runoff of pesticides and herbicides and the ingestion of plastic debris have been suspected of causing the death of Antillean manatees. In the Amazon basin, the water pollution associated with mining activities may be harming manatees.

NOISE pollution is a problem of which people around the world have become increasingly aware, but about which few data exist. Many scientists suspect that noise pollution negatively affects manatees, but studies examining this relationship are needed. Underwater noise of anthropogenic origin has been demonstrated or suggested to cause some marine mammals to vary their normal patterns of habitat use and to expend more energy than usual in order to avoid disturbance, and these behavioral changes could logically be expected in manatees too. In the coastal waters of Florida, where more than 750,000 boats are registered and many additional boats are also found, any cumulative effects of anthropogenic noise are a real cause for concern. Even in Costa Rica, where boat traffic is sparse compared to that in Florida, hunters and scientists have noted that manatees react to the noise of approaching boats and that manatee distribution is inversely related to the amount of boat traffic.

Behavioral and anatomical evidence suggests that manatees hear boat motors, but a recent audiogram suggests otherwise. Nevertheless, the suggestion (unwise in our opinion) has been made to put noise makers or acoustic alarms on boats to alert manatees. Not only may such devices be unnecessary if manatees do, indeed, already hear boats, but because their use would greatly increase existing levels of underwater noise, they would most probably disturb or harm not only manatees but many other organisms as well.

Disturbance can occur in ways besides those associated with boat traffic or boat noise as described earlier. At Crystal River and nearby springs in Florida, tourists gather in large numbers to swim with manatees when the animals aggregate in winter. Although most people behave responsibly, some stand on, ride,

or tie ropes to the manatees. Such behavior by humans could cause manatees to avoid seeking refuge at warm-water springs in winter, which could lead to even higher than usual manatee mortality in very cold weather. Disturbance of females accompanied by calves could lead to abandonment of a calf, contributing to escalating levels of "perinatal" mortality.

In Southern Lagoon, Belize, and other locations, ecotourism focusing on manatees has developed. Although the financial benefits to local residents may be significant, such activities should be carefully planned to minimize the negative effects on the manatees residing in and using the resources of such locations.

As noted earlier, disturbances from hunting pressure have apparently induced nocturnal or crepuscular behavior in manatees in certain parts of the world.

We have discussed many of the harmful ways that humans have affected manatees—noise, chemical contamination, boat traffic, and ecotourism, for example—but in at least one way, we humans may be helping manatees. Most biologists feel that thermal discharges from power plants and other sources have provided winter habitat that has helped the populations of manatees in Florida to survive and even to grow in at least some areas. However, these plants have finite lifetimes, and manatee dependence on them creates a long-term dilemma for managers. What will the manatees do if warm water is no longer available at a spot where they have learned to depend on it? Industry (primarily Florida Power & Light Company) and the U.S. Fish and Wildlife Service have initiated discussions to attempt to solve this problem.

Another way in which people have helped manatees is by the introduction of exotic aquatic plants into Florida's waterways. Such plants as *Eichhornia crassipes* (water hyacinths) and *Hydrilla verticillata* have proliferated to such an extent that they provide important and abundant food resources for manatees in certain regions of the state. In fact, the exotics displace native vegetation and may grow so luxuriantly that they create navigation problems in some waterways; manatees in Florida have been suggested as possible economical weed-clearing agents, a role that they fill well in some canals in Guyana.

Other human-related habitat modifications have not been helpful to manatees. Dams or other structures prevent manatees from pursuing normal MIGRATION routes along rivers in South America and West Africa. Finally, the eradication of millions of hectares of rain forest each year in Amazonia cannot help but negatively affect *all* species occupying that area because of factors such as reduced productivity, siltation, and changes in hydrological cycles.

Manatees are maintained in nearly 20 different facilities worldwide. They breed in several of the facilities. In certain facilities in Florida, injured or diseased manatees are routinely rehabilitated and released back into the wild, thereby assisting wild populations.

Without entering the debate about the appropriateness of captivity, we simply note here that facilities that display manatees to the public provide important venues for educating people about manatees and their conservation, as well as for conducting basic and applied research on the different species.

Acknowledgments

We thank Holly Edwards, Judy Leiby, Bill Perrin, Sentiel Rommel, and an anonymous reviewer for their valuable comments on the manuscript. We are also grateful to Leslie Ward for producing the species range maps and to Patrick Rose, Florida Power & Light Company, and the Sirenia Project (U.S. Geological Survey) for permission to use slides.

Marine Parks and Zoos

DANIEL K. ODELL

LORAN WLODARSKI
SeaWorld Florida, Orlando

I. The History of Zoological Parks

Humans have held wild animals in captivity for hundreds if not thousands of years. The earliest zoos were not meant for the average citizen but for the elite, as wealthy rulers collected unusual animals for their enjoyment. Slowly these private collections turned public such as when the animals gathered at Schloss Schönbrunn, Vienna, Austria, first opened to the public in 1765 (Courcy, 1999). The park is considered the first modern zoo. Polar bears (*Ursus maritimus*) and various pinnipeds were probably among the first marine mammals to be held by humans. Polar bears may have been held since about 1060 and harbor porpoises (*Phocoena phocoena*) since perhaps as early as the 1400s, but the majority of marine mammals seen more commonly in marine facilities were not displayed until the late 1800s and early 1900s (Reeves and Mead, 1999). Many types of cetaceans have never been displayed and some have only been seen recently in marine parks. Killer whales (*Orcinus orca*), for example, were first displayed in 1961.

II. Zoos and Marine Parks Worldwide

How many zoos, aquaria, and marine zoological parks exist worldwide? More specifically, how many of these facilities display marine mammals? It is likely that no one has an exact count. New facilities are being built, some facilities close, and some facilities change the animals that they have on display. The Conservation Breeding Specialist Group (CBSG) of the IUCN maintains a global zoo directory on its worldwide web page <www.cbsg.org/gzd.htm>. The directory lists nearly 1800 institutions but does not give information on marine mammals in the collections. A similar list is published in each issue of the International Zoo Yearbook. The yearbook also includes a list of zoo and aquarium associations with postal, phone/fax, and email addresses. Kisling (2001) is the most recent review of zoo and aquarium history and includes an admittedly incomplete listing of over 900 zoos and aquaria worldwide. For example, 230 facilities are listed for the United States; 140 for Japan; 56 for India; and 155 for Asia (Table I). A survey by Couquiaud-Douaze (1999) of facilities holding cetaceans lists 166 institutions in 42 countries located on all continents except Antarctica (Table I). If pinnipeds and polar bears were added, the number of institutions would grow considerably. For example, a 1995 survey (Andrews *et al.*, 1997) of the United States and Canada listed 109 facilities that held 1460 marine mammals, including 11 species of cetaceans, 11 species of pinnipeds, the sea otter (*Enhydra lutris*), and the Florida manatee (*Trichechus*

manatus latirostris). Polar bears were not included.

Zoological parks can be found through web sites maintained by regional organizations. The following list is representative and not necessarily all inclusive: American Zoo and Aquarium Association <www.aza.org>; Australian Regional Association of Zoological Parks and Aquariums <www.arazpa.org.au>; Canadian Association of Zoos and Aquariums <www.caza.ca>; European Association of Zoos and Aquaria <www.eaza.net>; Japanese Association of Zoological Gardens and Aquariums <www.jazga.or.jp>; PanAfrican Association of Zoological Gardens, Aquariums and Botanical Gardens <www.paazb.org>; South East Asian Zoos Association <www.seaza.org>; World Zoo Organization <www.worldzoo.org>; Zoological Society of London <http://www.zsl.org/ioz/research/>; and Zoos Worldwide <www.zoos-worldwide.com>.

III. Challenges

As zoos and aquaria developed, there is no question that the quality of the facilities has improved dramatically, especially over the past several decades and especially in developed countries. Enclosure and pool sizes have increased and have gone from caged to cageless exhibits. Governments have enacted (or are considering) legal standards for the care, maintenance, and display of captive animals (e.g., the United States Animal Welfare Act) and these standards are continually evolving. Marginal facilities, including many traveling or temporary exhibits, have been eliminated. However, on a worldwide basis, there remains much room for improvement. These improvements often have a high financial cost and there is often an unavoidable trade-off with funding for other human activities (e.g., health care). If facilities cannot provide proper care for their animals, perhaps they should be closed and the animals relocated to other facilities. Unquestionably, it is in the best interests of all zoo and aquariums staffs to provide the best possible care for the animals in their charge. Whether institutions are formally "for profit" or "not for profit," it still takes large amounts of money to build, operate, maintain, and expand exhibits. Captive breeding is becoming more and more important for marine mammal facilities. These programs often require additional, separate facilities (e.g., maternity pools) and additional animals. Another challenge is the acquisition of high-quality marine mammal food (primarily fish and squid) on a reliable basis. As fish stocks are depleted around the world, marine mammal facility managers must plan accordingly. Some are considering the development of a mass-produced fish replacement for marine mammal food. Such a product could be produced as needed and would not require the storage of a year's supply.

A (perhaps) more difficult challenge deals with the ethics of keeping wild animals (or, for that matter, any animal) in captivity for any purpose (Mench and Kreger, 1996). Worldwide, one will encounter any number of groups dedicated to the elimination of facilities holding cetaceans for any purpose. Interestingly, one seems to see little, if any, opposition to holding pinnipeds. Marine parks and zoos are often targeted by protests when new exhibits are proposed or opened or when new animals are acquired. The effectiveness of these protests and similar activities remains unclear. Ultimately, each person will have to reach her/his own conclusions on the ethics of keeping animals in captivity. One can only ask that people seek factual information (zoos and aquariums have an obligation to provide the best available information on the animals in their charge), even if they choose to ignore it, before making their personal decisions.

IV. Research

The mission statements of most zoological parks and aquaria probably include "recreation, education, conservation, and research" in one form or another. Whether the institution is private, for-profit; private, not-for-profit; or public and supported to some extent by taxes (i.e., public funds), the recreation component is the most visible followed by the education component. The extent to which these institutions are involved in research and conservation programs varies and is, to some extent, dependent on financial resources. However, even the smallest of institutions (in size or in financial resources) can participate in local or multipartnered national or international research and conservation projects.

Research on wild marine mammals, especially cetaceans, is often expensive and subject to the vagaries of environmental conditions (i.e., weather) among other things. Modern technology (radio and satellite tags, time-depth recorders, GPS tags, "critter cams," hydrophone arrays, etc.) have made huge contributions to our knowledge of free-ranging marine mammals. However, short of "Star Trek Tricorder" technology, there is still much that cannot be learned from wild animals that can be learned from captive marine mammals. Behavior, including acoustic emissions, can be observed and recorded 24 hr/day if desired. Animals can be trained to hold position for body measurements, collection of body fluids (blood, urine, milk), various medical procedures (i.e., ultrasound examinations), and collection of expired gases. Animals can be trained for a variety of visual, acoustic (hearing, ECHOLOCATION), locomotion, and learning studies. The birth, growth, and development (behavioral and physiological) of offspring can be detailed. Therefore, studies on captive animals are not a replacement for, but a supplement to, studies on free-ranging animals, and the results must be applied with the limits of these "laboratory" studies in mind.

One measure of the involvement of zoos and aquaria in research can be obtained from annual reports of individual institutions and regional organizations. For example, the American Zoo and Aquarium Association's (AZA) annual report on conservation and science for 1996–1997 (Hodskins, 1998) lists over 1100 publications of all types (abstracts, magazine articles, journal articles, etc.) for all animal groups produced by the AZA member institutions during that time period.

V. Education

Marine parks, zoos, and aquaria offer a wide variety of education program [in-park graphics, exhibit narrations, behind-the-scenes tours, curriculum-specific programs for various age and grade levels from preschool through college, camp programs, classroom programs, off-site outreach programs, and, in the electronic age, satellite television and internet (worldwide web) offerings]. In fact, United States facilities holding marine mammals for public display are required by federal law to have an approved education program.

The world we live in might be remarkably different if everyone could travel to the plains of Africa to view cheetahs (*Acinonyx jubatus*) stalking their prey, to view diminutive Humboldt penguins (*Spheniscus humboldti*) basking in the South American shorelines, or perhaps see meandering Florida manatees slowly grazing on vegetation along the coasts of the state of Florida. However, for most people around the planet, such encounters will never occur. In a 1995 Roper poll, 87% of those who participated stated that their only opportunity to see wild animals came from visiting zoological facilities (Roper Starch Worldwide, 1995). Given the fact that most people cannot afford the time and money of a jet-set lifestyle, zoological parks are vital links to connect mankind with the plethora of animals on the planet.

Zoological parks alert people to the increasing threats these animals face. For example, because most people will not travel to view wild cheetahs in Africa, they may not see how these creatures are slaughtered for their hides, how Humboldt penguins are disappearing due to the mining of their guano (feces) deposits where they nest, or how Florida manatees are highly endangered thanks to an ever-increasing presence of humans in their habitat. Zoological facilities may be entertaining, but education, research, and conservation are now cornerstones of major parks. The same Roper poll revealed that 92% of those surveyed agreed that zoological parks are vital educational resources.

Although approximately 71% of the planet is covered by oceans, this realm and its inhabitants remain a mystery to a majority of people. Marine life parks helps (1) educate the public about the seas and (2) clear up long-rooted misconceptions about ocean animals. A prime example of this is how killer whales were perceived in the past and how they are viewed today.

Some cultures, like aboriginal tribes of the Pacific Northwest, respected killer whales, although several major whaling countries feared these animals. Indeed, the name *Orcinus* is probably derived from Orcus, an ancient mythological Roman god of the netherworld—a reference to the ferocious reputation of this animal. In 1835, Hamilton wrote that the killer whale ". . . has the character of being exceeding voracious and warlike. It devours an immense number of fishes of all sizes . . . when pressed by hunger, it is said to throw itself on every thing (sic) it meets with . . ." In modern civilization, many still envisioned killer whales as terrifying threats to humans, with a 1973 United States Navy diving manual warning that killer whales "will attack human beings at every opportunity." In the not too distant past, governments such as Japan, Greenland, Canada, and the United States sanctioned the use of lethal force to be used against killer whales. Killer whales were hunted for commercial use and despised by whalers who would ". . . often carry a rifle expressly for the Killer's benefit," according to Bennett in this book "Whaling in Antarctica." In 1961, a killer whale was displayed publicly for the first time and afterward the perception of these animals began to change. Coupled with a growing environmental awareness in the 1960s, public sentiment rallied to protect cetaceans like killer whales from hunting. Cetaceans are now protected by various national laws and international agreements, and killer whales are generally perceived in a positive way thanks in part to the educational programs of zoological parks.

VI. Conservation

Conservation programs are linked inextricably with both research and education programs. Zoos, aquaria, and marine parks that hold marine mammals can incorporate conservation messages (i.e., do not feed or swim with wild dolphins or manatees; proper field etiquette and trash disposal) into static graphics and show and exhibit scripts and narrations, as well as in classroom programs and the electronic media. The American Zoo and Aquarium Association's annual report on conservation and science for 1996–1997 (Hodskins, 1998) listed over 1200 conservation projects in which the AZA's 185 members were involved during that time period.

Facility staff experienced in handling marine mammals can provide advice and assistance to field workers. Facilities located near an endangered species' habitat can assist with rescue and rehabilitation of sick or injured animals [e.g., monk seals (*Monachus* spp.) in Hawaii and the Mediterranean/eastern Atlantic; manatees in Florida; sea otters in Alaska and California; and Steller sea lions (*Eumetopias jubatus*) in Canada and Alaska]. Unfortunately, no facility is large enough to handle a blue (*Balaenoptera musculus*) or right whale (*Eubalaena* spp.), although SeaWorld California had remarkable success with an orphan gray whale (*Eschrichtius robustus*) calf (Antrim *et al.*, 1998). It may even be possible for facilities to start breeding colonies of severely endangered marine mammals [e.g., the baiji (*Lipotes vexillifer*)] if field conservation efforts prove inadequate. In addition, institutions can make direct monetary contributions to conservation programs and encourage their visitors to make their own contributions to bona fide programs.

Mass Die-Offs

JOHN HARWOOD
University of St. Andrews, Scotland, United Kingdom

The term "mass die-off" has been used rather imprecisely in the scientific literature. In general, it is an event that involves the death of many hundreds of individuals in a relatively short interval (usually 1–2 months). Mass die-offs of rare species may involve smaller numbers of individuals, but the use of this term can be justified if a large proportion of the population is involved in the die-off. STRANDINGS of groups of social cetaceans, such as pilot whales (*Globicephala macrorhynchus* and *G. melas*) and false killer whales (*Feresa attenuata*), should probably not be regarded as mass die-offs. However, large numbers of dead bodies may wash up along a short section of coast during a mass die-off, and this may, initially, resemble a stranding event. Marine mammals spend most of their lives at sea and only a fraction of the number of individuals that die during a mass die-off are likely to be observed. As a result, the true magnitude and effect of a mass die-off cannot be assessed from a simple body count. The scale of the die-off is usually best estimated by comparing abundance estimates made before and after the event.

I. Diagnosis

The fact that marine mammals spend most of their lives at sea makes it not only difficult to determine how many individuals have died during a mass die-off, but also difficult to diagnose the cause. Many days may elapse between the death of an individual and the recovery of its carcass. To make matters worse, many die-offs occur along remote stretches of coastline where access is difficult, further increasing the time between death and examination. The problem is further complicated because many of the agents that can cause mass die-offs also reduce resistance to diseases. Exposure to these agents may then allow other pathogens, which would otherwise by relatively harmless, to contribute toward an individual's death.

Despite these problems, it has proved possible to identify with some confidence the causes of several of the mass die-offs that were observed in the last 20 years of the 20th century. Three factors appear to be particularly important: infectious diseases, naturally occurring toxins, and environmental events. Several of these factors may act together, and the effects of any one of them can be amplified by anthropogenic factors (such as previous exposure to potentially toxic chemicals).

II. Disease

Disease of one kind or another is a frequent cause of mortality in marine mammal populations, but highly infectious disease organisms (particularly viruses) can cause the death of large numbers of animals in a very short period. An influenza virus probably caused the death of at least 450 harbor seals (*Phoca vitulina*) along the New England coast of the United States in 1979–1980. The family of viruses that is most often associated with disease-induced die-offs, however, is the morbilliviruses. Measles is the most familiar virus in this family. Canine distemper virus (probably contracted from domestic dogs or farmed mink) caused the death of several thousand Baikal seals (*Pusa sibirica*) in the Russian Federation in 1987–1988. The closely related phocine distemper virus caused the death of 18,000 harbor seals in the North Sea during 1988, and a dolphin morbillivirus caused the death of several thousand striped dolphins (*Stenella coeruleoalba*) in the Mediterranean Sea between 1990 and 1992. The death of more than 740 bottlenose dolphins (*Tursiops truncatus*) along the Atlantic coast of the United States in 1987 was initially attributed to poisoning by algal toxins (see later), but more recent evidence suggests that this was also caused by dolphin morbillivirus. Morbilliviruses tend to suppress their host's immune system, thus increasing the risk of secondary infection by a wide range of disease agents. These secondary infections are often the final cause of death for an individual infected with a morbillivirus, which can make it difficult to diagnose the real cause of a die-off.

III. Toxins

Some species of single-celled algae (notably diatoms and dinoflagellates) produce poisonous compounds (known as phycotoxins), which can accumulate in any fish or invertebrates animals that eat them. When environmental conditions are particularly suitable, these organisms multiple rapidly, creating "blooms." The resulting high concentrations of phycotoxins can cause mass mortalities of fish and fish predators. The best documented event of this kind involving marine mammals was the death of over 400 California sea lions (*Zalophus californianus*) along the central California coast during May and June 1998. This coincided with a bloom of an algal diatom, which is known to produce domoic acid, a dangerous neurotoxin, in the same

area. Domoic acid was detected in northern anchovies, which are plankton feeders and a well-known prey of sea lions, and in the body fluid of sick sea lions. These sea lions also showed many of the neurological symptoms commonly associated with domoic acid poisoning.

Toxins produced by dinoflagellate protozoa have been implicated in the deaths of Hawaiian monk seals (*Monachus schauinslandi*) in 1978, in the death of 14 humpback whales (*Megaptera novaeangliae*) in Cape Cod Bay in 1987, and in the death of large numbers of manatees (*Trichechus manatus*) in Florida in 1982 and 1996.

In May and June 1997 the bodies of over 100 Mediterranean monk seals (*Monachus monachus*) were found along a short stretch of the West African coast near the border between Mauritania and the former Western Sahara. Initial investigations revealed that at least some of these individuals had been infected with a morbillivirus, which most closely resembled dolphin morbillivirus, and the mass die-off was originally attributed to this agent. However, most of the seals died quickly with few, if any, overt signs of disease. This was very different from what had been observed in other morbillivirus-induced events. Subsequent analysis provided evidence of the presence of several phycotoxins in dead seals and high concentrations of a dinoflagellate known to produce at least one of these phycotoxins in local coastal waters. It is possible that both agents were involved in the die-off. On the basis of the evidence currently available, it is not possible to say with any confidence that either was responsible.

IV. Environmental Effects

Unusual environmental conditions can cause high levels of mortality, particularly among young animals. For example, severe storms coupled with unusually high tides during the winter of 1982–1983 resulted in the death of up to 80% of all northern elephant seal (*Mirounga angustirostris*) pups born at some California colonies.

Even more dramatic effects can be caused by changes in oceanographic conditions. For example, El Niño southern oscillation events can dramatically alter the availability of prey species around marine mammal colonies. The severe 1982–1983 El Niño event had wide-ranging effects on fur seal and sea lion colonies throughout the eastern Pacific. Its effects were even evident in populations of seals in the Antarctic.

An intrusion of low oxygen content water into the coastal waters of Namibia in early 1994 resulted in a massive reduction in the availability of fish. Colonies of Cape fur seals (*Arctocephalus pusillus pusillus*) in Namibia suffered the highest levels of pup mortality ever observed: approximately 120,000 pups had died by the end of May 1994. There was also very high mortality among those subadult males that remained on the breeding grounds.

V. Anthropogenic Effects

Deliberate killing by humans can cause mass die-offs of marine mammals, but the effects of such activities are dealt with elsewhere. However, human activities can also result in mass die-offs through indirect effects. The most obvious of these is the exposure of marine mammals to harmful chemicals that are spilled or discharged into the marine environment. Although marine mammals are probably less vulnerable to the effects of oil spills than seabirds, species such as the sea otter (*Enhydra lutris*), which rely on their dense fur for insulation, can be seriously affected. Indeed, it is estimated that 3500 to 5500 sea otters died in 1989 after the tanker *Exxon Valdez* spilled 42 million liters of oil in Prince William Sound, Alaska. Other chemicals may have a more insidious effect. A wide range of man-made halogenated organic compounds are preferentially soluble in fat and can accumulate at high concentrations in the blubber of predatory marine mammals. These compounds can lower resistance to disease, and individuals with high tissue levels may be particularly vulnerable during mass die-offs caused by disease agents. High organochlorine levels may well have been a contributory factor to mortality during the morbillivirus epidemics in the North Sea and Mediterranean.

A combination of environmental factors and fishing activity may also result in die-offs. For example, large numbers of harp seals (*Pagophilus groenlandicus*) appeared off the north coast of Norway between 1985 and 1988, probably as a result of the collapse of the stocks of capelin, an important prey species, in the Barents and Norwegians Seas. Many of these seals became entangled in fishing nets and subsequently drowned. The Norwegian government compensated fishermen for the damage this caused, and these compensation statistics provide an estimate of the minimum number of seals that drowned. Compensation for 79,000 seals was paid in 1987 and 1988.

VI. Effects on Populations

Determining the effect of mass die-offs on the marine mammal population is often difficult because baseline data on the size and status of the affected population are lacking. However, their impact can be substantial. For example, the morbillivirus-induced die-off in the North Sea killed approximately 40% of the harbor seal population, and local mortality rates were as high as 60%. The mass die-off of Mediterranean monk seals in 1997 killed 70% of the local population and about one-third of the world population of this species.

Some marine mammal populations have shown a remarkable ability to recover from the effects of die-offs. The North Sea harbor population returned to its pre-epidemic level within 10 years of the seal die-off, although some local populations (e.g., those along the eastern seaboard of England) are still depleted. However, species whose populations are already small (such as the Mediterranean monk seal, whose world population was less than 1000 individuals at the time of the die-off) may be reduced to such low levels that they are more susceptible to other problems associated with low population size (such as increased levels of inbreeding and the loss of genetic diversity through genetic drift). As a result, their risk of extinction may be increased substantially.

VII. Future Trends

There are a number of grounds for predicting that the frequency of mass die-offs will increase during this century. Certainly marine mammals populations, like many other species, will be exposed ever more frequently to novel pathogens as a result of the increased movement of humans and their domestic animals who can act as vectors for these agents. Global

warming is also likely to lead to new movement patterns, which will increase the exchange rate of these pathogens.

Exposure to toxins, particularly those produced by dinoflagellate algae, is also likely to increase. Levels of nutrients and minerals, which are normally in short supply, are periodically increased in coastal waters by large-scale run-off of rainwater from agriculture land. This occurs more frequently now because of modern drainage techniques and can create conditions that are favorable to algal blooms. In addition, dinoflagellates are particularly well adapted to transportation in the ballast water of large ships because, when conditions are unfavorable, they become encased in a protective cyst. As a result, many species that historically had a very restricted distribution now have a global one. For example, *Gymnodinium catenatum* (one of the species implicated in the mass die-off of Mediterranean monk seals) was, until recently, confined to the east coast of the United States, but since 1970 it has been recorded in Japan and Australia, as well as off the west coast of Africa.

Mating Systems

SARAH L. MESNICK
Southwest Fisheries Science Center, La Jolla, California

KATHERINE RALLS
National Zoological Park, Smithsonian Institution, Washington, DC

Animal mating systems are diverse, complex, and variable. The key to understanding this variation in mating systems is the realization that individuals behave so as to maximize their lifetime reproductive success and that males and females maximize reproductive success in different ways. In general, males tend to maximize reproductive success by mating with as many females as possible to increase the number of offspring they sire. In contrast, females can produce only a limited number of young and tend to maximize their reproductive success by producing and successfully rearing high-quality offspring. Males and females are thus subject to different selective pressures and do not necessarily cooperate. They may, in fact, be in direct conflict over mating arrangements or try to deceive one another. Together, the mating strategies of males and females define the mating system of a species. This article presents an overview of male and female mating strategies and describes how the different groups of marine mammals solve the problem of finding mates.

Mating systems have traditionally been categorized on the basis of three criteria: the number of partners each sex copulates with during the breeding season, whether the male and female form pair bonds, and how long these bonds are maintained. We focus on a single criterion, the number of mating partners for each sex during a breeding season, to facilitate comparisons among taxa. Thus, we define four mating systems: *monogamy,* in which each individual has a single partner; *polygyny,* in which some males have two or more partners; *polyandry,* in which some females have two or more partners; and *polygynandry,* in which some males and some females have multiple partners.

In marine mammals, as in most other mammals, maternal gestation and lactation provide the majority of nutrient requirements for developing young and males often contribute nothing but sperm to their offspring. Consequently, males are free to devote the bulk of their time and energy to competing for access to receptive females. Thus, theory predicts that most marine mammals should be polygynous.

The potential for polygyny, and the extent to which that potential is realized, is determined to a great extent by the degree to which receptive females are aggregated in space and time. The distribution of females, in turn, is determined by phylogenetic constraints (such as the retention of terrestrial birthing in pinnipeds) and by ecological and social conditions. Among the most important of these conditions are the distribution of resources necessary for breeding, predation pressure, and the costs and benefits of group living. Several types of polygynous mating systems have been identified in marine mammals. Males may defend resources that are vital to females, such as parturition sites (resource defense polygyny), or they may defend females directly either simultaneously (female defense polygyny) or sequentially (sequential female defense polygyny). They may aggregate on traditional display sites and advertise for females (lekking) or they may search widely and spend little time with females except to mate (roving).

It is becoming increasingly clear that females of many species mate with more than one male during a breeding season. Polygynandry is the most accurate term for these mating systems where at least some members of both sexes mate with more than one individual. However, the reproductive success of a female marine mammal does not vary with the number of times she mates per season, as she usually gives birth to only a single offspring and therefore can be inseminated by only one male. Thus, some marine mammals have polygynandrous mating systems but polygynous fertilization patterns.

I. Male Mating Strategies

Male competition for access to mates takes at least three general forms: aggressive interactions to limit the access of other males to females (contest competition), competition to disperse and find sexually receptive females (scramble competition), and competition in courtship to be chosen by the female (mate choice competition). Each of these behavioral strategies has, in turn, generated a number of structures and physiological adaptations. For example, marine mammal males are often distinguished by large body size, big canines, or tusks that can be used as weapons in combat with other males (Fig. 1). In most mammalian species, males disperse more widely than females, and there is increasing evidence that the pattern holds in some marine mammals [e.g., Dall's porpoise (*Phocoenoides dalli*), Escorza-Treviño and Dizon (2000); beluga (*Delphinapterus leucas*), O'Corry-Crowe *et al.* (1997)]. Males are typically more active in courtship and are the more conspicuous and ornamented sex. They may attempt to entice and attract females through visual, acoustic, and pheromonal displays (Fig. 2).

More recently, several additional forms of male competition have been described. Males may attempt to outcompete other males by producing higher quality or greater quantities of sperm or by removing other male's sperm (sperm competition). When a male cannot monopolize access to females on his own, males may cooperate and form alliances. These alliances effectively act as a single male in competing for access to females and have been described for Indian Ocean bottlenose dolphins from Shark Bay, Australia (*Tursiops aduncus;* Connor *et al.* 1996), and common bottlenose dolphin from Sarasota Bay, Florida (*T. truncatus;* Wells *et al.*, 1987). The existence of male alliances is suspected in a growing number of other marine mammal species. Males may also form consortships with females in which the male attempts to associate and copulate with a female during the presumptive fertile period. In common bottlenose dolphins, such consortships often correlate with the later birth of offspring (Wells *et al.*, 1999). In species in which males are larger than females, possess dangerous weapons, and aggressively pursue copulation, some males may forcibly coerce the female to mate [forced copulation; northern elephant seals (*Mirounga angustirostris*), Le Boeuf and Mesnick (1990)]. Moreover, some males "cheat." They may sneak copulations when alpha bulls are distracted [northern elephant seals; Le Boeuf (1974)] or abduct females from the territories of dominant males [kleptogyny; northern fur seals (*Callorhinus ursinus*), Gentry (1998)].

Figure 1 *Adult male northern elephant seals* (Mirounga angustirostris) *fight for positions in a dominance hierarchy that confers access to receptive females. Photo by Sarah L. Mesnick.*

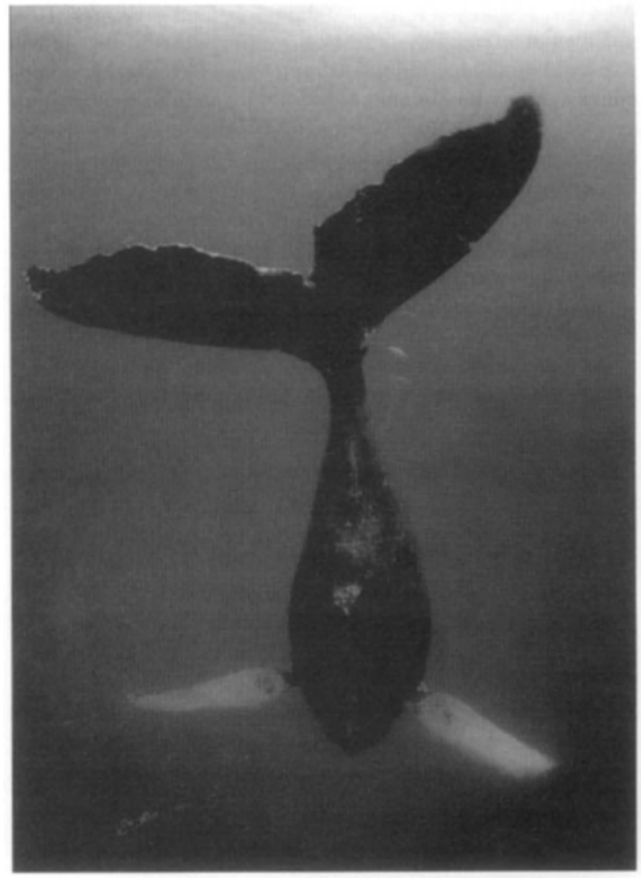

Figure 2 *A singing adult male humpback whale* (Megaptera novaeangliae). *Singing by humpback males presumably acts to attract females, although whether songs contain cues to mate quality remains in dispute. Singing may also function to space males in a breeding area or to aid in the establishment of dominance hierarchies. © Flip Nicklin (Minden Pictures).*

These forms of competition need not be mutually exclusive. It is likely, based on better-studied taxa, that individual males within a marine mammal population will utilize different strategies depending on their age, size, dominance rank, and the number and quality of available females. Although competition between males is obvious in many species of marine mammals, the possibility that males of some species may also prefer to mate with particular females is an area that deserves further attention.

II. Female Mating Strategies

Females of most marine mammals produce only a single offspring at a time. The interbirth interval ranges from 1 year in most pinnipeds and small cetaceans to 5, 6, or even 7 years in larger toothed whales such as sperm whales (*Physeter macrocephalus*),

killer whales (*Orcinus orca*), and short-finned pilot whales (*Globicephala macrorhynchus*). Females can thus produce only a limited number of young and must maximize their reproductive potential by successfully rearing high-quality young. To give offspring a competitive edge, females can enhance their fitness by choosing males that offer resources or genetic benefits. This choice may occur either pre- or postcopulation (the latter may lead to sperm competition). At present, precopulation mate choice has been studied in only a few pinniped species and virtually nothing is known about postcopulatory choice by female marine mammals.

In other well-studied taxa, such as birds, females are highly discriminating in their choice of sexual partners. Moreover, most females choose in a similar way so that a few males achieve many copulations and many other males none. Females may choose among potential mates directly (based on resources, size, strength, dominance, or display) or indirectly (by mating with the winner of contests for access to females). Some marine mammal females actively seek out particular males and mate. For example, in California sea lions (*Zalophus californianus*), some females change pupping locations from one year to the next to remain with a territorial male who changed territory location (Heath, 1989). Females may also incite male–male competition. By protesting male sexual advances loudly, female northern elephant seals instigate fights among males and subsequently mate with the winner of these battles.

It is difficult to establish the presence of female choice and even more difficult to determine why females choose particular mates or to quantify the benefit to females of exercising choice. Direct benefits to the female, in the form of nutritional resources to the female or parental care, are not known to exist in marine mammals. Females can, however, benefit by choosing males with higher-quality territories, which provide better parturition or thermoregulatory sites, or by choosing males that give protection from harassment by subordinate males, which provides uninterrupted time for lactation and reduces vulnerability to aggression from other conspecific males. Females can also benefit by discriminating among potential mates on the basis of indirect (genetic) benefits. These include choosing males of the correct species, males with immunologically compatible genes, males with "good genes" who can produce offspring of higher quality. Females can also choose males with better fertilization ability or virility.

Females may make very different decisions regarding which males they associate with, which males they mate with, and which male sires their offspring. In land-breeding pinnipeds, for example, a female may reside with one dominant or territorial male during lactation but later leave this male to copulate with another male elsewhere (extraterritorial copulation). In some marine mammal species, such as the bottlenose dolphin, sexual behavior is a frequent and important component of nonreproductive social life and has little to do with fertilization. As with males, female strategies need not be mutually exclusive and it is likely that different females will utilize different strategies depending on their age, dominance rank, and the number and quality of available mates.

III. Mating Systems in Different Groups

A. Pinnipeds

For all pinnipeds studied to date, data support, or are highly suggestive of, a polygynous mating system. Pinnipeds are predisposed to polygyny because they give birth on land, which results in the spatial clustering of females, and have an annual birthing cycle, which results in reproductive synchrony among females. The degree of polygyny varies both within and among species with the extent of reproductive synchrony and spatial clustering. Most species have a peak availability of receptive females lasting about 1 month, but the availability of receptive females ranges from 10–15 days in harp (*Pagophilus groenlandicus*) and hooded (*Cystophora cristata*) seals to a period of several months for species that breed in tropical habitats such as monk seals (*Monachus* spp.) and Galapagos sea lions (*Zalophus wollebaeki*).

Variation in the degree of spatial clustering within and among species is due to a variety of factors, including the spatial distribution of suitable breeding sites, whether mating takes place on land or at sea, the intensity of male harassment, predation pressure and/or thermoregulatory needs. Polygyny and sexual dimorphism are generally much more extreme in species that mate on land than in those that mate in the water.

1. Otariids Otariid females feed during lactation. Lactation is energetically costly so females must raise their young on sites near highly productive marine areas. Because these sites are limited, females typically occur in dense aggregations (numbering from a few individuals to more than a thousand) on beaches or rocky shelves on islands. Mating occurs on land, although evidence of at least some mating at sea exists for a few species [e.g., Juan Fernández fur seal (*Arctocephalus philippii*) and the California sea lion]. The combination of dense female aggregations and terrestrial mating gives some males the opportunity to monopolize mating with many females. Sexual dimorphism among otariids is correspondingly extreme; males are on average three times, and sometimes up to six times, heavier than females and have other traits favored in physical combat over females: large canines, thick chests, and dense manes.

The northern fur seal is among the most polygynous of the otariids: a single male at the St. George Island rookery mated with 161 females and hundreds of males had no copulations at all (Gentry, 1998). The lowest levels of polygyny probably occur in the Juan Fernández fur seal, the South American sea lion (*Otaria flavescens*), the Galapagos fur seal (*Arctocephalus galapagoensis*), and Hooker's sea lion (*Phocarctos hookeri*), in which the ratio of sexually active adults ranges from two to six females per male (Boness *et al.*, 1993).

Male otariids typically defend territories containing resources needed by females—parturition and thermoregulatory sites—rather than individual females (Fig. 3). However, female defense has been demonstrated in at least one otariid, the South American sea lion. The two types of polygyny are difficult to distinguish and are not necessarily mutually exclusive. There is some evidence suggestive of lekking in three species (the California sea lion, the South American fur seal (*Arctocephalus australis*), and Hooker's sea lion), although this interpretation remains controversial.

A male's ability to acquire and defend a territory depends on his size and age, his ability to compete with other males, and his ability to fast during his tenure (contest competition). Un-

Figure 3 *A Steller sea lion* (Eumetopias jubatus) *territory. Adult males defend resource-based territories that encompass female parturition and thermoregulatory sites. Females choose among males in a surprisingly consistent way. As a result, some males holding territories never or rarely mate, while a few males mate with many females. Photo by Robert L. Pitman.*

der most circumstances, the boundaries of territories are fixed and are delineated by breaks in the topography. Males use a species-specific threat display when defending the boundaries of their territory. A male that secures a territory will probably, but not necessarily, mate with many of the females that give birth on his territory. Climate and rookery topography also play important roles in determining a male's mating success. Those males defending territories containing access to the water, tide pools, or shade acquire a disproportionately large number of females.

Most otariid bulls fast while maintaining their territories, sometimes for the entire 2- to 3-month breeding season [e.g., Steller sea lions (*Eumetopias jubatus*) and northern fur seals]. Some males return to the same territory in subsequent years whereas others move to new territories or are not seen again. Territorial males may try to herd females to prevent them from leaving their territories, but in most species, females determined to leave generally can. The males of some species, however [e.g., northern fur seal and the South American and Australian (*Neophoca cinerea*) sea lion], are able to prevent females from leaving their territories by threats, herding, and sometimes physical aggression leading to injury.

The importance of male courtship displays in otariids is not well understood. For example, it is not known whether male displays, such as the incessant barking of male California sea lions, are used as threat displays for males, or as displays for females, or both. Alternative male mating strategies are widespread and generally thought to be practiced by subadult or subordinate males. These include gang raids by groups of nonterritorial males (up to 40) to abduct or mate with females in the main breeding territories (South American and Australian sea lions), males stealing females from the territories of their neighbors (kleptogyny; northern fur seals), and males trying to sneak copulations (several species). How successful these strategies are in inseminating females is not known.

Female mating strategies are less well understood than male mating strategies, but several lines of evidence suggest that females exercise more choice among males than previously suspected. Female otariids choose which territory to haul out in and usually, but not always, move freely in and out of a male's territory. Estrus occurs within 1 to 2 weeks postpartum in all but one species (California sea lion, about 21–27 days). When it is time to mate, females may leave the male's territory in which they have given birth and mate with another male. This has been documented through behavioral observations in California sea lions and South American fur seals and by paternity studies in fur seals on Macquarie Island.

Climate, ROOKERY topography, and the intensity of male harassment influence the ability of females to exercise mate choice. Females of species breeding in hot climates have more opportunity for mate choice due to their frequent thermoregulatory movements between their birthing site and the water. Intense male herding restricts female choice and may injure females. Female northern fur seals are thought to successfully reduce the risk of injury from males by forming dense aggregations and competing for central locations within these groups, which minimizes contact with males, and by acting submissive around males. In this species, females do not appear to choose males directly. Rather, by gathering on traditional mating grounds, the result is that males fight and females subsequently mate with the winners of these contests. Female otariids may also directly solicit and initiate copulation from males. In Steller sea lions, for example, females gain the sexual attention of males by lateral neck swings, dragging of the hindquarters, and sinuous movements of the female's body against the male's body. While females tend to direct most solicitation behavior toward the older "proven" territorial males, the extent of female choice remains unclear. Multiple mating is known in 30% of otariids studied (Boness *et al.*, 1993) and suggests an important and variable role across species for sperm competition and mate choice.

2. Phocids Most phocid females fast during a short and concentrated lactation period, utilizing energy stored as fat before parturition. Because phocid females are not dependent on concentrated marine production during lactation like otariid females, they can mate in more dispersed locations. Moreover, in 16 of the 19 phocid species, the majority of mating takes place in the water near or after the end of lactation. Females of many of these species give birth on ice and do not aggregate as densely as those of terrestrially breeding species. Thus, during the breeding season, females are dispersed spatially (solitary or dispersed in small- to moderate-sized well-spaced colonies) and mobile during mating. Because males have less opportunity to defend and mate with multiple females, aquatically mating phocids are less polygynous and sexually dimorphic than otariids.

Moreover, the breeding season is short and, in species that breed on ice, mating takes place when temperatures are well below freezing. Reverse sexual dimorphism, with females larger than males, occurs in several species. Large female size may help a mother provide greater quantities of fat-rich milk to her pup and protect her from low polar temperatures. Small size in males is thought to facilitate agility underwater, where males may defend

territories and mate with females. Nevertheless, aquatically mating species are considered to be slightly or moderately polygynous. Mating takes place within a few days of the weaning of the pup.

We have limited knowledge of male and female mating strategies in most aquatically mating phocids. In some cases, males defend the lactating female and her vicinity directly, a strategy akin to roving and sequential defense of a single female or a small group of females. A typical group consists of a female and her pup and an adult male who may have to wait before the female comes into estrus and is receptive to mating. Presumably, the male will mate with the female when she enters the water after weaning her pup. This system can be described as sequential polygyny, as males may leave after mating to search for another receptive female. It occurs in crabeater seals (*Lobodon carcinophaga*), spotted seals (*Phoca largha*), and hooded seals. Other males may surround these "triads" and they may compete for access to the female, typically with threats and sometimes bloody fights.

In some cases, males appear to defend aquatic territories (called "maritories") off the beach or ice where females reside. Males spend considerable time in these territories giving vocal and visual display. This characterizes such phocids as bearded (*Erignathus barbatus*), harp, and Weddell (*Leptonychotes weddellii*) seals and, in some cases, harbor seals (*Phoca vitulina*). A male may mate with any receptive female that enters his territory. Genetic studies of harbor seals on Sable Island show that male success is moderate to low, with most males fertilizing one or no females and the maximum number of females fertilized for any male being five (Coltman *et al.*, 1998).

Males of many aquatically mating species are thought to use visual and acoustic displays to threaten other males and to attract females. "Eerie but melodious" songs have been described for male bearded seals and "trills," "knocks," "buzzes," and "chirps" for male Weddell seals. Male hooded seals make numerous sounds underwater and also produce sounds in air as they inflate and deflate their hood and red nasal sac. In ringed seals (*Pusa hispida*), there is much social interaction and sniffing between males and females (males have a strong odor during the breeding season), which raises the question of whether there may be preferred mates. Virtually nothing is known of female mating strategies among aquatically mating phocids.

The northern and southern (*Mirounga leonina*) elephant seal and some populations of the gray seal (*Halichoerus grypus*) are unusual among phocids in that mating takes place on land. These species exhibit a form of female defense polygyny. Males maintain a position near a receptive female or females and attempt to exclude other males from their vicinity. In elephant seals, males use visual and acoustic threats as well as physical fighting to compete for dominance in a social hierarchy that confers access to females. Polygyny in elephant seals is extreme; at the Año Nuevo rookery in California, as few as five males may be responsible for 48 to 92% of the copulations observed during a breeding season (Le Boeuf, 1974). The lifetime reproductive success of most males is nil or low. Many die before reaching breeding age and higher-ranking males prevent some of those that survive from breeding.

Genetic analyses confirm that the proportion of pups sired by alpha males is consistent with that expected from observed mating success in southern elephant seals but show that behavioral observations overestimate the success of some northern elephant seal alpha males (Hoelzel *et al.*, 1999). The relatively lower success of northern elephant seal males was probably due in part to the behavior of the Año Nuevo females, which copulate more frequently, the greater success of non-alpha males, and/or reduced fertility of specific alpha males. Female elephant seals may exercise mate choice by competing for central positions in harems where dominant males reside and by inciting male–male competition and subsequently mating with the winner of these battles.

Mating behavior among the geographically widespread gray seal is difficult to categorize. Gray seal females do not cluster as tightly and are more mobile in the colony than elephant seal females. Dominant males maintain their proximity to females by using visual threat displays and occasional fights to deter other males. In the Scottish Islands, behavioral observations suggest a classical polygynous system. Genetic studies, however, reveal that many fathers spend little time at shore, that some pairs of seals show partner fidelity, and that dominant males to not father as many offspring as behavioral observations would suggest (Worthington Wilmer *et al.*, 2000).

3. Walrus Walruses (*Odobenus rosmarus*) have the most elaborate courtship displays of all pinnipeds. Walruses show marked sexual size dimorphism and are thought to be strongly polygynous. Atlantic walruses in the Canadian High Arctic exhibit a mating system that resembles female defense polygyny. Pacific walruses in the Bering Sea may have a lek-like mating system. Groups of males cluster around females, which form dense aggregations on pack ice. Males are aggressive toward one another and produce intricate visual and vocal displays, consisting of barks, whistles, growls, and underwater bell-like sounds. The massive tusks of the male walrus also appear to play an important role as a symbol of rank (to threaten other males) and as a visual signal to females, who may choose among males partly by the size of their tusks.

B. Cetaceans

1. Odontocetes In contrast to pinnipeds, which are relatively sedentary and clustered during the breeding season, female odontocetes are mobile and dispersed. This has two important consequences for male mating strategies: males have less opportunity to control access to aggregated females and less assurance of paternity. It is not surprising, therefore, that the basic mating strategy of male odontocetes appears to be one of searching for receptive females and spending little time with them other than to mate. It is likely that mate guarding, or monopolization of females long enough to ensure conception, also occurs, although the phenomenon has been well documented only in bottlenose dolphins.

Female mating strategies in odontocetes are little understood. Given their mobility and three-dimensional habitat, it is generally thought that females are able to exercise choice by outmaneuvering males or by rolling belly-up. Observational and hormonal evidence suggests that females of several species copulate frequently both during and outside the breeding season and may be polyestrous. Frequent copulation may function

to induce sperm competition, aid in assessing future mates, or help to establish social bonds with potential future partners. In many odontocete species, sexual behavior is an important component of nonreproductive social interactions and often has little to do with fertilization, making it difficult to infer mating strategy from incomplete observations. Perhaps the best example is the intriguing "wuzzling" behavior of Hawaiian spinner dolphins (*Stenella longirostris longirostris*). Wuzzling refers to interweaving masses of caressing and copulating dolphins of both sexes and all ages, which are especially common in the summer months, when many females come in estrus. Is the behavior social? Sexual? Both?

We know little about mating systems in the vast majority of odontocetes. However, there are substantial data on bottlenose dolphins, sperm whales, and killer whales. A mating system of female defense or sequential defense polygyny has been suggested for Indian Ocean bottlenose dolphins. Males form stable coalitions of a few males that may work alone or with other closely associated coalitions to form temporary consortships with individual females, often through aggressive herding (Shark Bay, Australia; Connor *et al.*, 1996). Male common bottlenose dolphin individuals and members of long-term pair bonds form temporary consortships with females without obvious aggressive herding (Sarasota Bay, Florida; Wells *et al.*, 1999). The extent to which this sequential female defense strategy is successful is uncertain, however, as individual females can cycle multiply and associate with several males during the season in which they conceive. These behaviors may facilitate female mate choice and promote sperm competition. In another location, male common bottlenose dolphin apparently do not form alliances or aggressively herd females, although single males may accompany groups of females throughout the breeding season (Moray Firth, Scotland; Wells *et al.*, 1999). Among sites, the level of male bonding may be inversely related to male body size and the degree of sexual dimorphism (Tolley *et al.*, 1995). At sites where animals are small, males may form alliances to gain and maintain access to females; where animals are large, males can do this on their own.

Most sperm whales in the Galápagos Islands appear to rove between groups of females searching for potential mates. One or more large mates may attend a group of females (sometimes simultaneously) for short periods of time ranging from a few minutes to several hours (Fig. 4). Rather than herding female groups, females have been observed to alter course and speed so that they could join a large male hundreds of meters away. Males did not interact aggressively with each other within female groups, despite several accounts in the literature of males fighting outside of groups. Given the apparent roving strategy of males, the role of the tremendously large nose of the male sperm whale and its possible use as a sound-generating organ remains unclear. The loud clicks may function in male–male competition or advertisement to attract females (Cranford, 1999).

Pods of resident killer whales in the Pacific Northwest are frequently observed associating with one another in the summer months when prey (and observer) abundance is high. In these multipod groups, there is much sexual activity among all pod members, young and old alike. Because no dispersal of either males or females occurs from resident pods, it is thought that mating takes place during these encounters. Considering that the entire pod engages in these encounters, it is likely that their function is both sexual and social. Similarly, genetic analyses of long-finned pilot whales captured in a Faroese fishery indicate that males remain in their natal groups but do not mate within them (Amos *et al.*, 1993). Young were sired by males not captured with the group, implying that pilot whales must mate when two or more groups meet or when adult males pay brief visits to other groups.

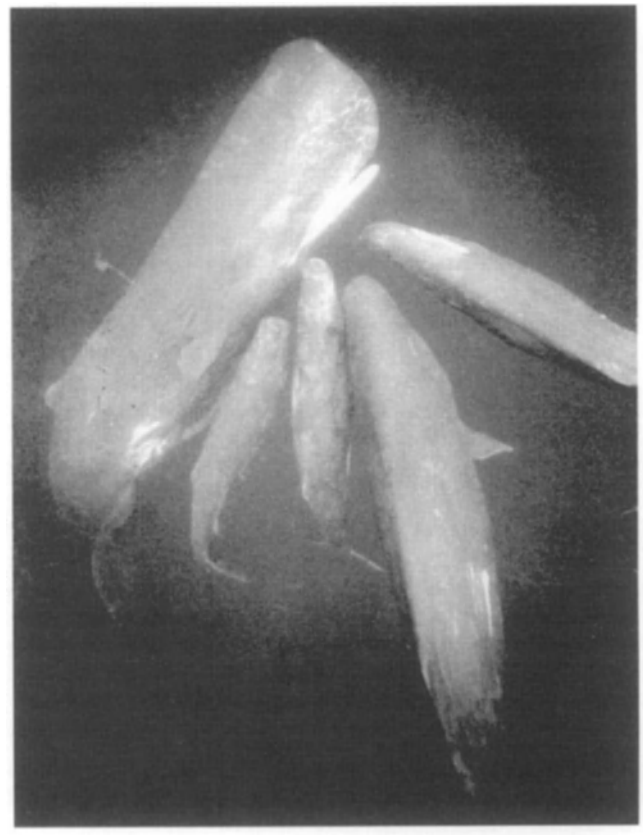

Figure 4 *Adult male sperm whales* (Physeter macrocephalus) *rove among female groups searching for receptive individuals and staying with each group for only a few hours at a time.* © *Flip Nicklin (Minden Pictures).*

Very little is known about mating systems in the remaining species of toothed whales. However, we can infer something about the mating strategies of these species from the type and degree of sexual dimorphism and its association with other characteristics, such as bodily scarring and relative testis size. For example, testis size ranges dramatically among odontocete species, from less than 0.05% [several *Mesoplodon* species, the franciscana (*Pontoporia blainvillei*), the baiji (*Lipotes vexillifer*), and sperm whale] to 5% or greater [harbor porpoise (*Phocoena phocoena*), finless porpoise (*Neophocaena phocaenoides*), and dusky dolphin (*Lagenorhynchus obscurus*)]. These data suggest the importance of sperm competition in several odontocete species, especially among some of the delphinids and porpoises. The importance of mate choice competition, attempts to entice and attract females through elaborate displays, is suggested by differences between the sexes in song

and exaggerated visual signals such as the postanal hump or enlarged dorsal fins. At present, sexually dimorphic acoustic signals are known only in sperm whales. However, because odontocetes produce a wide range of sounds, acoustic displays are likely to occur in several other species as well. The importance of contest competition for access to mates is suggested by sexual dimorphism in size, weaponry (teeth and tusks), and the presence of scarring of conspecific origin (tooth rakes). Sperm whales, the beaked whales, narwhal, and bottlenose whale exhibit these traits.

2. Mysticetes Among the mysticetes, substantial data on breeding behavior exist only for the humpback, (*Megaptera novaeangliae*), right (*Eubalaena* spp.), and gray (*Eschrichtius robustus*) whales. Even in these species, virtually nothing is known about female behavior. The humpback whale has been studied most intensively. Male humpbacks adopt one or more of three primary strategies: display by singing long, complex songs; direct competition with other males for females in "competitive groups"; and escort of females, including those with newborn calves. Males escorting females are most likely waiting for mating opportunities or guarding females after copulation. Two secondary strategies, roving and sneaking, have also been suggested. The relative importance and success of each of these strategies are unknown.

Female humpbacks sometimes aggressively reject subadult males and they may incite competition among males. Although molecular analysis of paternity has shown that females are mated by different males between years (Clapham and Palsbøll, 1997), it is unknown whether females mate multiply within a given breeding season. Singing by male humpbacks is an intriguing phenomenon, as songs change over time, yet all members of a population sing essentially the same song at any one time. Singing by humpback males presumably acts to attract females, although whether songs contain cues to mate quality remains in dispute. Singing may also function to space males in a breeding area or to aid in the establishment of dominance hierarchies. Whether the aggregation and displaying of humpback whales at specific sites constitutes lekking also remains controversial.

Little else is known about the mating systems or other balaenopterid whales. Blue (*Balaenoptera musculus*) and fin (*B. physalus*) whales seem to be widely dispersed during the winter breeding season. Male fin whales have a patterned call, which has been termed a breeding display. The question of whether male blue whales have specific calls that may function as mating displays is currently under investigation.

Right whales show sexual activity throughout the year, although calving is strongly seasonal. Because the gestation period is 1 year and there is no evidence of diapause, mating leading to conception presumably occurs primarily in the winter. The function of sexual activity during other seasons is unknown. Observations of multiple male right whales mating with single females, together with the huge (1 ton!) testes, strongly suggest that sperm competition is a principal mating strategy in these species, and also probably in bowhead (*Balaena mysticetus*) and gray whales (Brownell and Ralls, 1986). The level of aggression in male–male interactions in these species is low compared to that observed in humpback whales, data consistent with the predominance of sperm competition as a mating strategy.

C. Sirenians, Sea Otters, and Polar Bears

Male manatees (*Trichechus* spp.) and dugongs (*Dugong dugon*) tend to be solitary and search for potential mates by roaming over large areas that include the home ranges of several females. Groups of males sometimes follow and try to mate with a single female, forming a "mating herd." In both manatees and dugongs, males in these herds threaten and fight with each other but it is still unknown whether this behavior is a form of scramble competition or is more akin to a type of lekking. In Shark Bay, Australia, dugongs associate in a more classical kind of lekking, with several males patrolling exclusive areas and engaging in activities usually indicative of both male competition and mate attraction, including acoustic signaling. In both manatees and dugongs, the mating season extends over several months and sexual dimorphism is slight. Interbirth intervals are at least 2 years and may be as much as 5 in some cases.

Female sea otters (*Enhydra lutris*) typically give birth annually. Births generally peak in the spring, although females in warmer areas may give birth in any month. Adult males are larger than females. Male sea otters establish territories, usually overlapping one or more female home ranges, that contain food resources and sheltered resting places. Males may defend territories seasonally or all year. Other males congregate in groups outside of the areas occupied by territorial males. Courtship and mating, as are typical for many mustelid species, are rough and females may be injured or killed by males. Copulation occurs with both the male and the female on their backs near the water's surface. The male grasps the female's head or jaws, including the nose, in his own jaws. Recently mated female typically have red, swollen noses. After mating, the pair may stay together for a few days in which they feed, groom, play, and rest in close company.

Polar bears (*Ursus maritimus*) are highly sexually dimorphic and polygynous; adult males may be over twice as heavy as adult females. Female polar bears have extensive home ranges, and males travel over large areas when searching for mates. Males apparently fight among themselves for access to females. Specific courtship behaviors are lacking or are yet undescribed. The largest and strongest males apparently do most of the mating, while other males sometimes wait in the distance. Polar bears are notable among marine mammals in that they are the only species in which females give birth to multiple young (one or two is the most common litter size and rarely three or four). The interbirth interval is about 3 years.

IV. Mating System Studies and the Future

This is an exciting time for the study of marine mammal mating systems as technical advances such as the use of molecular markers and underwater acoustic and visual recording devices are providing new insights and making it possible to investigate previously inaccessible species. The results of molecular studies have confirmed some hypotheses regarding marine mammal mating systems and refuted others. Paternity analyses in a number of species are revealing that dominant males are not as successful in siring offspring as expected from behavioral observations alone. These results suggest that female choice plays a more important role than was previously suspected. Fe-

male mating strategies, such as the incitation of male–male competition, extraterritory copulation, and the promotion of sperm competition by frequent mating, are gaining increasing attention. As our understanding of the physiology of female receptivity grows, we will be better able to interpret both female and male mating behavior. At the same time, our increasing ability to hear and see underwater will enable us to tap into the little known realm of underwater acoustic and visual displays.

Melon-Headed Whale

Peponocephala electra

WAYNE L. PERRYMAN
Southwest Fisheries Science Center, La Jolla, California

The melon-headed whale is one of a group of small, dark-colored whales that are often referred to as "blackfish." It is only recently that much has been known about these little whales because they generally occur far offshore and in many areas they avoid approaching vessels.

I. Characters and Taxonomic Relationships

The melon-headed whale (Fig. 1) is mostly dark gray in color with a faint darker gray dorsal cape that is narrow at the head and dips downward below the tall, falcate dorsal fin. A faint light band extends from the blowhole to the apex of the melon. A distinct dark eye patch, which broadens as it extends from the eye to the melon, is often present and gives this small whale the appearance of wearing a mask. The lips are often white, and white or light gray areas are common in the throat region and stretching along the ventral surface from the leading edge of the umbilicus to the anus. At sea, this species is difficult to distinguish from the pygmy killer whale (*Feresa attenuata*). It differs externally from the pygmy killer whale by having a more pointed or triangular head and sharply pointed pectoral fins. Both of these characters are difficult to recognize at sea unless these small whales are seen from above. Experienced observers often rely more on behavioral than physical characters to separate these two blackfish in the field. In stranded specimens, the melon-headed whale can be distinguished from all other blackfish by its high tooth count, 20 to 26 per row, compared to generally less than 15 teeth per row for pygmy killer whales.

Melon-headed whales are about 1 m in length at birth (Bryden *et al.*, 1977) and continue to increase in length until they are 13 to 14 years old. Asymptotic length for males (2.52 m) is greater than for females (2.43 m), and males also have

comparatively longer flippers, taller dorsal fins, and broader tail flukes (Best and Shaughnessy, 1981; Miyazaki *et al.*, 1998). In addition, some males exhibit a pronounced ventral keel that is found posterior to the anus. The longest specimen reported was a 2.78-m female that stranded in Brazil (Lodi *et al.*, 1990). A 2.64-m male that stranded in Japan weighing 228 kg is the heaviest specimen reported (Miyazaki *et al.*, 1998).

The SKULL of the melon-headed whale is typically delphinid in shape, with the exception of a very broad rostrum and deep antorbital notches. It is similar to the skull of the common bottlenose dolphin (*Tursiops truncatus*), but the TEETH of the melon-headed whale are much smaller and appear more delicate. The high tooth count of this species separates its skull from those of other small beakless whales.

The melon-headed whale is a member of the subfamily Globicephalinae where it is closely allied with the very similar pygmy killer whale and the larger pilot whales (*Globicephala melas* and *G. macrorhynchus*). Investigations regarding the interrelations of these species have yet to produce definitive results.

II. Distribution and Ecology

Melon-headed whales are found worldwide in tropical to subtropical waters. They have occasionally been reported from higher latitudes, but these sightings are often associated with incursions of warm water currents (Perryman *et al.*, 1994). They are most often found in offshore, deep waters, and nearshore sightings are generally from areas where deep oceanic waters are found near the coast. Squids appear to be the preferred prey of this species, but small fish and shrimps have also been found in their stomachs (Jefferson and Barros, 1997).

III. Behavior and Life History

Melon-headed whales are most often found in large aggregations, a behavior that separates them from the very similar pygmy killer whale. They are often seen in large mixed aggregations with Fraser's dolphin (*Lagenodelphis hosei*). They have also been sighted in mixed herds with spinner dolphins (*Stenella longirostris*) and common bottlenose dolphins (Dolar, 1999). Although they are reported to flee from approaching vessels in the eastern Pacific, it is not uncommon for melon-headed whales to briefly ride the bow wave of passing ships in other areas. They may bow ride for longer periods if the vessel slows to a speed of a knot or less.

Mass STRANDINGS of melon-headed whales have been reported on several occasions; the cause of the strandings is unknown. In two strandings from Japan and one in Brazil, the specimens had high loads of internal PARASITES, which might have caused some animals to strand. It has also been suggested that mass strandings of these highly social animals may be caused by a panic response in the school when a few members accidentally strand (Miyazaki *et al.*, 1998).

IV. Interactions with Humans

When captured live and transferred to aquariums, melon-headed whales have not thrived and have been difficult to train. They have been aggressive toward keepers and have caused injuries by ramming individuals with their heads or raking them with their teeth. In Hawaiian waters, melon-headed whales have approached divers in an aggressive manner, swimming rapidly and opening and closing their jaws causing an audible clapping sound. Swimmers should be cautious if entering the water around these small whales.

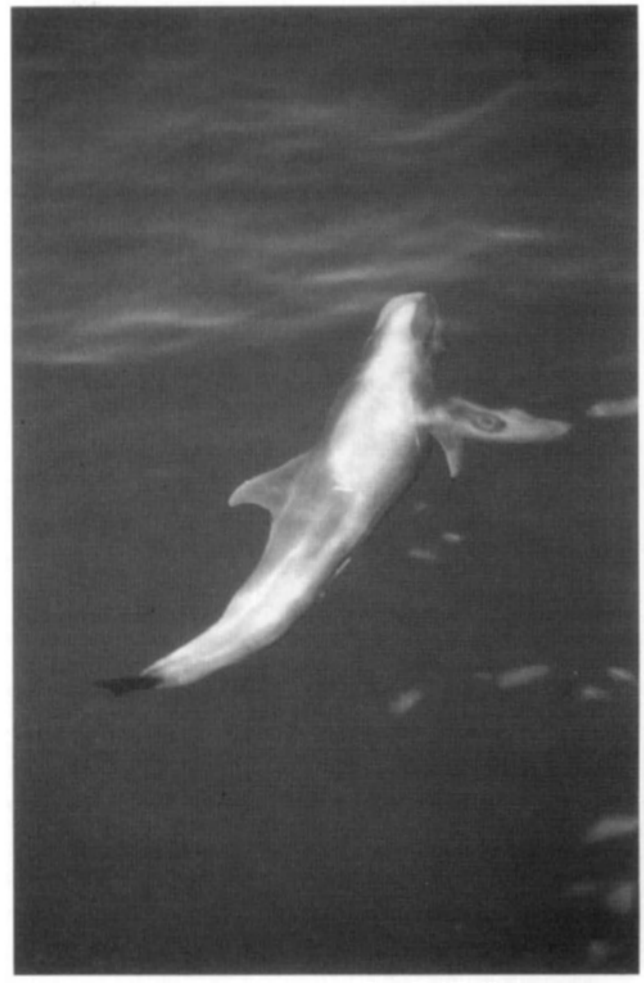

Figure 1 *Melon-headed whales,* Peponocephala electra, *occur around the world in subtropical and tropical waters. Photographed by R. L. Pitman in the Gulf of Mexico.*

Melon-headed whales are taken in small numbers in harpoon and drift net fisheries in the Philippines (Dolar, 1994), Indonesia, Malaysia, and in the Caribbean near the island of St. Vincent. Schools of melon-headed whales have been taken in the drive fishery operated from the port of Taiji, Japan. On rare occasions, a member of this species is taken in the purse seine fishery for yellow-fin tuna in the eastern tropical Pacific. Because most of these fisheries are not extensively monitored, the effect of these direct and incidental takes on local populations is unknown.

Mesonychia

MAUREEN A. O'LEARY
State University of New York, Stony Brook

Mesonychians are an extinct group of four-footed land mammals that lived in the Early Tertiary and are recognized by paleontologists to be the closest relatives of whales. This hypothesis has, however, been difficult to reconcile recently with the molecule-based hypotheses that cetaceans may be most closely related to hippos. Mesonychians were unique because they possessed hooves like many plant-eating mammals, but sharp teeth like many carnivorous mammals. Mesonychians obtained a relatively wide distribution throughout the globe; their fossils are found in North America, Europe, and Asia in rocks dating from the early Paleocene through the end of the Eocene, an interval of about 30 million years. Despite a relatively wide geographic DISTRIBUTION, mesonychian fossils remain some of the rarest elements of early Tertiary faunas. Most species have been described only from jaws and teeth but several are also well known from skulls and postcrania. The first appearance of mesonychians in the fossil record precedes the first appearance of whales by approximately 10 million years. Unlike whales, mesonychians became completely extinct around the end of the Eocene. Mesonychians are significant because they provide scientists with a hypothesis of how whale ancestors may have looked before they left land for a life in water (Fig. 1).

I. Origins and Relationships

Mesonychians were first named for specimens discovered in North America in 1874. Since then about 20 genera of varying sizes have been recognized, none of which contains many species (Table I). Mesonychians were initially thought to belong to the order Creodonta, an extinct group of mammals closely related to the CARNIVORA. This was proposed because mesonychians are similar to both creodonts and carnivorans in having tall, pointed lower molar teeth (Fig. 2). Paleontologist Leigh Van Valen argued in 1966, however, that because mesonychians also have hooves and certain other features of the skull, their anatomy more closely resembles that of hoofed mammals. Hoofed mammals include, among other species, artiodactyls, perissodactyls, and all of their extinct relatives. Van Valen argued that as mesonychians evolved they diverged from other hoofed mammals, which are primarily herbivorous with short, square teeth and independently developed dental similarities resembling those of certain meat-eating animals like carnivorans. The teeth of mesonychians also resemble the teeth of early whales, also thought to have been carnivorous, not only because their living descendants are carnivorous but because of the sharp pointy shape of their teeth. Mesonychians thereby became an important fossil intermediate to link a carnivorous group like whales to living and extinct hoofed mammals, which primarily eat plants.

Van Valen's hypothesis has since been corroborated by phylogenetic analyses of mammals that show that mesonychians are the extinct species mostly closely related to whales and that artiodactyls are the living mammals most closely related to this whale + mesonychian group. The features that mesonychians and whales share are primarily those of the dentition (Fig. 2) and the skull. Mesonychians, whales, and artiodactyls, however, all share cranial and postcranial features in common, including possession of a paraxonic foot (Fig. 3). Paraxonia is a specially evolved condition in these mammals in which the weight of the body is transmitted along an imaginary line between digits

TABLE I
Mesonychian Taxa and Their Stratigraphic and Geographic Ranges[a]

Genus	*Stratigraphic range*	*Geographic range*
Yantanglestes	Paleocene	Asia
Hukoutherium	Paleocene	Asia
Dissacusium	Paleocene	Asia
Ankalagon	Paleocene	North America
Sinonyx	Paleocene	Asia
Dissacus	Paleocene–Eocene	North America, Asia, Europe
Pachyaena	Paleocene–Eocene	North America, Asia, Europe

three and four (Fig. 3). Digit one (which is equivalent to the thumb or big toe in a human) is reduced such that it is not weight bearing and in some animals it is completely lost.

When generating phylogenetic analyses of Cetacea on the basis of DNA it is difficult to evaluate the full impact of mesonychians because they are completely extinct and information about their genes remains unknown. Mesonychians may nevertheless have been a very pivotal group.

II. Anatomy and Function

Study of the best-preserved skeletons of mesonychians, primarily the genera *Dissacus*, *Pachyaena*, *Mesonyx*, and *Sinonyx*, indicates that these animals evolved the ability to run fast relative to their Early Tertiary contemporaries. Paleontologists surmise this from the structure of mesonychian vertebral columns, limbs, ankles, and feet. Many of the joints of these mammals have evolved to restrict motion of the limbs to flexion and extension as is typical of many cursorial animals. In so doing many mesonychians sacrificed having a wide range of mobility of their joints for having increased joint stability within a limited range of mobility. This condition may be advantageous for an animal that is moving at high speeds across a terrestrial substrate. Study of the vertebral column of the mesonychian genus *Pachyaena* indicates that it was a stiff-backed runner, meaning that its vertebral column did not exhibit much motion side to side or up and down during running. This feature characterizes many large-bodied hoofed mammals, and observation of this functional similarity is another shared feature of mesonychians and hoofed mammals. These functional characters are perhaps best understood in the genus *Pachyaena* (Fig. 4), which includes some of the larger mesonychian species, and which in one species is estimated to have had a body weight of approximately 400 kg. The earliest whales, therefore, may have evolved into fully aquatic animals by modifying a body that had originally evolved for running on land.

The dentition of mesonychians is simplified such that they have lower premolars and molars that resemble each other in exhibiting three main cusps (Fig. 2). Upper teeth are simplified and triangular in all taxa. The morphology of the lower dentition resembles that seen in living piscivorous mammals such as seals and toothed whales, and some paleontologists have argued that mesonychians may have been piscivorous also. Mesonychians had a chewing mechanism that was restricted largely to orthal motions (up and down as opposed to side to side). Carnivorans chew in a similar fashion; however, the mesonychian chewing mechanism appears to have been less tightly interlocking than that of carnivorans as evidenced by the variable position of tooth-wear facets on mesonychian molars (Fig. 2).

Studies of endocasts (molds made from the inside of the skull to estimate brain size and shape) of mesonychians indicate that these animals had more specialized BRAINS than con-

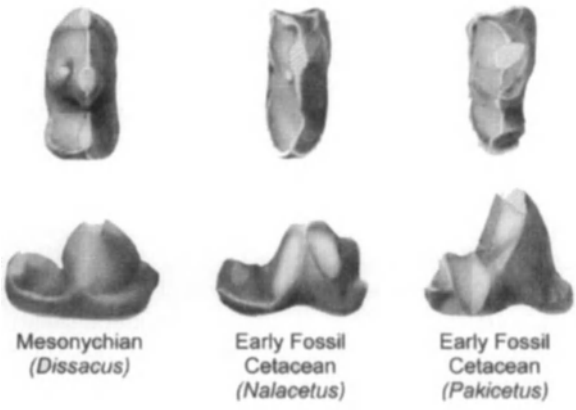

Figure 2 *Right lower molars of a mesonychian and primitive whales for comparison. The top row of teeth is shown from a view of the chewing surface, and the bottom row of teeth is shown from a view from the cheek side. Reprinted with permission from O'Leary and Uhen (1999).*

temporaneous hoofed mammals and carnivorans. In particular, mesonychians had reduced olfactory lobes, suggesting a decreased reliance on the sense of smell.

III. Paleoecology

Because of their strange combination of hoofed mammal and carnivoran characteristics, mesonychians have no close modern analogue, something that makes reconstruction of their paleoecology particularly challenging. In the Early Tertiary (Paleocene and Eocene) faunas in which mesonychians are found, they are among the largest predators and some of the largest mammals. Carnivorans did not reach the size of mesonychians until millions of years later. It was mesonychians and not carnivorans that filled the role of pursuit predators in the Eocene. Paleontologists continue to grapple with the question of why mesonychians have a cursorially modified skeleton. Was it important for defensive (escape) or offensive (attack) behavior? The diet of mesonychians has also been difficult to determine, with suggestions ranging from omnivory (a varied diet) to piscivory, molluscivory (mollusks), and carnivory. By further researching both phylogenetic and functional questions, paleontologists may better understand why whales left land and returned to water.

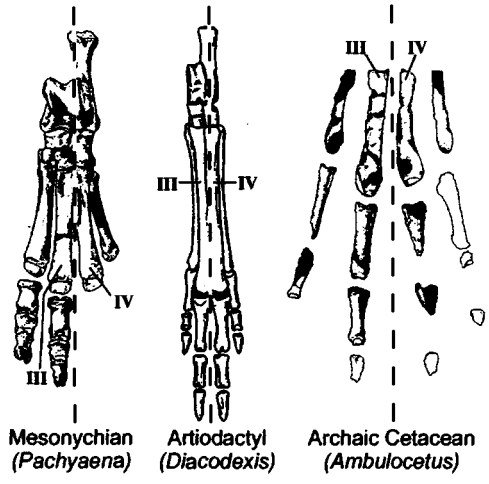

Figure 3 *Feet of a mesonychian, a fossil artiodactyl, and a fossil cetacean all shown as if looking down on the top surface of the foot. All exhibit a paraxonic foot, i.e., one in which the weight of the body passes along an imaginary line (dotted) between digits three and four and in which the foot is largely symmetrical.*

Mesoplodont Whales

Mesoplodon spp.

ROBERT L. PITMAN
Southwest Fisheries Science Center, La Jolla, California

The genus name *Mesoplodon* (Greek: *mesos*, middle: *hopla*, arms; *odon*, tooth; i.e., armed with a tooth in the middle of the jaw) was coined by Gervais in 1850. Ziphiids (beaked whales), including mesoplodonts, appeared suddenly in the FOSSIL RECORD in the lower Miocene (26 Mya), are well represented by the upper Miocene (5 Mya), and their diversity has declined steadily since then. Currently there are 13 recognized species in *Mesoplodon* (Table I), making it by far the largest cetacean genus, and it is likely that new species are yet to be discovered. In the eastern Pacific alone, two new species have been described (*M. peruvianus* in 1991 and *M. bahamondi* in 1995), and the description of a third is in preparation. Morphological and molecular genetic analyses confirm species limits within the group. Based on morphology, *M. bowdoini* and *M. carlhubbsi* have been suggested as possible subspecies, but genetic analyses indicate species level differences. Although there are no currently recognized subspecies, *M. mirus* has (apparently) disjunct populations in the North Atlantic and the Southern Ocean that have markedly different color patterns, suggesting at least a subspecific level of divergence. Another ziphiid, *Indopacetus pacificus*, up until very recently known only from two skulls, has often been included within *Mesoplodon*, but is now known to be generically distinct.

Historically, mesoplodont species have been diagnosed by features of the skull, relying mainly on the length of the rostrum, and the shape, size, and placement of teeth, especially of adult males (Fig. 1). However due to anatomical similarities (especially of females and young), specimens are often misidentified, even by experts, and molecular genetic analyses have recently become important for identifying individual specimens. Genetic techniques are also uncovering "cryptic" species. For example, geneticists recently reported a new species of mesoplodont that appears to be morphologically nearly indistinguishable from *M. hectori*.

I. Description

Mesoplodonts are small whales, ranging in size from 3.9 (*M. peruvianus*) to 6.2 (*M. layardii*) m; there are too few data to determine if there are consistent size differences between males and females, although in at least some cases, females appear to be slightly larger, as is the case for most ziphiids. The

TABLE I
Living Species of *Mesoplodon*[a]

Latin name	*English name(s)*	*Length (m)*	*Distribution*
M. hectori	Hector's beaked whale; New Zealand beaked whale	4.4	Circumglobal in temperate waters of Southern Hemisphere
M. mirus	True's beaked whale	5.3	Warm temperate North Atlantic and southern Indian Ocean
M. europaeus	Gervais' beaked whale; Antillean beaked whale; Gulf Stream beaked whale	5.2	Warm temperate and tropical waters of North Atlantic
M. bidens	Sowerby's beaked whale; North Atlantic beaked whale; North Sea beaked whale	5.5	Temperate North Atlantic from Europe to North America
M. grayi	Gray's beaked whale; Haast's beaked whale; scamper-down whale; small-toothed beaked whale	5.6	Circumglobal in temperate waters of Southern Hemisphere
M. peruvianus	Pygmy beaked whale; Peruvian beaked whale; lesser beaked whale	3.9	Eastern Pacific from northern Mexico to northern Chile
M. bowdoini	Andrew's beaked whale; deep-crest beaked whale	4.7	Known only from strandings in Australia and New Zealand
M. bahamondi	Bahamonde's beaked whale	?	One specimen from Juan Fernandez Island, Chile
M. carlhubbsi	Hubbs' beaked whale; arch-beaked whale	5.3	Temperate north Pacific from California to Japan
M. ginkgodens	Ginkgo-toothed whale; Japanese beaked whale	4.9	Tropical and warm temperate waters of the Indian and Pacific oceans
M. stejnegeri	Stejneger's beaked whale; Bering Sea beaked whale; saber-toothed whale	5.2	Sub-Arctic and temperate north Pacific from California to Japan
M. layardii	Layard's beaked whale; strap-toothed whale; long-toothed beaked whale	6.2	Circumglobal in temperate and sub-Antarctic southern waters
M. densirostris	Blainville's beaked whale; dense beaked whale	4.7	Circumglobal in tropical and warm temperate waters

[a]Lengths are maxima.

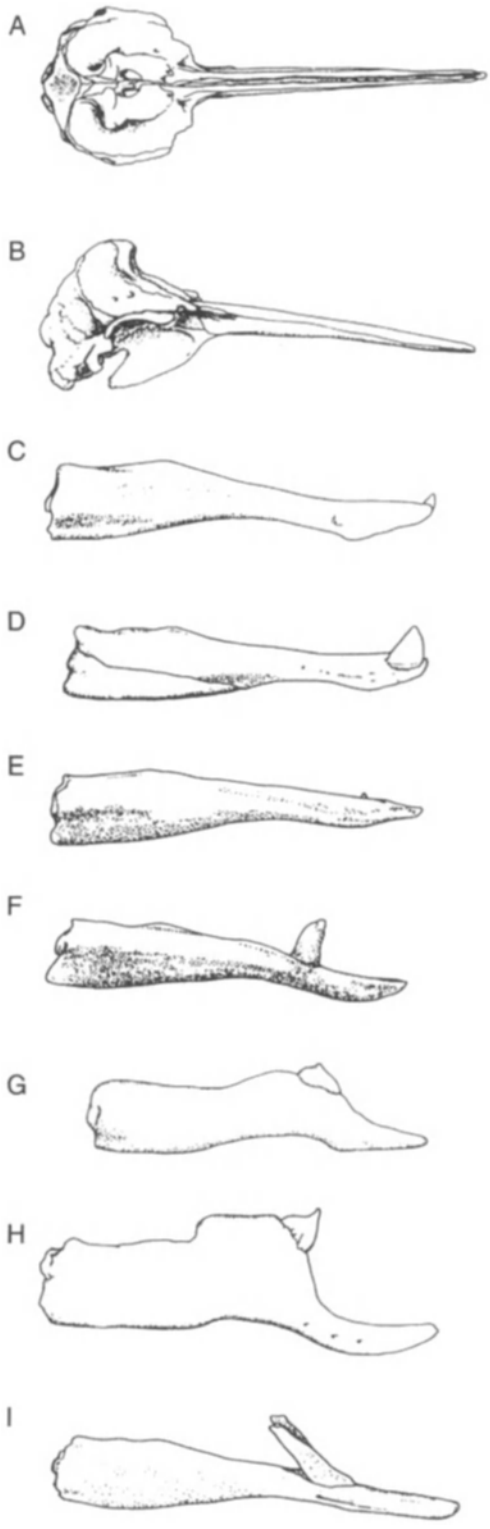

Figure 1 *Selected* Mesoplodon *skulls and mandibles. (A) Dorsal view of* M. grayi *skull. (B) Lateral view of* M. grayi *skull. Lower jaws of (C)* M. mirus, *(D)* M. hectori, *(E)* M. europaeus, *(F)* M. stejnegeri, *(G)* M. ginkgodens, *(H)* M. densirostris, *and (I)* M. layardii. *Jaws are all of adult males except E. Modifed after Jefferson* et al. *(1993).*

body is spindle shaped, with a small, usually triangular dorsal fin, located approximately two-thirds of the way back on the body. The flippers are small and narrow and fit into pigmented depressions in the body. The unnotched flukes are usually straight across the trailing edge or even slightly convex. A single pair of external throat grooves is present between the mandibles that apparently assists in suction feeding (see later). The head is small and tapered. The melon is small and blends without a crease into the beak. The blowhole is a half circle with the ends pointed forward and not always symmetric. Beak length is variable depending on the species, ranging from short (e.g., *M. densirostris*) to very long (e.g., *M. grayi*) (Fig. 2).

Most species show three sexually dimorphic traits, all of which relate to male aggressive behavior at the onset of sexual maturity: (1) only adult males have functional TEETH, (2) only adult males have extensive secondary ossification of the mesorostral canal, and (3) only adult males show extensive and conspicuous body scarring. These features are discussed later.

Males apparently use their teeth for intraspecific fighting with other males to establish breeding hierarchies. In fully mature males, a single pair of teeth erupts from the mandibles and projects up, outside of the mouth, along both sides of the rostrum. Depending on the species, the teeth are located anywhere from the tip of the lower jaw (apical) to about halfway back along the jaw, and they vary markedly in size and shape (Fig. 1). In most species, the teeth are laterally compressed, although in *M. mirus*, which has the most apical teeth, they are oval in cross section. The tooth usually has a sharp denticle on top for inflicting wounds, but this can be worn down smooth in older males. In some species, the tooth is raised up on a high bony arch in the lower jaw (e.g., *M. densirostris*); in other species, the mandible is relatively flat and teeth of varying length are surrounded and supported mainly by gum tissue.

A hypothesis of evolutionary trend for mesoplodonts proposes that the occurrence of apical teeth is a primitive condition

Figure 2 *Gray's beaked whale is unusual among the* Mesoplodon *species in having a long beak like a dolphin. This photo was taken in Antarctic waters by Richard A. Rowlett.*

and more posterior locations are derived. Teeth positioned further back on the mandible apparently allow animals to attack more forcefully with their rostrum with less risk of damage to the mandibles or teeth. However, teeth further back along the lower jaw need to be elevated or elongated so that they are not obstructed by the rostrum, which gets wider and deeper toward the base. These factors have probably contributed to the marked variation in tooth size and placement within this group (Fig. 1). As an extreme example, *M. layardii* has some of the most bizarre teeth of any known animal. They are long (to at least 34 cm) and curl back over the rostrum so that they sometimes overlap each other, clamping the jaws nearly shut (Fig. 3). These teeth have dorsally projecting denticles and, judging by the amount of scarring on adult males, are still effective for intraspecific fighting. However, in many individuals, tooth wear results from the rostrum rubbing against the inner sides of the teeth. This clearly indicates that jaw movement is impaired, and the adaptive significance of tooth shape in this species has never been adequately explained.

The mesorostral canal is a narrow groove in the midline of the upper rostrum that is filled with cartilage in most cetaceans. This cartilage is continuous with the mesethmoid and homologous to the nasal septum of terrestrial mammals. In adult male mesoplodonts, the cartilage is displaced by expansion of the vomer from below, which is composed of extremely dense bone, in some cases more dense than elephant ivory. When males attack, they make contact with the top of their rostrum and use their teeth with the mouth in the closed position. It has generally been assumed that the heavily reinforced rostrum was selected to allow fighting males to be more forceful with their attacks while reducing the possibility of damage to the rostrum. A recent study, however, suggested that the bone of the rostrum, although very dense, was too brittle to provide mechanical reinforcement and that it might, for example, have a hydrostatic role to assist in deep diving.

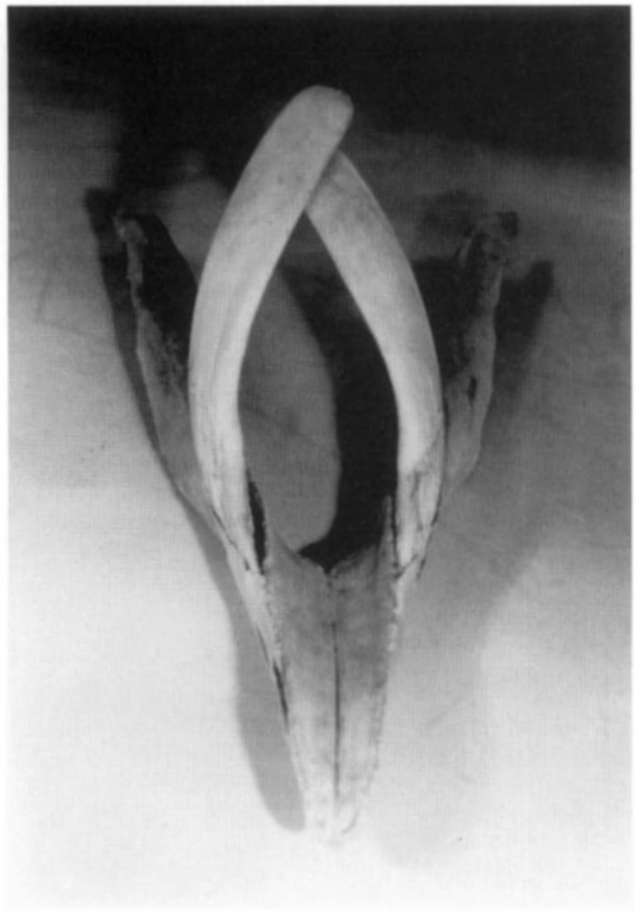

Figure 3 *Lower jaw of an adult male* Mesoplodon layardii *showing how the teeth wrapped around the upper jaw in the living animal.*

Color patterning among mesoplodonts is poorly known because animals at sea are sighted so infrequently and the few fresh animals that do strand on beaches lose their colors quickly. Most species are so similar, especially females and juveniles, that even on the rare occasion when animals are clearly seen at sea, few can be identified. This applies to stranded animals as well. Live animals are usually a nondescript gray or brown dorsally and somewhat paler ventrally. Most have no distinguishable overall pattern, although some are quite distinctively marked. For example, *M. mirus* (Southern Hemisphere form) has an all white tail stock, dorsal fin, and flukes; *M. layardii* has a very distinctive black and white pattern to the head, face, and beak, and adult males of an unidentified mesoplodont from the eastern tropical Pacific (probably *M. peruvianus*) have a broad white swathe across the body that forms a conspicuous chevron when viewed from above.

Most mesoplodonts exhibit sexually dimorphic COLORATION, with adult males patterned more conspicuously than females. This can be due either to pigment deposition (e.g., *M. carlhubbsi*) or, more often, to adventitious coloration from scarring. Most scars on mesoplodonts are attributable to tooth rake injuries from other males or wounds from cookie-cutter shark bites (see later). All mesoplodonts, except apparently *M. ginkgodens*, form white scar tissue over external wounds so that the body retains a permanent visual record of any injuries. As a result, adult males in groups of mesoplodonts are usually easily recognizable by their prominent scarring (Fig. 4), and it has been suggested that this may have evolved as a social signal for indicating male "quality." In addition to heavy scarring, adult males (and, to a lesser extent, females) of some species have white pigment patches that may serve to highlight important anatomical landmarks, including the beak tip, head, lips, and genital area.

II. Distribution and Zoogeography

Mesoplodonts are so difficult to approach and identify under normal conditions that there are several species that have never been identified alive in the wild (e.g., *M. bowdoini, M. hectori, M. bahamondi, M. europaeus, M. ginkgodens*). Consequently, nearly everything known about their distribution and abundance has been inferred from relatively infrequent stranding events. As a group they are widespread, occurring in all of the world's oceans except for the coldest waters of the Arctic and Antarctica. They normally inhabit deep ocean waters

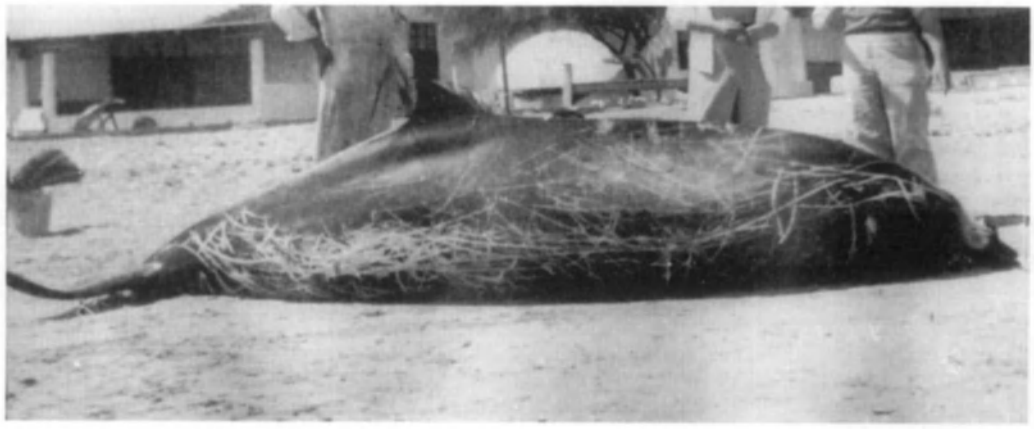

Figure 4 *A stranded specimen of an adult male* Mesoplodon *(probably* M. peruvianus*) from Paracas, Peru. Note white scarring over most of the body from fighting with other males. Photo by E. Link, courtesy of J. Mead, Smithsonian Institution.*

(>2000 m) or continental slopes (200–2000 m), and only rarely stray over the continental shelf. The distribution of most species tends to be somewhat localized (limited to single ocean basins; Table I), although *M. densirostris* is found in all tropical and warm temperate oceans and is perhaps the most widespread mesoplodont. Seasonality of stranding records suggests that at least some high-latitude species (e.g., *M. layardii*) may undergo some limited migration to lower latitudes during the local winter.

III. Food and Feeding

Based on stomach contents of stranded animals, mesoplodonts feed primarily on mesopelagic squid (e.g., *Histioteuthis* spp., *Taonis* spp., *Gonatus* spp.), although some mesopelagic fish may also be taken (at least some of these fish, however, are probably secondary, i.e., squid, prey). Most prey are probably caught at depths of 200 m or more. A reduced dentition among various species of odontocetes (toothed cetaceans) is generally interpreted as an adaption for FEEDING on squid. Most squid-feeding cetaceans, including mesoplodonts, are thought to be suction feeders: prey is sucked in and swallowed whole. Large muscles at the back of the tongue (hyoglossus and styloglossus) are anchored to an enlarged hyoid bone; this allows the tongue to be retracted in a piston-like manner while the throat pleats allow distention of the mouth floor, creating the necessary vacuum for sucking in prey. Because ziphiids in general no longer need their teeth for feeding this has freed them up to evolve for other purposes, i.e., as fighting weapons. It has been hypothesized that white pigmentation on the anterior floor of the mouth of many beaked whale species may serve as an attractant for BIOLUMINESCENT squid.

IV. Behavior

Almost nothing is known about mesoplodont behavior, partly because they are so rarely sighted, but also because their behavioral repertoire at the surface appears to be very limited and stereotyped. The most commonly reported behavior has been slow swimming, usually away from a vessel, and often a mile or more away. When undisturbed, they roll quietly several times at the surface and then dive from 20 to over 45 min at a time. Most groups surface simultaneously and within a few body lengths of each other, indicating that some communication is probably going on as they forage in total darkness of the deep ocean. While at the surface, either traveling or stationary, individuals in groups usually remain within a couple body lengths of each other. BREACHING (leaping out of the water) has been recorded on only a very few occasions. Long-beaked forms (e.g., *M. grayi*, *M. bidens*, and *M. layardii*) often bring their beak up out of the water at a 45° angle when they surface. Normally there is no visible blow, and none are known to lift their flukes when diving. Tail slapping has been reported once. Male mesoplodonts are assumed to use their erupted teeth as tusks to fight with each other, and although none of these battles have ever even reported by human observers, the extensive scarring found among males of this group suggests that it is of frequent occurrence (Fig. 4).

V. Other Life History Notes

Because of their shy nature, far offshore habitat, and apparent rarity, very little is known about the biology of mesoplodonts, and nearly everything that is known has come from the examination of stranded animals. As in all cetaceans, females give birth to a single calf. Mean body length for calves at birth has ranged from 2.1 m for *M. europaeus* to 2.5 m for *M. carlhubbsi*, representing from 40 to 48% of the adult female body lengths (these are neither the largest nor the smallest mesoplodonts). The smallest mesoplodont calf reported to date is 1.9 m (*M. hectori*), although *M. peruvianus* will probably prove to be smaller. There is no information on gestation or lactation periods.

Longevity data for mesoplodonts are virtually nonexistent, although they may be quite long lived: a count of tooth layers in a specimen of *M. europaeus* suggests that it was at least 27

years old. A female *M. densirostris* estimated to be 9 years old (based on tooth layer counts) had just recently become sexually mature. Very little has been recorded in the way of diseases, parasites, or commensals. Osteomyelitis has been reported twice. Endoparasites recorded have included cestodes and occasional heavy infestations of nematodes (*Crassicauda* sp.) in the kidneys. Ectoparasites recorded include *Penella* sp. (a parasitic copepod) and cyamids. The erupted teeth of males often have stalked BARNACLES (*Conchoderma* sp.) attached to them; bunches of these often appear as "tassels" on the teeth of live animals at sea. A pseudo-stalked barnacle, *Xenobalanus* sp., is sometimes attached to the flukes and dorsal fins. Almost nothing is known about mesoplodont vocalizations. Stranded animals on beaches have been reported to make cow-like sounds but there are no known recordings of vocalizations at sea. Because they almost certainly use sounds to coordinate deep diving behavior among herd members and locate prey in total darkness, it is likely that they do vocalize.

Mesoplodonts occur in small groups typically ranging in size from 1 to 6 animals, although groups of up to 10 have been reported, and a mass stranding of 28 *M. grayi* occurred in New Zealand. Mean school size for 125 *Mesoplodon* sightings (including at least three different species) from the eastern tropical Pacific was 3.0, with 2 being the most common group size. Although mixed groups of adult males with females and calves have been observed at sea, there is some evidence from both sightings and strandings data that there may be some segregation by sex or age class at times. Predators of mesoplodonts probably include killer whales and large sharks, although direct observations are lacking. Mesoplodonts often have white oval scars (diameter to about 8 cm) caused by the bites of cookiecutter sharks (*Isistius* sp.). These are small (to about 50 cm), mesopelagic sharks that feed by snatching mouthfuls of flesh off larger fish and cetaceans. Although individual mesoplodonts are often riddled with scores of healed bite wounds, these do not appear to contribute to mortality.

VI. Status and Conservation

So few mesoplodonts have been reliably identified at sea that it is impossible to accurately determine the population status of any species, although based on stranding data, at least some species may not be as rare as the sighting records indicate. *M. grayi* and *M. layardii* appear to be widespread and fairly common in the Southern Ocean, as is *M. densirostris* in tropical oceans. These may be the most abundant mesoplodonts. Most species, however, appear to be neither numerous nor widespread, and some may be quite rare (e.g., *M. bowdoini, M. hectori*). The large number of species in this group suggests a high rate of endemism with naturally small populations and restricted ranges. Although there has never been any directed fishery for mesoplodonts, a few are occasionally harpooned opportunistically by whalers, and unknown, but potentially significant, numbers are killed by high seas drift nets and long line fishing gear. Only stranded specimens have ever been kept in captivity and these have usually died within a few days (usually from preexisting conditions).

Migration and Movement Patterns

S. JONATHAN STERN
Florida State University, Tallahassee

Migration is a critical part of the life history strategies of a diverse group of organisms. An optimal strategy may include the need to move from one location to another and back in some systematic fashion. Migration is the large-scale movement between different parts of the home range, with some energy allocation to support movement or time to meet reproductive needs.

Migration underscores an individual's need for some resource such as food or mates. An individual has a home range that is a function of relative body size and mobility as well as a variety of other factors. In general, large animals need large home ranges. As home range increases in size, an individual experiences variability in environmental conditions. In the marine environment, two parcels of water 10 cm apart are more similar on average than two parcels of water 1000 km apart. Accordingly, waters of higher latitude have generally higher productivity than those of lower latitudes. In addition, a single parcel of water may have similar oceanographic conditions 2 days apart but may differ significantly between winter and summer. Length of the productive season is shorter at higher latitudes due to decreased sunlight in winter, in addition to other oceanographic changes. Thus resources are variable in space as well as time. In general, one part of a home range may be very different with respect to the availability of resources than another. Disparity in resource availability results in the necessity to move between places in the home range.

Resources for marine mammals include food, mates, and space. Mates may only be seasonally receptive or available, or

sexes may have a different spatial distribution in a particular season. Space is a variable resource because not all habitats are suitable. In territorial species, once a territory is occupied, other individuals of the same species are excluded. In nonterritorial species, crowding often occurs, and while habitat is nearby, and apparently suitable, there is a tendency to form a crowd. Space for hauling out may not be available at all times due to covering by tides once or twice a day.

Given that prey resources are variable in space and time, one strategy is to stay in one area and tough out the hard times by somehow reducing the effects of variability. This leads to formation of denser fur, thicker BLUBBER layer, or adopting a new strategy such as hibernation. Female polar bears (*Ursus maritimus*) hibernate over winter, giving birth and feeding cubs until emerging from the den in spring. Other segments of polar bear populations do not hibernate, but make large-scale movements in search of food. One benefit of staying in one location is that an individual does not face any energetic cost of moving or potentially adverse conditions along the way. For cetaceans, the cost of moving long distances while on migration is probably not very different than moving around in one location. Some pinnipeds may conserve energy by hauling out or lying at the surface for extended periods. The second strategy is to move to another part of their home range where conditions are more favorable, such as a higher resource density, or where environmental conditions are better. For example, Caribbean manatees (*Trichechus manatus*) move in relation to changing water temperature on a seasonal basis. They prefer waters warmer than 68°F and move in relation to these waters. Migration occurs in populations where some parts of a home range may have more and/or better resources of one type, while another part of the home range has more and/or better resources of another type than the first. The general pattern is movement between feeding and reproductive grounds or haul-out site.

For marine mammals, migration was assumed to occur based on the seasonal occurrence of large numbers of a particular species at different locations. However, migration can only be proven by Lagrangian studies, involving marking individuals in some fashion on one migratory destination and recapturing them on another. Whaling provided the first real evidence for migration in large whales. Numbered darts were fired into dorsal blubber and muscle. If that individual was killed during subsequent whaling operations, tagging and killing dates and locations could be compared and some assessment of movements could be made. Some pinnipeds were marked with numbered flipper tags. Censuses were conducted on a number of haul outs. Movement was documented as tagged individuals moved between haul-out sites. Movement and migration patterns have been described in varying levels of detail using photo-identification and satellite telemetry. For example, locations of individual northern elephant seals (*Mirounga angustirostris*) sent by satellites every 2 days provide valuable information on movement and migration to and from areas of high food productivity, inferred by persistent signals from a relatively confined location, such as over a seamount.

I. Terminology

Defining migration is the first step to discussing it because not all large-scale movements are migration. This is not an easy task, as literature on migration does not have a consistent definition. How do we distinguish between daily movements of a seal that returns to the same haul out every low tide from a whale that swims from the Antarctic ice edge to the waters off Brazil? Movement encompasses a hierarchy of displacements ranging from thousands of kilometers, encompassing thousands of surfacings. The following terms describe a variety of types of movement of increasing scale (Fig. 1). A step is a relevant distance moved, such as distance between sites of long dives. Kinesis refers to changes in turning or movement rates. Kinesis can often result in station keeping, where an individual maintains a relative position through relatively frequent turns. Foraging is a search for resources within a patch. A patch is an area within which resources are randomly distributed. Commuting occurs between adjacent patches. After searching patches in a region, animals can then move to another region, which is subject to a different set of local oceanographic conditions. Movement between regions is referred to as ranging. For example, fin whales (*Balaenoptera physalus*) make an overall east to west displacement through the Gulf of Alaska during a feeding season.

Migration is persistent and more or less rectilinear movement, presumably between two different parts of the home range, each with its own resources or use. For marine mammals, these destinations are areas for feeding/breeding/birth/lactation and, in addition, for pinnipeds, molting. General mysticete migration patterns are shown in Fig. 2. This movement occurs on a seasonal basis, with the majority of a population, sex, or age class undertaking the same overall movement pattern. Upon arrival at one destination, behavior changes to maintain relative location. For molting, breeding, and lactating pinnipeds, this is achieved by hauling out on land or, if on FEEDING grounds, floating in one spot or clusters of deep dives in a limited area.

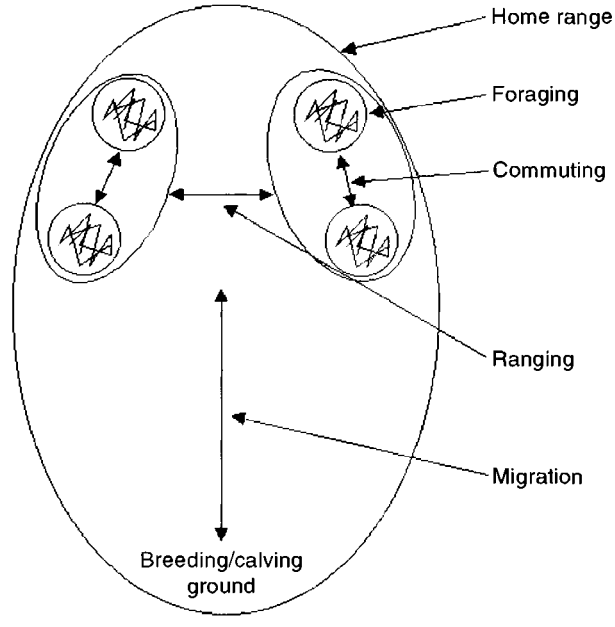

Figure 1 *Different type of movements are described in the text.*

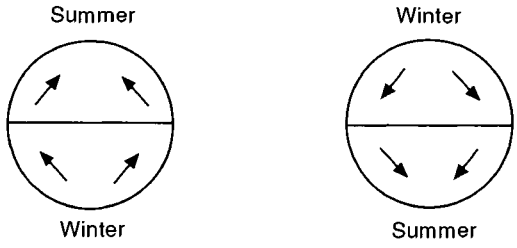

Figure 2 *Generalized migration patterns of baleen whales in the Northern and Southern Hemispheres. Whales spend summers on productive feeding grounds and then migrate to the winter breeding/calving grounds in warmer waters. Most species of whales are believed to feed little, if at all, while away from their feeding grounds.*

For cetaceans, station keeping involves changing the direction of travel relatively frequently.

One characteristic of marine mammal migration is seasonal changes in energy allocation and storage. This results in an increased fat store to support reproduction. Based on stomach contents analysis of whales killed on winter grounds, mysticetes are thought to feed little on migration routes and breeding grounds, living off stored blubber. However, recent evidence suggests that feeding occurs on the winter grounds, at least opportunistically. Some phocids such as elephant seals (*Mirounga* spp.) migrate long distances. They feed continuously to store energy to support time spent on breeding and molting haul outs. Stored energy is used for lactation in females and for mating and agonistic displays in males. Elephant seals lose much of their fat when hauled out and need to begin storing energy as rapidly as possible upon reentry into the water. Otariids feed daily around haul outs, although males may fast while defending a territory.

In this discussion, migration and movement focus in the horizontal dimensions (x and y). Displacement in the vertical dimension (z) is trivial by comparison, although is not a trivial part of foraging ecology. For marine mammals, migration is movement considerably greater than 2 hr, the maximum dive time recorded for a marine mammal and the maximum depth of a dive.

The following scenarios are not true migrations, but are often labeled as such in literature. Seasonal movement may be a response to changing prey distribution. The occurrence of some groups of killer whales (*Orcinus orca*) in the inland waters of the Pacific Northwest correlates with the seasonal migration of salmon (*Onchyrhynchus* spp.). Because these fish ultimately go upstream to die, the whales must find other prey during the winter. It is not clear if they feed on other species during the winter or go offshore to find other salmon schools. Gray seals (*Halichoerus grypus*) move to distinctly different areas on a seasonal basis to feed in productive areas in the Northwest Atlantic. Polar bears seasonally roam over large home ranges, searching for available food. Other large-scale movements are also not truly migration. For example, movement may be in relation to shifting environmental conditions, such as the seasonal advance or retreat of an ice edge. While geographic location of an individual changes, it is essentially maintaining itself in the same general environment.

Dispersal is not migration, as there is no return to the original area. Dispersal is colonization of new or recolonization of historic breeding habitats. For example, breeding sites of northern elephant seals were historically on islands off the mainland of California, likely due to the presence of terrestrial predators on the mainland. In association with postexploitation recovery and the decline of terrestrial predators, elephant seals returned to all historic breeding islands and invaded new sites on the mainland. Another example of a dispersal event was observed off California in response to the 1982/1983 El Niño Southern Oscillation event. Common bottlenose dolphins (*Tursiops truncatus*) moved from southern California to San Francisco with the northward advance of warmer waters. This group of dolphins remained after the warm waters retreated back south.

True migrating species have distinct adaptations. Because energy is a limiting resource, migration can be examined from the perspective of energy acquisition (Table I). Fasting species have different physiological and energy intake characteristics than nonfasting species. Fasting during some part of the year requires intense feeding during some other part of the year in order to store energy as well as to meet metabolic needs at the time.

Species that fast either spend their entire lives or part of the year in productive polar, subpolar, and temperate waters where they can feed intensely to form a blubber layer. Other than ice-breeding seals, migrating marine mammals have feeding grounds located pole-ward of the breeding areas.

II. Why Migrate?

Any strategy has associated costs and benefits. Natural selection weighs the costs and benefits of migrating; if the benefits are greater than the costs, a species will migrate. Different areas have different proximate currencies, with energy acquisi-

tion important in the feeding areas and reproductive success important in the breeding/calving areas. Feeding success, however, has a direct influence on reproductive success, the ultimate currency, for survival of the genes of an individual. For cetaceans, migration occurs for food and reproduction. Pinnipeds migrate for these reasons as well as for molting.

A. Pinniped Patterns

Pinnipeds are central-place foragers, moving from haul-out sites to feeding grounds at varying distances. Large-scale movement away from a haul out reduces pressure on local resources and has other benefits as well. Because predators may congregate around haul outs, an individual can reduce its chance of being killed by a predator by reducing the number of entrances to and exits from the water. Dive profiles of elephant seals suggest that while they feed along an entire migration route, there are areas with a higher frequency of deep dives, suggesting intense, localized feeding. Some of these highly productive areas are associated with seamounts. These seals make deep foraging dives for deep-water prey. The areas around their haul outs are seasonally productive and support a number of mysticete species. Therefore, productivity is not the key; rather it is productivity of a certain type of prey that makes migration beneficial. Some otariids make daily excursions from haul-out sites in search of food. For a lactating pinniped, large movements increase the time spent away from a pup, resulting in less rapid pup growth. While increased entrances and exists from the water increase the probability of being killed by a predator, the sheer number of other seals entering and exiting the water reduces the per capita probability of attack.

B. Mysticete Migration

The feeding grounds of baleen whales are in productive cold waters so it is clear why they migrate to these areas. A question remains as to why they must migrate to warm waters for reproduction. Four reasons have been suggested for migration to warm water breeding and calving areas. The first is to minimize thermal stress on calves. This is likely not a problem for a newborn calf. Smaller mammals with less insulation are able to survive in those conditions. Because of its large body size, a calf is not thermally stressed.

The second reason to move to warm waters is resource tracking, i.e., following prey. By definition, this is not migration. While an individual, school, or population is moving, movement results in reduced resource variability, as prey are always in the vicinity.

Killer whale predation on calves has been a suggested reason for mysticete migration. By migrating to warm, relatively killer whale-free waters to give birth, calf mortality would be reduced.

The final reason to migrate is essentially an evolutionary holdover: individuals migrate because their ancestors did. The evolutionary holdover hypothesis includes feeding and reproduction into a life history strategy. Intense feeding leads to energy storage as the short-term goal that maximizes reproductive success, the ultimate, evolutionary goal. Natural selection favors individuals that are successful at migrating, feeding, and reproducing.

C. Pleistocene Conditions

The productive waters of the higher latitudes have changed significantly over the past 20,000 years. These changes likely had a profound influence on regional productivity, affecting migration routes, destinations, and foraging areas of many cetaceans, pinnipeds, carnivores (bears, otters) and sirenians (Steller's sea cow, *Hydrodamalis gigas*). Increased ice extent and land emergence of the Pleistocene made current feeding grounds unavailable to gray whales (*Eschrischtius robustus*), bowhead whales (*Balaena mysticetus*), beluga whales (*Delphinaptrus leucas*), narwhals (*Monodon monocerous*), walruses (*Odobenus rosmarus*), Northern fur seals (*Callorhinus ursinus*), and other seals. The North Atlantic north of 45° was an ice-bearing polar sea with conditions similar to the Antarctic Convergence, resulting in a larger, more productive sea than at present. The distance between productive cold water and warmer water was much less, resulting in relatively little or no distance between feeding and breeding/calving areas (Fig. 3). In the Southern Ocean, an equator-ward shift in isotherms was in response to a northward extension of ice. The Antarctic convergence was 5° north of its current position.

D. Present Oceanographic and Migratory Conditions

At the glacial maxima, cold, productive waters were closer to the equator than at present. At these latitudes, the number of hours of sunlight per day were not as seasonally extreme as at the poles. Assuming that mid and lower latitude waters are relatively unchanged from Pleistocene conditions, the only difference would be the retreat of cold waters toward the poles. As cold, productive waters retreated toward the poles, sunlight for photosynthesis became more variable over the course of a year, leading to intense seasonal peaks in production followed by reduced production in winter. Over time, whale distribution followed the pole-ward retreat of fronts of productive oceans.

This explains the summer distribution of baleen whales, but does not address the need to migrate to warm waters for reproductive activities. Many species of marine mammals, and mammals in general, have highly seasonal reproductive strategies in order to time births relative to optimal environmental conditions. Day length is a cue for seasonal breeding in a number of birds and mammals. Photoperiod is an important seasonal cue because it is invariant from year to year. This means that the timing of reproduction and migratory movements can be the same from one year to the next. The advantage is that an individual can maximize its use of seasonal prey resources as well as seasonally available mates.

Both circadian (daily) and circannual (yearly) cycles use light as a cue: however, the specific cues from light, or *zeitgebers*, vary. Circadian signals are dawn and dusk, whereas circannual signals are perceived as the ratio of number of light to dark hours in a 24-h period. Thus both cycles are used for seasonal cues. Other cues may act as secondary synchronizers, although these, such as food availability, are more variable.

The pineal gland is responsible for time keeping in birds and mammals via the production of melatonin, as well as other compounds. The number of hours of darkness per 24 hr is "counted" by the biosynthesis of melatonin, which is produced

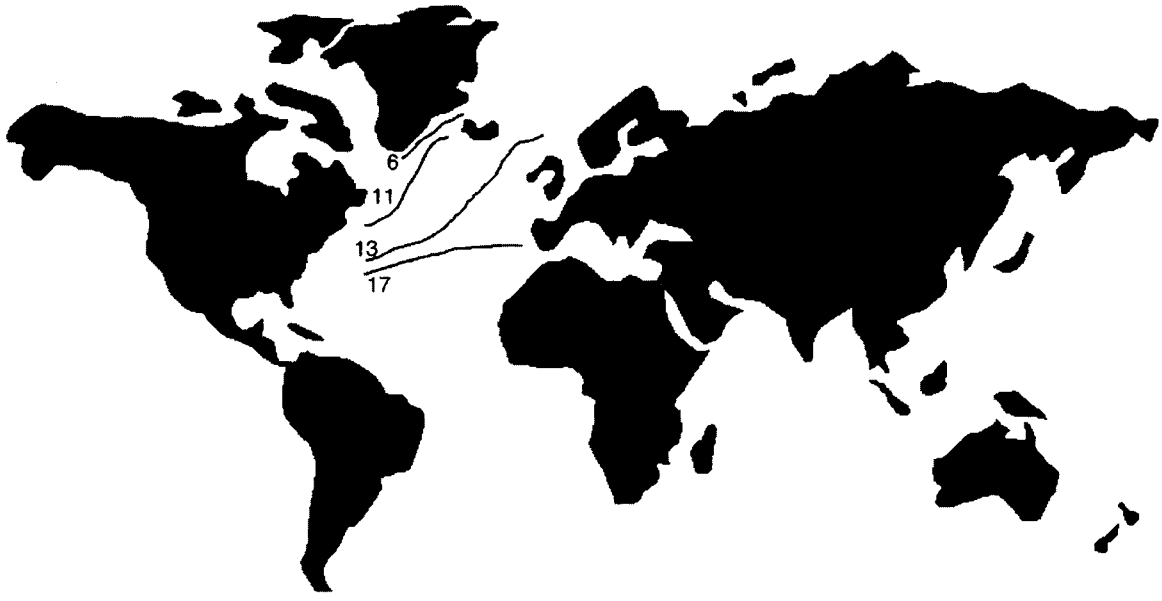

Figure 3 *Post-Pleistocene distribution of the polar front in the North Atlantic Ocean. Lines represent the southern extent of sea surface temperature relating to the polar front. Numbers associated with each line are thousands of years before present. Whale movement from warm-water calving/breeding waters to cold productive feeding waters would have been similarly truncated toward the equator in the past. The equator-ward extension of cold water meant that productive seasons were probably longer in the past than at present due to increased hours of daylight.*

more in hours of darkness. At seasonal scales, as winter approaches, the hours of daylight decrease and hours of darkness increase. In a given 24-hr period, the amount of melatonin produced increases, suppressing gonadal activity. In many mammals the breeding season of females corresponds to periods of decreasing daylight per 24 hr. Increasing daylight after the winter solstice is responsible for triggering estrus. Pineal glands are exceptional in size in polar species such as the Weddell seal (*Leptonychotes weddellii*), northern fur seal, and walrus, species that live where day length is most variable.

As productive waters retreated pole-ward, cetacean distribution shifted accordingly, changing the overall lighting regime from more or less equal hours of dark and light to one with more hours of darkness in winter, with resultant gonadal suppression. In addition, production decreases in winter so there is no benefit to stay in colder waters.

Individuals need to move to a lighting regime that switches on the gonads. In migrating animals, a shift in the lighting regime on the feeding grounds may trigger migration toward the equator. As an individual approaches the equator, the hours of daylight per 24 hr increase. In addition, after December 21, the fewest hours of daylight in the Northern Hemisphere, and June 21, the fewest hours of daylight in the Southern Hemisphere, the number of hours of daylight per 24 hr begins to increase. The rate change in the lighting regime reaches its maximum at the equinoxes. Together, these result in reduced melatonin levels and restored gonadal activity, which triggers mating behavior. This may be a triggering mechanism in the evolution of migratory behavior in mysticetes.

Testosterone and its metabolites trigger migratory behavior in some animals. Male California sea lions (*Zalophus californianus*) spend the bulk of the year hauled out in large bachelor groups. By June, they have left their haul-outs in central and northern California, Oregon, Washington, and Alaska and migrated to the Channel Islands off southern California. Here, breeding occurs as males set up territories and defend females against other males with whom they spend most of the year in relatively peaceful coexistence. Once migration back to the feeding grounds is triggered in July, an individual is exposed to increasing hours of daylight per 24 hr as it swims pole-ward. One benefit from such a signal is that it is invariant from year to year.

Curiously, the peak migration of gray whales is variable from year to year. The initiation of the southward migration to the breeding grounds may be linked to a change in foraging success or some other environment factor, such as the formation of sea ice. Individuals may be able to override these signals. Extended feeding seasons for baleen whales occur on occasion as prey are uncharacteristically available in late full. For example, blue whales (*Balaenoptera musculus*) were observed feeding on euphausiids in late November in Monterey Bay, California. Whales generally leave the area in late September.

In some cases, not all members of a migratory species actually migrate in a given year. For example, in every location where minke whales (*B. acutorostrata* and *B. bonaerensis*) feed, individuals are observed in winter.

III. Orientation and Navigation

The mechanisms of orientation, plotting their location at any time, and navigation, directing movement from one location to

another, are not known. Individuals are often seen in the same locations from one year to the next. In the interim, they have traveled thousands of kilometers, indicating that marine mammals use some type of cues for orientation and navigation between migratory destinations. Organisms tend to meander if they lack orientation and navigation cues. Therefore, marine mammals must know where they are at a given time (orientation) and where they are going next (navigation).

At the initiation of migration, a direction must be selected. Advancing ice may simply eliminate certain directions as a choice, displacing individuals toward the equator. In higher latitudes, changes in sea conditions influence prey availability, which may also trigger the migratory response.

Cues may vary over time and the course of migration. For example, once migration is initiated, the only cue necessary is which overall direction to travel: north, south, east, or west. Celestial navigation has been suggested as one mechanism of navigation. In the north/south directions, the relative location of the sun in the sky can be monitored. This may be as simple as "keep sunrise on the left side when migrating to the breeding ground and on the right side when migrating to the feeding ground" or as complicated as estimating latitude as a function of position of the sun. Navigation by star location has also been suggested as a mechanism.

Another possible large-scale cue is the direction of a major current if an animal is moving against it. Near the equator in the Northern Hemisphere, western boundary currents move from south to north, while eastern boundary currents move from north to south. Coastal processes and minor currents cause the deformation of major currents at higher latitudes, resulting in the formation of gyres and eddies. Migrating whales may use these currents for a free ride.

Magnetite in the brains of some species has been implicated as a mechanism by which individuals could track changes in the earth's magnetic field. Mass STRANDINGS often occur at the same location. These locations may have anomalies in the local earth's magnetic field, which cause whales to become disoriented and strand. A tantalizing example of the possibility of using magnetic cues is seen in humpback whales (*Megaptera novaeangliae*) migrating from Hawaii to Southeast Alaska. Tracks were within 1° of magnetic north.

At smaller scales, other cues could be used. For example, while mysticetes do not have a true sense of smell, they do have a well-developed Jacobsen's organ. This may allow them to "taste" differences in water mass composition. For example, freshwater from ice melt or riverine input might provide a "taste trail" to a rich feeding ground, as a lens of fresh water floats on denser salt water.

Routes to and from feeding and breeding grounds may be variable or essentially a retracing of the migratory path. Male humpback whales migrate south from the Gulf of Maine relatively far offshore, while the return trip is much closer to shore. Gray whales along the west coast of North America probably migrate between calving lagoons in Baja California and feeding grounds in the Bering, Chukchi, and Beaufort Seas by following contours of the coastline. Gray whales migrate along the same nearshore corridor in both migratory directions. There is spatial or temporal segregation based on age class or gender. Northern elephant seals disperse from haul-out sites into the Gulf of Alaska; however, males go further north than females.

In cases where a baleen whale species has a sufficiently long lactation period, offspring can learn migration routes and feeding locations from their mothers. In instances where offspring are weaned prior to reaching the feeding grounds, offspring are left to make exploratory migrations in hopes of finding suitable feeding grounds. This may be one reason that populations of some minke whales are segregated according to age class.

IV. Physiology of Migration

Marine mammals have a suite of physiological adaptations for energy allocation and fasting, as well as storage and mobilization of fats to and from blubber stores. Fats are the most important energy source, as lipids hold more energy per unit weight than other forms. Lipids are also less bulky than protein or carbohydrates because no water is required for storage. During feeding on productive feeding grounds, hyperphagia promotes increased lipid synthesis, fat uptake, and rate of fatty acid synthesis. Storage of fats occurs when the supply in blood exceeds metabolic demand. Mobilization of fats occurs when the demand for energy in blood exceeds supply.

However, little is known about hormonal activity in relation to migratory movements. Prolactin is a hormone responsible for promoting milk production and lactation in mammals. It has the effect of increased fattening in birds. If there were a similar effect on mammals, it would be of importance. For pinnipeds, where lactating females leave pups for one to a few days, increased fat storage for milk is vital. A lactating female mysticete on the feeding ground would store fat relatively faster. This would not only provide for milk for the offspring, but also help in restoring the female's blubber layer for subsequent migration back to the breeding/calving grounds.

V. Effects of Migration

Marine mammals may have localized seasonal effects on their feeding grounds. For example, nutrient recycling may be enhanced locally in bays and inlets used by groups of feeding humpback whales in Alaska. Benthic feeders such as gray whales and walruses represent a disturbance mechanism to these communities. Disturbance opens areas for colonization and settlement of pelagic larvae of benthic species. Other coadaptations occur in barnacles living on gray whales that have timed spawning activities to coincide to when whales are in the calving lagoons. Whales, barnacles, and thus released gametes of barnacles are concentrated in limited areas.

VI. Metapopulation–Removal Migrations

Stock boundaries are delineated by mark and recapture analysis, genetic, biochemical, demographic differences, or other techniques. These differences give the impression of little or no flux of individuals between stocks. Evidence from photographic identification studies of humpback whales in the North Pacific Ocean suggests that some differences may be artificial as individuals move between stocks. Within an ocean

basin, stocks can be viewed as a metapopulation, which is a number of populations connected by the dispersal of individuals between them. If a species is distributed into populations spread over a sufficiently large area, environmental conditions are more or less independent between areas; therefore a catastrophe in one area will not affect other populations. Dispersal reduces the risk of population extinction by minimizing the effects of chance environmental changes or changes in population demography. Further, genetic heterozygosity is maintained and the population is less likely to exhibit genetic problems.

A Steller sea lion (*Eumetopias jubatus*) metapopulation has been explored in Alaska. In the Aleutian Islands and Gulf of Alaska, these sea lions have declined by 50% since the 1960s. However, Steller sea lions from Southeast Alaska south to Oregon have remained stable or slightly increased during this time. Evidence from Alaska and the Aleutian Islands suggests that fragmentation will occur, with rookeries being reduced in size and eventually becoming extinct. One reason for hope would be if the population in Southeast Alaska became a source of dispersers into the Aleutian population. The Mediterranean monk seal (*Monachus monachus*) experienced a recent population decline with habitat fragmentation throughout its range. Large expanses of unsuitable habitat separate major pupping sites, with little chance of dispersal between the two remaining large populations, although each separate population may be viable over time.

VII. Migration, Movement, and the Future

One of the main reasons to construct models of movement and migration patterns is to develop descriptive and predictive models to study the effects of changing environmental conditions. Migration in marine mammals evolved within the context of constantly changing environmental conditions. Species had to adapt to deal with novel situations and conditions. A polar front in the Pleistocene as described earlier retreated at a rate that allowed individuals to adapt to its changing distribution. Climatologists predict that global temperatures will increase by as much as 4.5°C in the next century. While it is clear that marine mammals are capable of adapting to changing environments, they might not be able to adapt at a rate commensurate with that of the change in environmental conditions in the near future. The potential implications are profound, and the environmental effects are not entirely clear.

Global warming will likely have variable effects depending on latitude, with polar and temperate regions affected to a greater extent than more tropical areas. Because these areas represent feeding grounds for migratory as well as resident species, understanding these effects is of considerable importance. The effect on marine mammals will likely be through changes in the distribution of resources in space and time. Key to survival will be how individuals respond to changes in resource distribution over space and time, and how this affects reproductive success.

Mimicry

PETER L. TYACK
Woods Hole Oceanographic Institution, Massachusetts

he words "mimicry" and "imitation" often have a negative connotation in English of being an unoriginal fake. A mimic is often an annoying copy cat, while an imitation can be a second-rate copy of a more valuable original. However, mimicry and imitation are based on special cognitive abilities that are rare among animals and that form the basis of culture. Humans learn most cultural traits—from the words in our language to the way we prepare food or hold a tool—through observational learning and imitation. We must learn thousands of these cultural traits through imitation before we can make an original contribution to our culture.

Imitation is a form of social learning—it requires an animal to observe a "demonstrator" performing a behavior and then to be able to perform that behavior itself (Galef, 1988; Whiten and Ham, 1992). Many psychologists distinguish between vocal learning, in which an animal modifies the sounds it produces based on the sounds it hears, and motor imitation, which involves an animal watching a posture or movement of another animal and then copying that movement—"monkey see, monkey do." Some also distinguish between motor imitation of something like clapping, where the animal can watch its hands in the same way that it watches the demonstrator, versus facial gestures or whole body movement, where the actor cannot receive sensory input about its own performance that directly parallels the observation of the demonstrator.

There is strong evidence for vocal learning and imitation among a variety of animals, including marine mammals and birds (Janik and Slater, 1997). Perhaps the simplest evidence involves vocal mimicry where an animal demonstrates the ability to produce sounds after exposure to model sounds that were not part

of its pre-exposure repertoire. Animals such as parrots (Todt, 1975; Pepperberg, 2000), starlings (West *et al.*, 1983), and a harbor seal (*Phoca vitulina*) named Hoover (Ralls *et al.*, 1985) have demonstrated abilities to imitate the sounds of human speech. Other animals such as dolphins have been trained to imitate acoustic features of artificial sounds (Richards *et al.*, 1984).

Humpback whales, *Megaptera novaeangliae*, have not been kept in captivity where one could most easily study imitation of manmade sounds, but their songs have a structure that cannot be explained by any mechanism other than vocal imitation. At any one time, most singing humpback whales within a population sing songs that are similar (Tyack, 1999). These songs change week by week, month by month, and year by year, and individual whales have been shown to track these changes. Humpback songs have been recorded for decades, with no suggestion that the songs repeat. This suggests that humpback whales learn to produce the current song and to track the progressive changes that make up such a distinctive feature of this signal.

Vocal imitation has also been reported for the natural sounds of bottlenose dolphins (*Tursiops truncatus*). Most dolphins studied in either captive or wild settings develop an individually distinctive signature whistle. Dolphins can imitate the whistles of social partners (Tyack, 1986). Three male Indian Ocean bottlenose dolphins (*T. aduncus*) that formed a strong social bond were reported to modify their whistles over 3 years as the bond formed, such that all three converged on a shared whistle (Smolker and Pepper, 1999). The functions of this imitation are currently not known, but similar imitation has been suggested to function as a name for reference (Tyack, 1999), as a threat (Janik and Slater, 1997), or as an affiliative signal (Smolker and Pepper, 1999).

It has been controversial whether animals can perform motor imitation (Galef, 1988). This stems in large part from the difficulty of proving that a display of which the demonstrator was capable was not part of the pre-exposure repertoire of the animal. Ethologists expect that many animal displays represent fixed action patterns that are inherited. If an action pattern is simply triggered by sensing a conspecific performing the same action, that does not demonstrate observational learning. There are many anecdotes about motor imitation in marine mammals that are difficult to explain via any mechanism other than observational learning. Tayler and Saayman (1973) provided some of the most interesting examples. They reported captive bottlenose dolphins swimming with postures and motor patterns similar to those of seals, turtles, fishes, and penguins that were housed in the same pool. These postures and swimming patterns are so awkward and different from normal dolphin locomotion that it is scarcely credible that they represent anything other than learned behaviors. The most striking example of imitation involved a calf Indian Ocean bottlenose dolphin that observed through an underwater window a human blowing out a cloud of cigarette smoke. The calf swam over to its mother, suckled, swam back to the window, and expelled a mouthful of milk into a cloud that looked similar to exhaled tobacco smoke! This kind of anecdote clearly suggests that it would be worth conducting careful experimental tests of motor imitation in cetaceans.

A good teacher can shape our behavior in ways that may look like imitation, but only demand associative learning on the part of the student. Animal trainers can shape the behavior of animals in the same way. If wild animals were to train one another in this way, this could create a faulty appearance of imitation, but this is thought not to be a problem for there is little evidence that one animal will train another (Caro and Hauser, 1992). However, there are some indications of what might be called teaching in cetaceans. Tyack and Sayigh (1997) provided suggestive evidence for possible teaching of signature whistles in wild bottlenose dolphins, and Guinet and Bouvier (1995) suggested that killer whales (*Orcinus orca*) teach the young how to strand in order to catch pinnipeds on the beach. Rather than being an alternative to passive observational learning, teaching appears at least in our own species to function in tandem with observational learning. This potential synergy between teaching and imitation would be most likely to benefit highly social animal groups, such as carnivores, primates, and cetaceans, in which cultural traditions for foraging provide a strong selective advantage. These kinds of observations in wild cetaceans, coupled with careful experimental tests with captive cetaceans, suggest that cetaceans are promising subjects for the study of mimicry in the development of cultural traits in animals.

Minke Whales

Balaenoptera acutorostrata and *B. bonaerensis*

WILLIAM F. PERRIN AND
ROBERT L. BROWNELL, JR.
Southwest Fisheries Science Center, La Jolla, California

Minke whales are the smallest of the rorquals (family Balaenopteridae) and historically the last to be targeted by commercial whaling in the Antarctic as the greater whales were successively depleted.

I. Characters and Taxonomic Relationships

Until relatively recently, only one species of minke whale was thought to exist (common minke whale); all minke whales were referred to *B. acutorostrata* (Lacépède, 1804) (e.g., Stewart and Leatherwood, 1985). Morphological and genetic evidence of a second species accumulated through the last half of the 20th century, and the Antarctic minke whale, *B. bonaerenis* (Burmeister, 1867) came to be fully recognized in the late 1990s (Rice, 1998; IWC, 2001), although a few workers still treat the minke whales as consisting of one species (e.g., Reynolds *et al.*, 1999; Stewart, 1999) whereas others are withholding judgment about the best taxonomic arrangement pending further studies (e.g., Kato and Fujise, 2000). The two species are partially sympatric in the Southern Hemisphere, where a small form (unnamed subspecies) of the common minke whale, the dwarf minke whale, is much smaller than the Antarctic minke whale and possesses the distinct white flipper mark that is characteristic of the species in the Northern Hemisphere and absent in the Antarctic species (Fig. 1). The two species also differ in relative size and shape of several cranial features (Arnold *et al.*, 1987; Zerbini and Simões-Lopes, 2000; Kato and Fujise, 2000) and in mitochondrial DNA sequences (Pastene *et al.*, 1994).

Rice (1998) recognized three subspecies of the common minke whale: the North Atlantic minke whale (*B. a. acutorostrata*), the North Pacific minke whale (*B. a. scammoni*, formerly *B. a. davidsoni*), and the unnamed Southern Hemisphere dwarf minke whale. The dwarf minke whale is genetically closer to the North Atlantic than to the North Pacific form.

The common name comes from Norway. One story has it that a hapless whale spotter named Meincke identified a minke whale as a blue whale and thereafter small rorquals were called "Minkie's whale." Other common names that have been applied to the minke whales include "lesser rorqual," "little piked whale," "sharp-headed finner," and "lesser finback." Somewhat confusingly, the Antarctic minke is also called "ordinary minke whale" in IWC literature.

In both species, the rostrum is very narrow and pointed and there is a single ridge on the head. The dorsal fin is relatively tall and falcate and is located relatively far forward on the posterior one-third of the body (in comparison to the larger rorquals). The average length of the common minke whale in the North Atlantic at physical maturity has been estimated variously at about 8.5–8.8 m in females and 7.8–8.2 m in males (Horwood, 1990). One estimate for the North Pacific is 8.5 in females and 7.9 in males. Female Antarctic minke whales are estimated to average 9.0 m at maturity and males 8.5 m. The dwarf minke whale of the Southern Hemisphere is on average about 2 m shorter than the Antarctic minke whale (Kato and Fujise, 2000). The white flipper mark of the common minke whale extends up onto the shoulder in the dwarf subspecies of the Southern Hemisphere (Fig. 1). The BALEEN is white in the northern subspecies of the common minke whale but appears dark-gray or brown posteriorly in the dwarf subspecies due to a narrow dark fringe. In the Antarctic minke whale, the baleen plates are black on the left beyond the first few plates and on the right they are white in the first third and black in the rear two-thirds of the row. The baleen filaments in both species are coarser than in the sei whale but finer than in fin, blue, and bryde's whales, about 3.0 mm in diameter. The SKULL (Fig. 2) is larger in *B. bonaerensis* than in both northern and southern forms of *B. acutorostrata* (Fig. 3). The modal number of vertebrae in both species is about 49, ranging from 46 to 51.

II. Distribution and Ecology

In the North Atlantic, the common minke whale is found in summer as far north as Baffin Bay in the Canadian Arctic, Denmark Strait, and Svalbard in the Barents Sea (Brownell *et al.*, 2000). The wintering grounds are poorly known but extend at least to the Caribbean in the west and the Straits of Gibralter in the east. Affinities of minke whales reported from farther south to Senegal are unknown. In the North Pacific, the summer range extends to the Chukchi Sea. In the winter, common minke whales are found south to within 2° of the equator, although those south of central Baja California, Mexico, in the eastern North Pacific are of unknown relationship to the whales farther to the north. In the Southern Hemisphere, the distribution of the dwarf subspecies is poorly known. It extends as far north as 11°S in the western Pacific off Australia and 7°S off South America in the Atlantic nearly

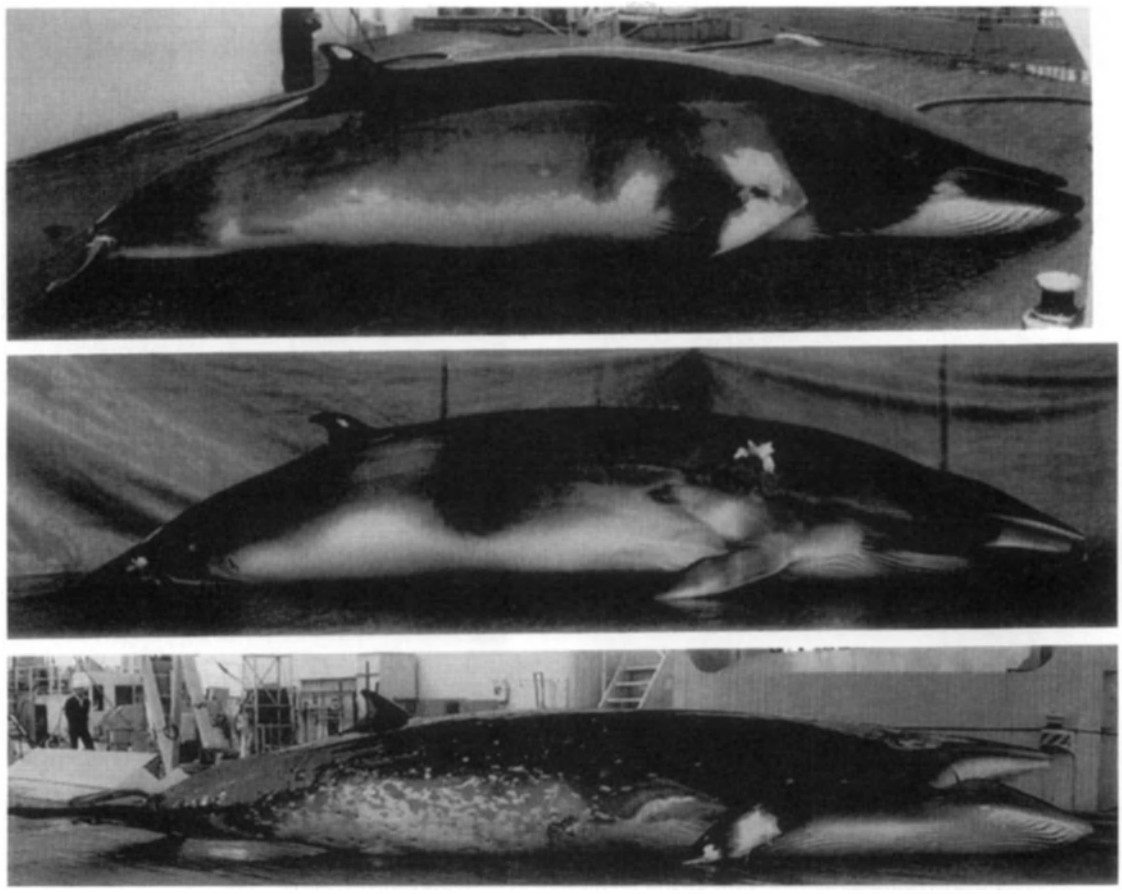

Figure 1 *(Top) Dwarf minke whale* (Balaenoptera acutorostrata *unnamed subspecies), (middle) Antarctic minke whale* (B. bonaerensis), *and (bottom) North Pacific minke whale* (B. acutorostrata scammoni). *Photos courtesy of Hidehiro Kato.*

year round. In the far south, it is seasonally sympatric with the Antarctic minke whale on the FEEDING grounds during austral summer and occurs off South Africa during the fall and winter. Where sympatric with the Antarctic minke whale, it tends to occur in shallower, more coastal waters over the continental shelf.

Antarctic minke whales are found from 55°S to the ice edge during the austral summer, some occurring in the loose ice pack. Some have been recorded to overwinter in the Antarctic. During the austral winter, most retreat to breeding grounds at midlatitudes: 10–30°S in the Pacific between 170°E and 100°W, off northeastern and eastern Australia, off western South Africa, and off the northeastern coast of Brazil. In these areas their distribution is primarily oceanic, beyond the continental shelf break. One specimen is known from Suriname in the Northern Hemisphere.

Both species of minke whales are catholic feeders but specialize with season and area. In the North Atlantic, reported diet items include sand lance, sand eel, salmon, capelin, mackerel, cod, coal fish, whiting, sprat, wolffish, dogfish, pollack, haddock, herring, euphausiids, and copepods (Stewart and Leatherwood, 1985); krill (euphausiids) are important off West Greenland, whereas capelin and cod are dominant prey in eastern Newfoundland. In the North Pacific, major food items include euphausiids, Japanese anchovy, Pacific saury, and walleye pollack. In the Antarctic, dwarf minke whales feed mainly on myctophid fishes but also on some euphausiids (Kato and Fujise, 2000), whereas Antarctic minke whales feed mainly on euphausiids.

Killer whales (*Orcinus orca*) prey on minke whales of both species. By one Russian estimate, Antarctic minke whales make up 85% of the diet of killer whales in the Southern Ocean (Stewart and Leatherwood, 1985).

III. Behavior and Life History

Common minke whales are noted for their curiosity about ships, often coming from afar to cross the bow or run with the vessel for minutes or hours. Their sudden appearance on the bow or alongside has startled many an observer. They are difficult to spot at a distance because of their small inconspicuous blow and brief surfacing behavior. Antarctic minke whales are reported to be easily approachable while feeding. Dwarf minke whales in the Great Barrier Reef region of eastern Australia readily approach and stay with divers and are the subject of a WHALE-WATCHING tourist operation.

Single animals are often seen and groups are usually small, consisting of two or three individuals, although larger aggregations of up to 400 may form on occasion in high latitudes.

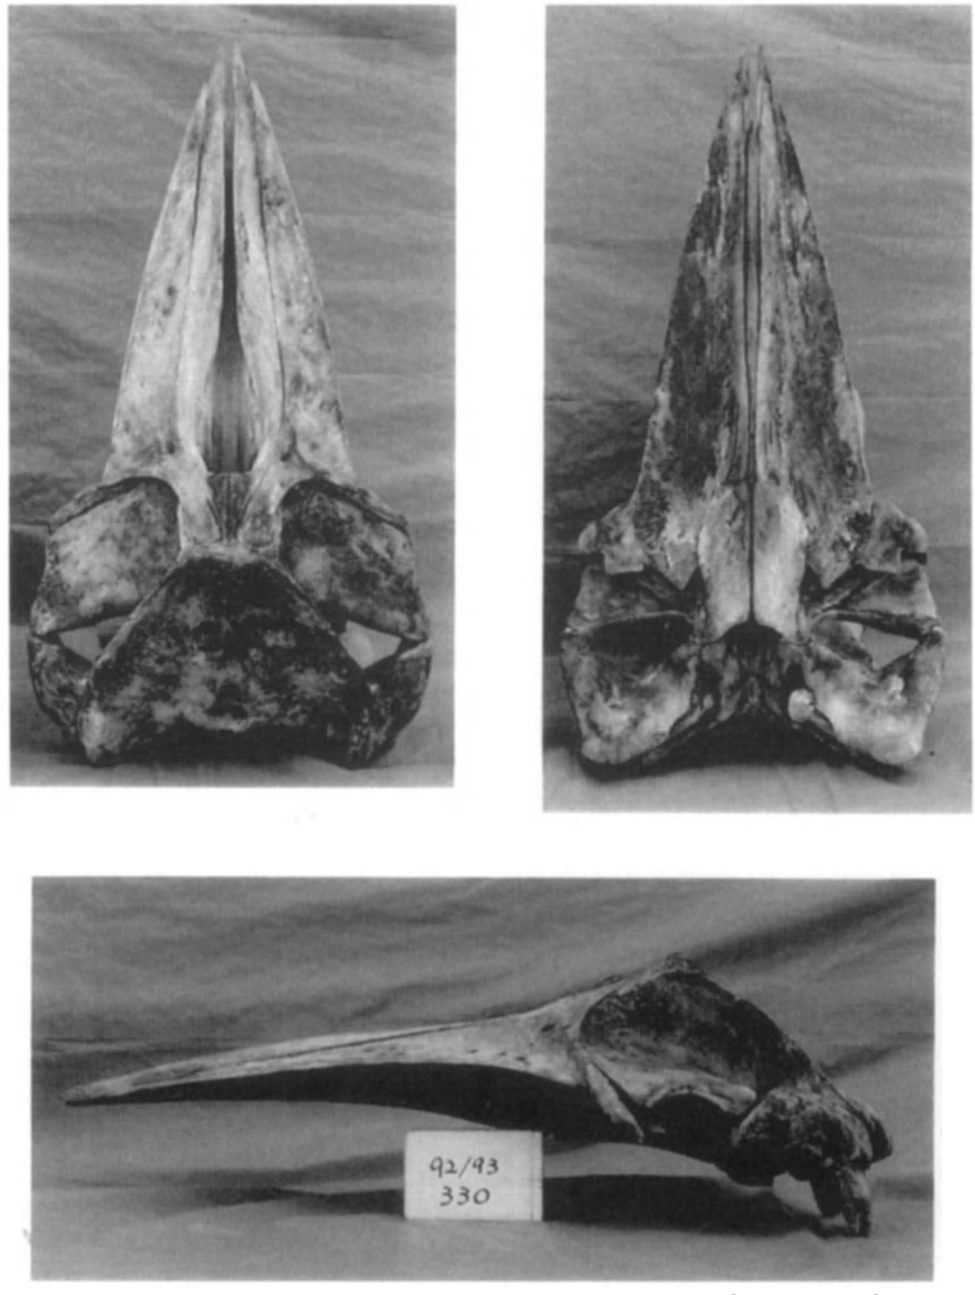

Figure 2 *Dorsal (left), ventral (right), and lateral views of a skull of a dwarf minke whale* (Balaenoptera acutorostrata *unnamed subspecies). Photos from Kato and Fujise (2000).*

Minke whale sounds recorded in the North Atlantic included grunts, thumps, and frequency downsweeps ranging to 200 Hz. Similar downsweeps have been recorded in the Ross Sea (Stewart and Leatherwood, 1985).

Differential migration by sex and age leads to segregation by sex and breeding condition. Mating behavior has not been directly observed. Breeding is diffusely seasonal in the common minke whale in the Northern Hemisphere, with calves of 2.4–2.7 m appearing approximately 10 months after conception. Lactation lasts 45 months. Age at attainment of sexual maturity has been estimated at about 7 years in males and 6 years in females. The pregnancy rate among adult females in some populations approaches 100%, suggesting an annual reproductive cycle. Little is known of the life history of the dwarf minke whale, but limited data available suggest similarity with that of the northern forms. The Antarctic minke whale also exhibits similar life history parameters (Horwood, 1990). Age at attainment of sexual maturity is 8 years in males and 7 to 8 years in females (although it may have been higher when overall whale densities were much higher earlier in the 20th century). Preg-

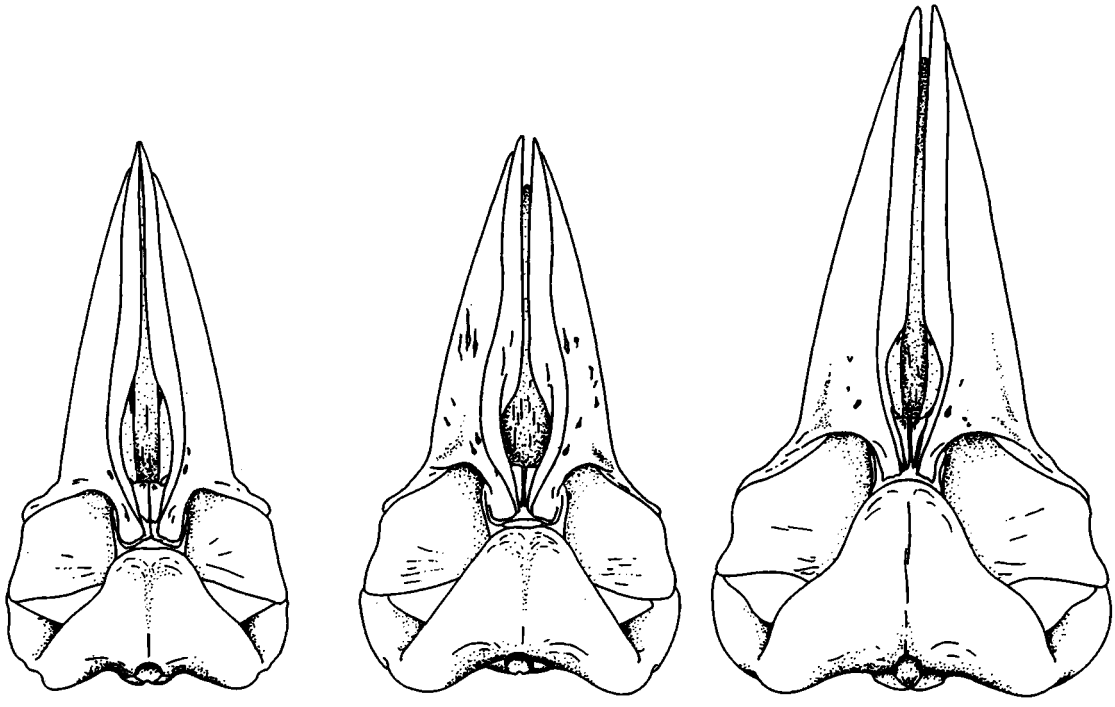

Figure 3 *Dorsal views of skulls (left to right) North Pacific minke whale* (Balaenoptera acutorostrata scammoni), *dwarf minke whale* (B. acutorostrata *unnamed subspecies*), *and Antarctic minke whale* (B. bonaerensis). *Figure from Kato and Fujise (2000).*

nancy rates remain at or near 90% for most of the year, again suggesting an annual cycle on average. Peak births are in July and August. During the feeding season, mature females are found closer to the ice than immature females, and immature males are more solitary than mature males.

IV. Conservation Status

The minke whales in the Southern Ocean were largely ignored in the early days of modern industrialized whaling because of their small size, but as the larger rorquals (blue, fin, and sei) were successively depleted, attention turned to the still abundant minkes in the early 1970s. After 1979, only minke whales were allowed by the IWC to be taken in factory-ship operations. Annual catches in the Antarctic ranged to about 8000 (details on all world catches are given in Horwood, 1990) by Japan and the USSR. Hundreds were also taken from land stations in Brazil and small numbers in South Africa. As of the 1985/1986 Antarctic season, all commercial whaling was banned under an IWC moratorium. Minke whale stocks in the Southern Hemisphere have been thought to be still in good condition and stable, with estimates (both species combined) in the neighborhood of 750,000. However, the results of most recent surveys have thrown these estimates into doubt; the estimates have been abandoned and a new assessment is planned for the year 2001 (IWC, 2001). Meanwhile, Japan has continued to take over 400 Antarctic minke whales annually under a research permit issued under the terms of the whaling convention.

Common minke whales have also been exploited commercially in the North Pacific and North Atlantic, in both land-based and pelagic whaling operations. Some stocks were depleted and became fully protected under IWC regulations, including the west Greenland, northeastern North Atlantic, and Sea of Japan–Yellow Sea–east China Sea stocks. The main whaling nations involved were Norway and Japan, with catches also by Korea, China, and the USSR. Catches from land stations in Japan continued until 1987. In the late 1990s, Norway recommenced commercial whaling on minke whales in the North Atlantic under an objection to the 1986 moratorium; the take in 2000 was 487 out of a self-imposed quota of 655. In the North Pacific, Japan began taking minke whales under a scientific research permit in 1994; the nationally established limit for 2000 was 100 animals [together with 50 Bryde's whales and 10 sperm whales (*Physeter macrocephalus*)].

Aboriginal subsistence whaling is exempt from the IWC moratorium on commercial whaling, and localized whaling for North Atlantic minke whales has continued under this provision in west Greenland. In 1999, 165 minke whales were landed. The impact of this whale fishery on the west Greenland stock is not known.

In summary, most minke whale stocks are in better condition than most stocks of the other large whales, but questions remain about the status of some populations and the effects of continued whaling.

Molecular Ecology

A. Rus Hoelzel

University of Durham, United Kingdom

From a practical point of view, molecular ecology broadly refers to ecological studies that employ the tools of molecular biology. However, studies in this young field are often more specifically about the genetic diversity and structure of populations in an ecological context. Just as behavioral ecology explores the evolutionary consequences of the interaction between organisms and their environment from a behavioral perspective, molecular ecology explores the same interaction in the context of gene flow, genetic drift, and natural selection. Mammals in the marine environment have adapted to the challenges of aquatic life with some dramatic changes in anatomy, physiology, and BEHAVIOR. This is especially relevant to molecular ecology when characteristics of the marine habitat, or behavior enabled by these adaptations, affect patterns of dispersal, reproductive behavior, and demographics.

For example, while many cetacean species can move great distances and have broad tolerance for different habitats with respect to breeding and foraging, pinnipeds are tied to suitable terrestrial habitat for breeding (e.g., isolated from predators), but must forage at sea. Characteristics of the resource exploited by pinnipeds mean that some populations can forage near breeding grounds, whereas others must travel great distances in search of prey. Resources can also limit the distribution of suitable breeding grounds. These factors affect population genetic diversity and structure through an impact on dispersal range and the "effective size" of populations. The effective population size (N_e) is the size of an ideal population (with random mating and unaffected by processes such as mutation and selection) that would show the same rate of decay in genetic diversity as the observed population. Population size can be very large at a breeding colony where the resource is local and abundant (and therefore genetic diversity can be high), as seen especially for some otariid species. Phocid seals, however, often travel great distances on foraging excursions, and breeding colonies are often smaller than for otariids.

Genetic diversity decays more quickly over time in populations with smaller effective population size. Within populations, reproductive strategy can impact the level of diversity, as reproductive skew (such as polygynous mating) reduces N_e. The potential for polygyny has been suggested to depend on various aspects of resource exploitation and, in pinnipeds, on the consequences this has for the clumping of females (see Boness, 1991). If females are clumped and not too synchronous in estrus, males can monopolize the mating of multiple females, to the exclusion of other males (polygyny). Most of the otariid species are polygynous, but only a few of the phocid seals.

Another important factor influencing genetic diversity is demographic history, especially for species that have been the subject of intensive hunting (e.g., the right whales *Eubalaena* spp., gray whale *Eschrichtius robustus,* bowhead whale *Balaena mysticetus,* sea otter *Enhydra lutris,* and numerous species of pinnipeds). Elephant seals provide a good illustration of both the potential role of polygyny and the impact of excessive hunting on the loss of genetic diversity. There are two closely related species, the northern (*Mirounga angustirostris*) and southern (*M. leonina*) elephant seal. Behavioral and genetic studies have shown that these species are among the most polygynous of mammals (e.g., see LeBoeuf, 1972; Hoelzel *et al.,* 1999).

In the 19th century, elephant seals were exploited heavily for their blubber in both hemispheres. The southern species retained relatively large population numbers, but the more accessible northern species was forced through a severe population bottleneck (Bartholemew and Hubbs, 1960; Hoelzel *et al.,* 1993). Molecular genetic variation in the northern elephant seal is now low at mtDNA, allozyme, immune system, and repetitive DNA loci (see review in Hoelzel, 1999), consistent with predictions based on simulation models, given the severity of the bottleneck (Hoelzel *et al.,* 1993; Hoelzel, 1999). By comparing post-population-bottleneck genetic diversity with

demographic simulation models and historic data, Hoelzel *et al.* (1993) estimated the severity of the population bottleneck to be less than 30 seals over a 20-year period, or a single-year bottleneck of less than 20 seals.

Simulation studies illustrate the role of polygyny in further reducing genetic variation during the period of recovery (Hoelzel, 1999). A survey of 54 allozyme loci at an average of 99 individuals per locus revealed no variation (Bonnell and Selander, 1972; Hoelzel *et al.*, 1993). The estimated bottleneck of 20 seals would not have been sufficient to eliminate variation at these loci in a monogomous species, but polygynous mating results in high variance in male reproductive success, which increases the impact on diversity. The reason is simply that relatively few males are contributing to the gene pool. Figure 1 illustrates how a bottleneck of less than 20 seals can account for the loss of allozyme diversity when the observed level of polygyny is taken into account. Only those simulations based on polygynous mating (Fig. 1, open bars) predict a level of post-bottleneck diversity that is low enough to be consistent with the measured levels of diversity.

Dispersal (and hence gene flow) among populations can be restricted by geographic barriers (such as continents) or by habitat specialization and energetic considerations. However, some marine mammal species exhibit dispersal over vast distances. For example, the sperm whale (*Physeter macrocephalus*) shows little genetic variation even among different ocean basins (Lyrholm *et al.*, 1999). Other species have been shown to be composed of geographically isolated populations that are differentiated genetically, such as Pacific vs Atlantic populations of humpback whales (*Megaptera novaeangliae;* Baker *et al.*, 1994)

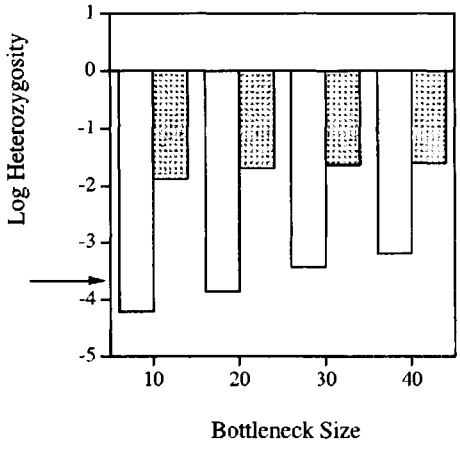

Figure 1 *This chart illustrates for the northern elephant seal the predicted impact of population bottlenecks of various sizes (along the* x *axis) on a measure of genetic diversity (heterozygosity) following the bottleneck. Shaded bars are based on simulations that assume monogamous mating, whereas open bars are based on simulations assuming observed levels of polygyny. No allozyme heterozygosity was found in the modern population, but the arrow indicates the average heterozygosity that would have been seen if just one individual had been heterozygous at just one locus (after Hoelzel, 1999).*

and walruses (*Odobenus rosmarus;* Cronin *et al.*, 1994). This "allopatric" pattern of differentiation is common among both marine and terrestrial species. What is more unusual, but perhaps quite important for the evolution of population structure in marine mammals, is the partitioning of the environment in a way that shows differentiation among sympatric (living in the same geographic region) and parapatric (neighboring regions) populations. This can happen when populations that differentiated in allopatry come back together or by processes that lead to choosing particular mates in preference to others ("assortative mating") in sympatry.

One mechanism for differentiation in sympatry is called "resource specialization" and has been described in detail for various terrestrial and aquatic species (see Smith and Skulason, 1996). It means that individuals of a species specialize on habitat or prey choice. Note, however, that these specializations can only lead to genetic differentiation if they also lead to assortative mating. Various studies show genetic differentiation between resource specialists in dolphin species. For example, the killer whale (*Orcinus orca*, the largest dolphin) travels in highly stable social groups (called pods). Pods, and populations of pods, tend to specialize on prey resources, with some focusing on marine mammal prey and others on fish prey. Sympatric populations of marine mammal and fish specialists in the eastern North Pacific were found to be differentiated genetically (Hoelzel and Dover, 1991; Hoelzel *et al.*, 1998a). The level of differentiation was great enough to suggest the possibility of two "cryptic" (morphologically indistinguishable) killer whale species, differing especially in foraging behavior. However, a global survey of genetic diversity did not support that interpretation (Hoelzel and Dover, 1991; A. R. Hoelzel *et al.*, unpublished results).

A number of dolphin species inhabit both coastal and offshore environments, which can differ with respect to the type and distribution of potential prey. Especially in regions where there is upwelling, the habitat in the marine littoral zone can be very different from the offshore habitat. Several studies of nearshore and offshore dolphin populations indicate intraspecific morphological and, in some cases, genetic distinctions. For example, nearshore and offshore forms of the pantropical spotted dolphin (*Stenella attenuata*) can be distinguished by tooth and jaw structure (Douglas *et al.*, 1984), and the Atlantic spotted dolphin (*S. frontalis*) is also found in nearshore and offshore populations. Two species of common dolphin (*Delphinus delphus* and *D. capensis*) have been classified by the length of the beak. In this case, ranges overlap, and both forms are sometimes found in the nearshore habitat. Rosel *et al.* (1994) found genetic differentiation between these forms.

The best-known example is that of the common bottlenose dolphin (*Tursiops truncatus*), which occurs in coastal and offshore populations throughout its range. In the eastern North Pacific, nearshore and offshore forms were originally classified as two different species—*T. gilli* (the nearshore form) and *T. nuuanu*—through a reappraisal recognizing extensive overlap in morphotypes later reclassified both as *T. truncatus*. In the western North Atlantic the nearshore and offshore forms have been described in some detail and show both morphometric (Mead and Potter, 1995) and genetic differentiation (Hoelzel *et al.*, 1998b). There were consistent differences between the two

types in feeding behavior, with the nearshore form feeding primarily on coastal fish, whereas the offshore form concentrated on deep-water squid (Mead and Potter, 1995). The genetic distinction indicated low levels of gene flow (or no gene flow in the recent past) between the two populations (Hoelzel *et al.*, 1998b).

Marine mammals are highly mobile and, in many cases, show seasonal differences in DISTRIBUTION, such as the annual migration between breeding and feeding sites seen in baleen whales. This is an important consideration for the identification of populations for protection and MANAGEMENT, especially when breeding "stocks" mix on feeding grounds where they may be hunted (see review in Hoelzel, 1998). For example, common minke whale (*Balaenoptera acutorostrata*) populations on either side of Japan (off Korean and in the western North Pacific) are differentiated genetically at both allozyme (Wada, 1991) and mtDNA loci (Goto and Pastene, 1996). Both studies found evidence of seasonal mixing on feeding grounds to the north in the Okhotsk Sea. In another example involving minke whales, in this case the Antarctic species, *B. bonaerensis*, a temporal mixing of two genetically differentiated populations from Antarctic management areas IV and V was described based on mtDNA variation (Pastene *et al.*, 1996).

In general, the pattern and degree of genetic differentiation among populations are not predicted easily by geographic patterns for marine mammal species and instead depend on a complex interaction between life history and habitat. Even for the highly mobile and pelagic species, such as the minke whales, there can be considerable genetic differentiation among regional populations and, for some species (such as the killer whale), among populations in sympatry. What we know of the molecular ecology of these species emphasizes the need for more data and a careful consideration of the mechanisms affecting patterns of diversity within and among populations.

Monk Seals

Monachus monachus, *M. tropicalis*, and *M. schauinslandi*

WILLIAM G. GILMARTIN
Hawaii Wildlife Fund, Volcano, Hawaii

JAUME FORCADA
Southwest Fisheries Science Center, La Jolla, California

The genus *Monachus* includes two endangered phocid species that live in the world's tropical and subtropical seas of the Northern Hemisphere: the Mediterranean monk seal (*M. monachus*) and the Hawaiian monk seal (*M. schauinslandi*). The numbers of these reclusive seals and a

third species, the extinct Caribbean monk seal (*M. tropicalis*), once widely distributed around the Caribbean (Timm *et al.*, 1997) and last seen in 1952, have all declined due to killing by humans, habitat loss from coastal development and other activities, and prey resource competition with fisheries.

I. Characters and Taxonomy

Monk seals originated in the North Atlantic, with the Hawaiian species of probable Caribbean origin at least 15 million years ago across the Central American seaway. Unique among pinnipeds in some primitive, unspecialized skeletal and vascular anatomy, the Hawaiian monk seal is known as the "most primitive of living seals" (Repenning and Ray, 1977).

Mediterranean monk seals are uniformly black at birth with a conspicuous white ventral patch unique to each individual and distinct in shape by sex (Fig. 1). Newly molted seals of all ages are silvery gray dorsally and lighter ventrally, with the ventral patch pattern persisting through life. Juveniles have a medium to dark gray pelage, similar to that of adult females but with less COLORATION disruptions caused by scarring. Near the age of 4, adult males become almost uniformly black, with their white ventral patch; coloration in females is more variable, but not as dark as males dorsally and the ventral fur is also lighter. Adult males may also be slightly longer than females (Samaranch and González, 2000). Adult lengths are 2.3–2.8 m and weights are 240–300 kg.

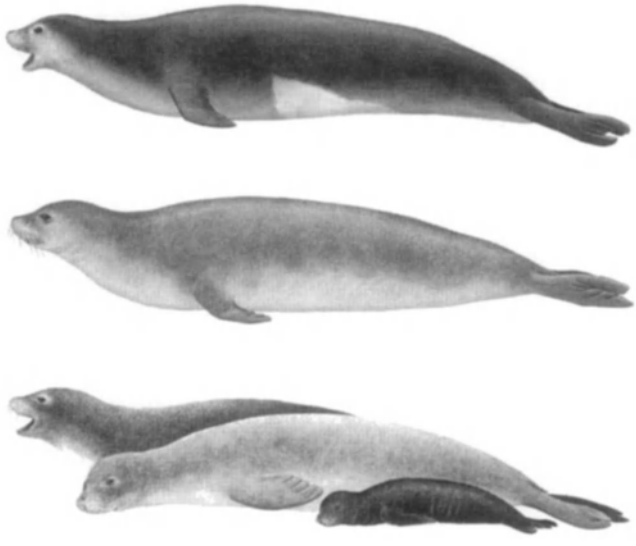

Figure 1 *Three species of monk seals once existed: today only two species survive. The two living species are widely separated geographically, the Mediterranean monk seal being in the Mediterranean* (Monachus monachus: *top) and the Hawaiian monk seal occurring in Hawaiian waters* (M. schauinslandi: *bottom). Interestingly, Mediterranean males are larger than conspecific females and Hawaiian males are smaller than conspecific females. The Caribbean monk seal* (M. tropicalis: *center) is now extinct and, as a result, little is known of its biology. (Pieter A. Folkens/Higher Porpoise DG).*

Hawaiian monk seals are also black at birth, with some showing small white patches at various sites. These seals are also silvery gray following molt, with the fur color changing in juveniles to a yellow brown prior to the next molt and darkening through the year in adults. Hawaiian seals show no differences in fur coloration by sex. Adult females may attain a slightly larger size than males. Adult lengths are 2.1–2.4 m and weights are 170–240 kg.

II. Distribution and Ecology

Historically, the Mediterranean monk seal inhabited the entire Mediterranean Basin and the southeastern North Atlantic, from the Azores Islands to near the equator. The current distribution is severely contracted and fragmented (Aguilar, 1999), with the largest population (ca. 250–300 seals) in the Eastern Mediterranean, on the islands in the Aegean and Ionian Seas, and along the coasts of Greece and Turkey. Only two breeding populations are known in the Atlantic, one at the Cap Blanc peninsula in the Western Sahara and Mauritania (ca. 100 seals) and a smaller group in the Desertas Islands at the Madeira Islands (ca. 20 seals). Sightings are rare now in other areas within the historical range.

Hawaiian monk seals occur only in the Central Pacific in the mostly uninhabited northwestern Hawaiian Islands. A small breeding population also inhabits the main Hawaiian Islands, and monk seals have been reported on rare occasions south of the Hawaiian Archipelago at Johnston Atoll, Wake Island, and Palmyra Atoll. Hawaiian monk seals have a high fidelity to their island of birth; only about 10% of seals born at any of the major breeding islands will move to another island during their life. Very low genetic diversity is also evident in this species, which now includes 1300–1400 individuals.

Both monk seal species consume a highly diverse diet of diurnally and nocturnally active fish, octopus, squid, and lobster (Marchessaux, 1989; Goodman-Lowe, 1999). Proportions of these prey species in the diet vary by location, season, and age of the seals. Although most of the prey species are benthic in the coral reef ecosystem, a few are pelagic. Hawaiian monk seals have a broad prey base of at least 40 species. They forage within their resident atolls and along the fringing reefs; at one site, where the population is food stressed, some individuals forage at reefs 60–200 km from their breeding islands. Foraging commonly occurs near the breeding atolls and at sea mounts to depths of 100 m.

III. Life History and Behavior

Both monk seal species have protracted reproductive seasons, and copulation occurs in the water (Kenyon and Rice, 1959; Marchessaux, 1989; Ragen and Lavigne, 1999). Some female Mediterranean monk seals may be reproductively active at 3 years and Hawaiian monk seals at 4 years. However, in the Hawaiian seal, the mean is perhaps 6–7 years and maturity is as late as 10–11 years in females at a site where prey abundance is low, showing nutritional status is a critical factor in maturation. Mediterranean monk seals give birth year round, but mostly in the summer through early winter months. Monk seal births in Hawaii usually occur from February to August, peaking in April–June, but births are known in all months. At

birth, Mediterranean monk seal pups weigh between 15 and 26 kg and gain weight fast during a suckling time of up to 4 months, with the females mixing feeding trips with pup attendance. Hawaiian monk seal pups are born at about 16 kg and are weaned at 6 weeks, after attaining a weight of 70–100 kg. Hawaiian females do not forage during the lactation period. After weaning, pups of both species survive on their fat reserves while they acquire prey-catching skills.

Females of both species have four functional mammary glands, and while they can give birth to single pups in consecutive years, they will also skip some years. Hawaiian females exhibit an average 381-day interval between annual births; thus these females give birth later each year until a year in which they do not give birth, and then they cycle earlier the following year. Some females give birth on a more interrupted schedule.

When Hawaiian monk seal female–pup pairs are near each other, accidental exchanges of the pups between the females can occur. Serious consequences result when the exchanged pups have suckled for very different times and are of very different size. The mothers will still wean their foster nursing pups after about 6 weeks of lactation, leaving one pup larger than normal size and one smaller, with the latter's survival chances highly compromised.

A mating tactic of some nondominant male Hawaiian monk seals is an attack by a group of these males (a few to over 20) on an adult female or an immature seal on some occasions. The attention of the dominant male in consort with the female becomes distracted by one or more of the challengers in the group, allowing the others to then breed with the female during bouts that may last over 3 hr in the water. The repeated and prolonged biting on the back of the female by males attempting copulation results in extensive trauma and tissue and fluid loss, often leading to her death. This detrimental behavior occurs primarily at seal colonies where the adult sex ratio is skewed toward males.

Mediterranean monk seals typically haul out to rest, molt, and give birth in protected sea caves throughout their range. They haul out on open beaches rarely, although this was believed to be a normal behavior for the species before the extensive exploitation of the last centuries. Hawaiian monk seals commonly haul out on open sandy beaches and will use rocky shorelines as well. Sea caves are rare in Hawaii.

Both the hair and the epidermis are sloughed and replaced during the annual molt in monk seals. This type of molt is similar to elephant seals, but unlike all other seals. In the Hawaiian monk seal the actual observed molting period is about 10 days, but based on an observed high proportion of time ashore before and after the hair–skin sloughing period, the entire physiological process is probably much longer.

The maximum known age for Mediterranean monk seals is 44 years and 30 years for a male Hawaiian seal.

IV. Conservation Status

Both living species of monk seals have been impacted greatly by human activities, from direct killing to competition for prey with fisheries and incidental disturbance of seals due to human presence on or near hauling and breeding beaches. Extinction of *M. tropicalis* in the 1950s and the international endangered status of the two remaining *Monachus* species result from this high sensitivity of the genus to direct and indirect human interactions.

The Mediterranean monk seal has been exploited since ancient times, and a significant decline in all of its range occurred in the second half of the 20th century. The total population was thought to be between 600 and 1000 individuals in the 1970s but at present is estimated at 350–450. Pup mortality increases sharply for Hawaiian monk seals when human beach use of a preferred habitat forces females to give birth at unsuitable pup-rearing sites (Kenyon, 1972; Gerrodette and Gilmartin, 1990). Both monk seals also interact with fisheries—bottomfish and longline hooks have been observed in Hawaiian seals, and Mediterranean seals have been entangled in active fishing gear and shot. ENTANGLEMENT in marine debris is a threat to both monk seals. Usually affecting pup and juveniles, the frequency of observations of entangled Hawaiian monk seals is increasing and, in many cases, where the debris is not removed, the seals are likely to be seriously injured or die.

Although the monk seal colony on the Western Sahara coast had been characterized by high adult survival rates, it also exhibited high pup mortality and very low recruitment, yet this colony had been considered the most viable population of the species. However, during May–July 1997, the size of this colony was tragically reduced by two-thirds due to a large-scale mass mortality event (Forcada *et al.*, 1999). The probable cause was a phytoplankton paralytic toxin; a morbillivirus was also implicated. The age structure of the surviving population was severely altered because juvenile mortality was insignificant compared to that of adults. This high mortality event severely compromised the recovery potential of the species in the Atlantic.

Hawaiian monk seal numbers have also been reduced due to human activities (Kenyon, 1972; Gerrodette and Gilmartin, 1990). Currently, however, all of the major breeding islands of the Hawaiian monk seal occur within federal and state government refuges where access is controlled and the foraging habitat is partially protected and managed to reduce fishery interactions (Wexler, 1993). The Hawaiian seal has a well-organized research and recovery effort, with guidance provided by a "recovery team" of scientists.

Recovery actions (Ragen and Lavigne, 1999) have included disentanglement of seals and two successful programs to enhance female survival. Underweight female pups were collected, rehabilitated, and then released back to the wild during the 1980s and early 1990s. In another effort, adult male seals that were killing females were captured and relocated to areas remote from the main breeding populations (Winning, 1998). Both projects contributed to population recovery in some colonies during the 1990s.

The remaining populations of both monk seal species are highly vulnerable to random catastrophic events such as die-offs due to introduced disease, the effects of inbreeding depression and low genetic variability, human disturbance, and competition with fisheries. The stability of the extant populations relies on high adult female survival rates. Fortunately, the Hawaiian monk seal population is moderately buffeted from anthropogenic pressures by the isolation and protected status of its major breeding habitat. The Mediterranean monk seal is not as fortunate. While a few protected areas have been established for the Mediterranean seal by Greece in the Aegean and by Portugal at the Desertas Islands in the Atlantic, only an im-

mediate and significant reduction in anthropogenic pressures on the Mediterranean species and a range-wide coordinated recovery effort will avoid its extinction in the 21st century.

Morphology, Functional

Christopher D. Marshall
University of Washington, Seattle

> Function [is] the dynamic aspect of structure—structure changing in time. —Picken

Functional morphology is a diverse field of biology that integrates anatomy, biomechanics, physiology, and behavior. It is the study of structure and its relationship with function; it is a way of viewing the world. The functional morphologist asks, "How does it work? The aquatic realm presents serious physical and physiological challenges for mammals. How mammals have overcome these challenges and adapted to the marine environment is the focus of marine mammal functional morphology. While our knowledge of the anatomy of marine mammals is extensive and continues to grow quickly, our understanding of the function of anatomical structures, organ systems, and functional complexes is incomplete. This article considers body size as an aquatic adaptation and then reviews major organ systems of marine mammals for which function is well established. Innovative solutions to aquatic challenges (i.e., buoyancy, thermoregulation, locomotion, diving, and feeding) are the focus. Because different groups have evolved different solutions for overcoming these challenges, this survey of marine mammal functional morphology is comparative in nature. Where appropriate, marine mammal function is contrasted with that of terrestrial mammals. Although the dog is one of the best known mammals anatomically, valuable comparisons can also be drawn using other subjects of veterinary anatomy, such as the horse and the ox.

"Marine mammal" is a general name for a diverse collection of nonrelated mammals that have returned to the sea for all or a portion of their lives. Generally, five groups of marine mammals are recognized: Cetacea (whales, dolphins, and porpoises), Pinnipedia (seals, sea lions, and walruses), Sirenia (manatees and dugongs), sea otters (Mustelidae), and polar bears (Ursidae). Only one ursid and two mustelids have exploited this habitat. Several mustelid species spend a majority of their time in freshwater, but only the sea otter (*Enydra lutra*) and the marine otter (*Lontra felina*) make the sea their primary habitat.

I. Body Size, Thermoregulation, and the Aquatic Environment

Thermoregulation is of utmost importance for marine mammals. Because the thermal conductivity of water is 25 times greater than air, marine mammals lose heat 25 times faster than terrestrial mammals. Like all mammals, marine mammals are warm-blooded and must maintain a constant body temperature. This can be a difficult task considering that many marine mammals inhabit the near-freezing waters of the polar oceans. One relatively simple solution to reduce heat loss is to increase body size. Large body size is advantageous because of the simple physical relationships among body size, surface area, and volume. As an animal gets larger and the linear body dimension (L_b) increases, surface area (SA) increases proportionally ($\propto$) to the second power, and volume (V) increases proportionally to the third power.

$$\text{a. } SA \propto L_b^2 \qquad \text{b. } V \propto L_b^3 \tag{1}$$

These relationships can be clearly demonstrated by the following example. Imagine that the body of an animal is represented by a cube with 2-cm edges. Such a cube has a surface area of 4 cm and a volume of 8 cm. If we double the dimensions of the cube (4-cm edges), the surface area of the new cube would be 4^2 cm^2 or 16 cm^2, and the volume would increase to 4^3 cm or 64 cm^3. Small animals have large SA to V ratios, whereas large

animals have a low SA:V. Heat is lost at the interface with the environment; a lower SA:V means lower heat loss. Compared to terrestrial mammals, marine mammals are large. Polar bears (*Ursus maritimus*) are the largest species in their family and sea otters are twice as large as their largest terrestrial relative. Aquatic life frees mammals from the constraints of gravity, allowing larger body sizes to be attained. Rorquals (whales of the family Balaenopteridae) have exploited this freedom; the blue whale (*Balaenoptera musculus*) is the largest living animal. In addition to increasing body size, marine mammals can decrease heat conduction through various adaptations of the integument and cardiovascular systems.

II. Integument System

The mammalian integument includes the skin, hair, associated glands (sebaceous and apocrine), claws, and digital pads. Mammalian skin is multifunctional. It provides protection from trauma and microbial intrusion, prevents desiccation, provides sensory information to the central nervous system (touch, pressure, vibration, temperature, and pain), and aids in thermoregulation.

A. Thermoregulatory Function of the Integument

The dense coat of hair (pelage) of mammals provides a layer of insulation. This adaptation is unique to mammals and has allowed them to move into cooler climates and to be active at night. Most mammals have two insulative types of hair: overlying guard hairs and an underlying layer of fine hair often called woolly hair (underfur). Hair keeps mammals warm by trapping and maintaining a layer of air close to the skin. Muscles spanning from the epidermis to guard hair follicles (arrector pilli muscles) can raise or lower the hair shaft, altering the thickness of the trapped air layer. The insulative power of the pelage is correlated with fur depth and hair density. As we have seen, heat loss or heat conduction (Q) is related to surface area. It is also related to the difference between body and environmental temperatures, and the physical material that heat must pass through (e.g., skin or air). The thicker the insulating layer (e.g., fur depth), the lower the heat loss. These relationships are summarized by the following equation:

$$Q = K\,SA[(T_b - T_e)]/L \qquad (2)$$

where SA is surface area, T_b is body temperature, T_e is environmental temperature, L is the distance between T_b and T_e, and k is the thermal conductivity constant of the material heat is being transferred through (e.g., skin and air). Thermal conductivity is simply a measurement of how easily heat flows through a material. Increasing fur depth effectively increases the distance (L) between T_b and T_e, which slows heat loss.

To be an effective insulator, hair must be kept dry. This is accomplished by a thin coating of oil on the hair shafts. The oil is secreted by sebaceous glands at the base of each hair follicle. The dense guard hairs and large amount of oil on the pelage of marine mammals maintain a layer of air even when an animal is completely submerged. The sea otter's pelage is mostly a dense undercoat with relatively few guard hairs; groups of 60–80 underfur hairs surround each guard hair (Kenyon, 1969). It is also the densest pelage of any mammal, approximately 130,000 hairs/cm^2, but ranging as high as 164,000 hairs/cm^2 on certain regions of the body. Its sebaceous glands secrete squalene (a lipid) instead of oil, which repels water more effectively. Frequent grooming is necessary to maintain the insulative properties of the pelage. Fur seals also have a dense, nonwettable pelage; hair density of the northern fur seal (*Callorhinus ursinus*) ranges up to 60,000 hairs/cm^2. The hair density of cats, dogs, and humans is 16,000 to 32,000 hairs/cm^2, 200–9000 hairs/cm^2, and 100,000 total, respectively. Sea otters and fur seals are particularly susceptible to oil spills. Oil penetrates to the skin, which results in loss of the thermal air layer.

To increase streamlining and reduce drag, some marine mammals have secondarily lost their hair and rely on blubber for thermoregulation. BLUBBER is simply the enlargement of the hypodermis and associated adipose tissue. The insulation provided by blubber is lower than fur; fat transmits heat three to five times faster than a dry, high-quality pelage (Schmidt-Nielsen, 1990). According to Eq. (2), Q can also be reduced by increasing the distance (L) between T_b and T_e, by changing k, or both. The insulative properties of blubber depend strongly on both thickness and lipid content. Blubber can be quite thick. Right whale (*Eubalaena* spp.) blubber can be as thick as 50 cm in some regions (Slijper, 1962). Thick blubber increases the distance between the body cavity and the water. The percentage of lipid content of the adipose tissue is seasonally variable and species specific, but can vary between 9 and 82% of wet blubber weight. Increasing the lipid content of the blubber (which is independent of blubber thickness) effectively changes the thermal conductivity constant (k).

B. Modification of the Integument to Reduce Drag

Seawater is 60 times more viscous than air and its density is three orders of magnitude greater. The increased viscosity and density of seawater resists movement through it; this resistance is called drag. The integument of marine mammals is designed to reduce drag. Energy saved by this reduction can be used for other activities, such as feeding and reproducing. Alternatively, reduced drag may allow individuals to swim faster or further for the same amount of invested energy. There are two types of drag to consider: frictional and inertial. Frictional drag occurs as fluid moves past the body. Water in contact with the skin or hair does not move; this region is called the boundary layer (Vogel, 1994). The fluid above this layer is forced to shear or slide past the boundary layer. A gradient is created in which thin layers of fluid move at different speeds around the body. Layers further away from the boundary layer move faster than those close to it. Frictional drag is proportional to the surface area in contact with the water. Marine mammals with hair usually lack arrector pilli muscles. This may allow their hair to lie flatter (although with some loss of thermal protection), which would create a smoother, low-drag profile compared to terrestrial mammals that swim (e.g., muskrats, *Ondatra* spp.). To decrease frictional drag further, some marine mammals have secondarily lost their hair. Smooth surfaces create less frictional

drag than rough surfaces. The exceptionally smooth skin in some marine mammals is accomplished by high turnover rates of outer cell layers. The bottlenose dolphin (*Tursiops truncatus*) replaces the outermost epidermal cells every 2 hr. This high turnover rate also keeps the surface free of algae, barnacles, and other settling organisms. As marine mammals move through the water, pressure is generated. This pressure generates another form of drag, inertial drag. Water pressure is highest near the head and lowest at the widest point of the body. Fluid flows from areas of high pressure to low pressure. Fluid departs the body at the widest point and results in a wake trailing the animal. The size of the wake is proportional to the amount of inertial drag generated. Inertial drag can be reduced by delaying the departure of the fluid from the body for as long as possible. This is accomplished by a streamlined, fusiform body. This shape results in a smaller wake and therefore a smaller inertial drag. Blubber is important in STREAMLINING and sculpting the contour of body shape. The goal of body sculpting is to reduce both types of drag.

C. Buoyancy Function of the Integument

A thick, dense, insulating pelage has the disadvantage of being buoyant. Increased buoyancy is also a potential problem associated with thick blubber. Materials that are less dense than water (blubber, lungs) float, whereas materials that more dense than water (bone, muscle) sink. Archimedes' principle states: the buoyant force on a body immersed in fluid is equal to the weight of the fluid displaced by that object. If body weight is less than the weight of displaced water, then the animal experiences an upward force, buoyancy (B). If body weight is greater than the weight of displaced water, then the animal experiences a downward force, gravity, and sinks. Proper buoyancy is critical to survival. The relationship between tissue density and weight of displaced water is shown by the expression:

$$B = (\rho_b - \rho_w)Vg, \tag{3}$$

where ρ_b is density of the body, ρ_w is density of water, V is volume of the body, and g is the force of gravity. Marine mammals are generally more dense than water and tend to sink. They can alter their buoyancy by altering ρ_b. Buoyancy can be increased by a reduction of the density of heavy materials (e.g., bone), an increase in the volume of organs that are less dense than seawater (e.g., lungs), or some combination thereof. The integument of marine mammals that use blubber for insulation may impose an additional buoyant force on the animal because blubber is less dense than seawater. It has been shown that air trapped by pelage imposes an additional buoyant force in an aquatic opossum (*Chironectes minimus*). Sea otters likely experience a buoyant force from their pelage as well. Energy not expended toward maintaining neutral buoyancy can be used for other activities. Preliminary evidence for sirenian integument suggests that it may be heavier than water and may function as ballast.

III. Musculoskeletal System

The musculoskeletal system is responsible for movement of the body. It consists of muscle, bone, tendons, ligaments, and joints. It is of primary importance in locomotion, feeding, and respiration. It also provides support and protection for internal organs and aids in sculpting the shape of the body. Marine mammals locomote in diverse ways, which is reflected in the design and adaptations of their musculoskeletal system.

A. Leverage

Muscles are contractile elements that are attached to bones and cross bony joints by tendons; shortening of muscles produces movement at the joint. This design is based on leverage. Levers are simple devices that transmit forces from one place to another using a pivot. For example, a person might want to move a large rock that is too heavy to pick up. With the aid of a rigid beam and a smaller rock, one could build a simple lever by placing the tip of the beam under the large rock and pivoting the beam on top of the small rock. The large rock can be moved by imposing force on the beam at the end opposite to the rock. This force is known as the in force (F_{in}), the small rock is the fulcrum, and the force generated to move the load is the out force (F_{out}). The distance between the fulcrum and the in force is the in-lever arm (L_{in}), and the distance between the fulcrum and the load is the out-lever arm (L_{out}). The directions of F_{in} and F_{out} are called the lines of action. In the simplest case, the lines of action of F_{in} and F_{out} are parallel to each other and at right angles to the lever. Torque (τ) is the rotational movement of the lever. It is the product of a force and its lever arm; therefore, each lever has an in torque and an out torque:

$$\text{a. } \tau_{in} = F_{in}L_{in} \qquad \text{b. } \tau_{out} = F_{out}L_{out} \tag{4}$$

When $F_{out}L_{out} = F_{in}L_{in}$, no motion occurs. If $F_{out}L_{out} > F_{in}L_{in}$, the direction of the force is toward F_{out} and the load is moved. If $F_{out}L_{out} < F_{in}L_{in}$, the direction of the lever moves toward F_{in}. Changes in the distance between the fulcrum and the load change the effort needed to move the rock. Mechanical advantage (MA) is the ratio of the in-lever arm to out-lever arm and also the ratio of the out force to the in force:

$$MA = L_{in}/L_{out} = F_{out}/F_{in} \tag{5}$$

The SI (Système Internationale) unit for force is the newton (N). A lever system in which a F_{in} of 5 N results in a F_{out} of 10 N would have a mechanical advantage of 10/5 or 2. Greater mechanical advantage is attained with levers that have a long L_{in} and short L_{out}. Consider the forelimb (Fig. 1), which extends by the contraction of the triceps. The triceps spans posteriorly from the scapula and humerus (arm), across the joint of the proximal limb to a bony process of the forearm (ulna) called the olecranon. The contraction of the triceps contributes the F_{in}, the joint is the fulcrum, the olecranon process is the in lever, and the forearm is the out lever. Notice that the length of the olecranon (L_{in}) is longer and the forelimb is shorter (L_{out}) in the sea lion compared to the dog (Fig. 1). Another component to levers is velocity (v). Each lever arm possesses a velocity (v_{in} and v_{out}). The length of the lever arms influences the velocity such that $v_{in}L_{out} = v_{out}L_{in}$. This is the opposite of the force-lever arm relationship ($F_{out}L_{out} = F_{in}L_{in}$). Therefore, animals that can flex their distal limbs quickly (a high v_{out}) must

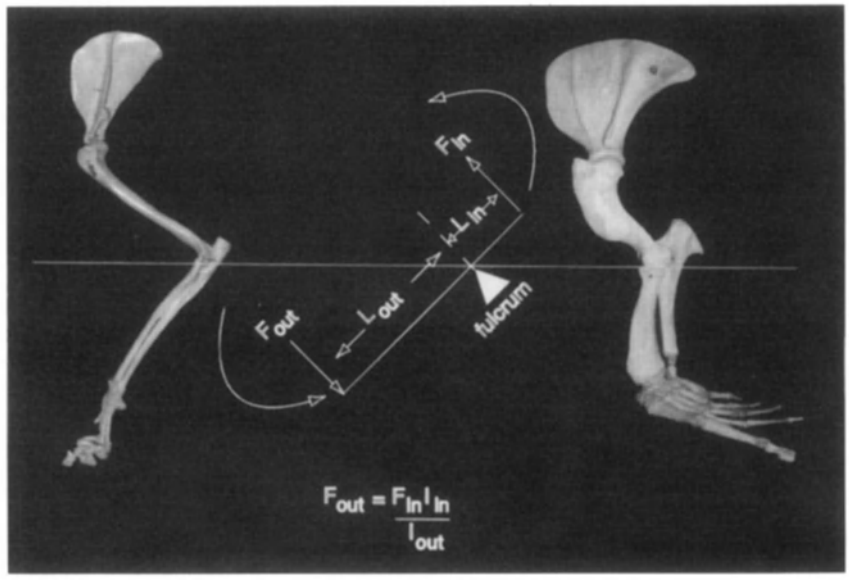

Figure 1 *Forelimb lever. (Left) Forelimb of a dog. (Right) Forelimb of a Steller sea lion* (Eumetopias jubatus). *The horizontal line indicates the pivot point or fulcrum in both forelimbs. The humerus (arm) lies just above the line. The ulna and radius of the forearm lie just below the line. Note the difference in length of the in-lever arm between the dog and the sea lion.*

possess a short L_{in}. However, this reduces mechanical advantage, which increases with increasing L_{in}. There is a trade-off between mechanical advantage and velocity. Associated structures of the musculoskeletal system such as sesamoid bones, bursae, and synovial tendon sheaths function to increase the surface area of attachments, protect tendons that pass over bony prominences, redirect contractile forces for greater effective applied force during movement, and reduce friction at joints.

B. Locomotion

The postcranial skeleton consists of the vertebral column (axial skeleton) and appendages (appendicular skeleton). The skeletons and musculature of cetaceans and sirenians have been modified greatly compared to the dog (Howell, 1930; Slijper, 1962, Evans, 1993; Rommel, 1990; Domning, 1977, 1978; Pabst, 1993, 1999). The sacrum, sacral vertebrae, and hindlimbs have been lost and only rudiments of the pelvis remain. The forelimbs are modified hydrofoils (wings) that assist in aquatic locomotion. Pinnipeds still possess hindlimbs, but differences occur between the more aquatically adapted phocids (seals, family Phocidae) and otariids (sea lions, family Otariidae). Compared to other marine mammals, polar bears and sea otters have not modified their limbs greatly.

Thrust is an important function of the postcranial musculoskeletal system; it can be increased by generating large in forces (F_{in}) and high mechanical advantage. A larger F_{in} can be obtained by increasing the number of muscle fibers in parallel; the force that a muscle can produce is directly proportional to its cross-sectional area. In obligate marine mammals such as cetaceans and sirenians, thrust is primarily generated by oscillation of their axial skeleton. The remaining marine mammals generate thrust in water with their appendages. Otariids locomote using their forelimbs whereas phocids and sea otters generally use their hindlimbs. Walruses (*Odobenus rosmarus*) and polar bears use all four limbs to produce thrust.

The vertebral column of cetaceans is similar to that of the dog with several modifications. The cervical vertebrae are compressed anterioposteriorly; normally the first and second vertebrae, if not all cervical vertebrae, are fused. This compression shortens the neck and aids in streamlining the body. The cervical and thoracic vertebrae of cetaceans are greater in height (dorsoventral) than in length (anterioposterior), which stiffens the anterior body. The lumbar and caudal vertebrae are longer than they are high, which allows a greater range of motion in the dorsal–ventral direction. The lower vertebral column functions as a variably flexible beam that is bent dorsally by epaxial muscles and ventrally by hypaxial and abdominal muscles. Some marine mammals have modified the spines of their vertebrae (Figs. 2A–2C). Compared to the dog, the spinous and transverse processes of cetacean thoracic and lumbar vertebrae are long, which increases the surface area for the attachment of large epaxial and hypaxial muscles (Fig. 2B) and increases mechanical advantage. Only the transverse processes of sirenian lumbar (Fig. 2C) and caudal vertebrae are enlarged; their vertebral column likely functions in a manner similar to cetaceans, but with decreased power and a smaller range of motion.

Flukes at the end of the vertebral column deliver forces produced by muscles to the water, whereas the dorsal and pectoral fins are used for stability and maneuverability. Fins, flippers, and flukes can be thought of as hydrofoils (Vogel, 1994). They are streamlined in cross section. The rounded leading edge

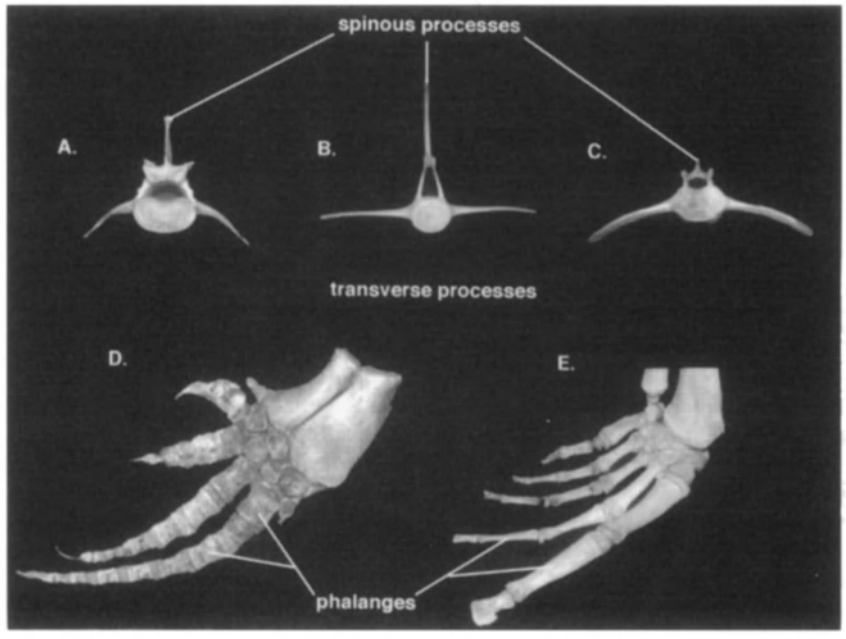

Figure 2 *Vertebrae and flippers. Lumbar vertebra of a dog (A), bottlenose dolphin (B), and a West Indian manatee (C). Note the length of the spinous and transverse processes. Note that the increase in flipper length is achieved by hyperphalangy in the dolphin and elongation of the phalangeal bones in the sea lion.*

tapers to a trailing edge much like an airplane wing. The dorsal fins and flukes are not supported by skeletal elements. However, the pectoral fins of cetaceans and the flippers of other marine mammals are supported by bones of the forelimb and manus (hand). The bones of the forelimb are flat and form the basis of the pectoral fin shape; the radius is located on the leading edge of the flipper and the ulna on the trailing edge (Figs. 2D and 2E). The aspect ratio (AR) is the ratio of the length of the fin (span) to its width (cord) parallel to the fluid flow. The AR of the fin affects the magnitude of lift and drag forces produced. Hydrofoils with a high AR produce large lift forces with minimal drag forces, whereas low AR hydrofoils produce small lift forces and greater drag. Dolphins have a moderate-to-high AR relative to other aquatic vertebrates, a design that may lower the energetic cost of swimming. The high AR in dolphins is accomplished by elongation of the manus by hyperphalangy (increased number of phalanges or finger bones per digit; Fig. 2D), which is unusual among mammals. The bones of the manus and the forelimb are encased in connective tissue and skin and are relatively immobile. The mobility of the entire pectoral fin varies among cetaceans. For example, bottlenose dolphins have relatively immobile flippers that maintain stability during locomotion, whereas the long pectoral fins of humpback whales (*Megaptera novaeangliae*) are very mobile and specialized for high maneuverability. The pinniped forelimb is also flattened and the humerus is short. As in dolphins, the forelimb is rigidly immobilized by connective tissue and skin. The entire limb is mobile and important in maneuvering during locomotion. Forelimbs of sirenians can be used alone for slow locomotion and to move the body across the bottom during feeding. As mentioned previously, otariid and phocid locomotion are divergent. Otariids swim using their forelimbs as hydrofoils to generate lift (thrust) and their hindlimbs as a rudder (Hildebrand, 1988; Fish, 1996). Their scapulae (shoulder blades), which are modified compared to the dog and other marine mammals, have a prominent spine and an accessory spine that subdivides the supraspinous fossa. The humerus possesses large tuberosities, and the ulna has a long olecranon process (Fig. 1). This increased surface area is indicative of larger brachial (arm) muscles. Larger muscles have a greater cross-sectional area and are capable of producing more force. These specializations increase the mechanical advantage not only by increasing F_{in}, but also by increasing the in-lever arm and decreasing the length of the out-lever arm. Although pinnipeds do not exhibit hyperphalangy, the individual metacarpals (hand bones) and phalanges of otariids are elongated (Fig. 2E). The increased length of the foreflipper increases the AR of the entire forelimb. On land, otariids are able to rotate their hindlimbs beneath the body and ambulate as tetrapods; they are remarkably agile. The forelimbs bear much of the weight. The entire palmar surface of the elongated manus is placed on the ground and each forelimb is alternately moved when walking. The head and neck are swung side to side to facilitate the movement of their bulky flippers. The larger transverse processes of the cervical vertebrae reflect the greater behavioral repertoire of head movement during land-based locomotion. Transverse and spinal processes of the lumbar vertebrae among otariids are small and differ little from those of the dog.

Thrust in phocids is generated by the hindlimbs using short, alternate, medial strokes toward the midline (King, 1983; Fish, 1996). During each power stroke the hindflippers expand, increasing their surface area. The hindflippers narrow during lateral recovery strokes, reducing drag. The medial–lateral motions of the hindlimbs are amplified by the simultaneous side-to-side movement of the posterior vertebral column. The transverse processes of lumbar vertebrae are enlarged for greater surface area for muscle attachment, although not to the extent seen in cetaceans and sirenians. Attachment of large hindlimb muscles, which presumably have a larger cross-sectional area compared to otariids, increase F_{in}. Additionally, the ilium (part of the pelvis) of phocids is angled such that the medial face is oriented more anteriorly, increasing the surface area for axial swimming muscle attachment. The femur of phocids is short and flattened. As with the humerus of otariids, the short femur decreases the out-lever arm, which increases the mechanical advantage. The ball and socket of the femur–pelvic joint is shallow and several ligaments are absent. These modifications increase the range of motion. The phocid forelimb lacks the specialization of the otariid forelimb; an accessory scapular spine is absent and the manus is not elongated. The forelimbs are held close to the body and used only for changes in direction. The shorter neck of phocids produces a more streamlined body than otariids. The shorter neck is a result of the slight retraction and greater curvature of the cervical vertebral column, relatively smaller neck musculature, and differences in sculpting effects of blubber. The length of the cervical region relative to the entire vertebral column is the same proportionally in phocids, otariids, and dogs.

Walruses incorporate aspects of both otariid and phocid locomotion. Thrust is produced by the hindlimbs but the forelimbs also contribute. The cross-sectional area of the hindlimb muscles of walruses is relatively larger than that of sea lions and therefore walruses are able to produce a greater F_{in}. The femur is short compared to phocids. Their forelimb musculature is not as enlarged as that of sea lions. The walrus scapula is intermediate between that seen in otariids and phocids; it does not possess an additional scapular spine, but the supraspinous fossa is enlarged compared to phocids.

The sea otter swims on the surface by undulation of its hindlimbs and tail in the vertical plane (Howell, 1930). Although no mechanical studies of sea otter swimming are available, the muscles of the hindlimb are large, the femur is short, and the digits and phalanges are elongated. These characteristics suggest an emphasis on hindlimb propulsion.

Polar bears are excellent shallow divers. They use all four limbs in a paddle stroke much like a dog. Their appendages are not modified for increased thrust and little information exists regarding their mechanics.

C. Musculoskeletal System and Buoyancy

Buoyancy can be modified by altering the density of body tissues. Bone is the densest material of the body and a likely place to investigate for buoyancy modifications. One might imagine that the skeleton of cetaceans would be denser than terrestrial mammals to offset the buoyant nature of the blubber. The long bones of cetaceans are solid and lack a medullar canal; this condition could increase the density of the forelimb. However, relative skeletal density data of aquatic and terrestrial mammals are not well established. Sirenians have clearly modified their skeletal density. These marine mammals possess a heavily mineralized, dense, and thickened skeleton compared to terrestrial and aquatic mammals. Sirenian skeletons are commonly described as exhibiting pachyostosis (thickening of the bone). In addition to increased cross-sectional area, cancellous (spongy) bone has been replaced by compact (hard) bone, a condition known as osteosclerosis. The sirenian condition is best described as pachyosteosclerosis. This condition is not pathological and may result from altered functions of the endocrine system. Typically, mammalian long bones contain a marrow-filled cavity, the primary center for red and white blood cell, and platelet production (collectively called hemopoiesis). Both sirenians and cetaceans lack this medullar canal; the site of hemopoiesis is in the vertebrae. The increased size and density of the sirenian skeleton is hypothesized to function as ballast and aid in buoyancy compensation.

D. Skull Structure

Marine mammals display an amazing amount of divergence and diversity in their SKULL structure compared to their terrestrial counterparts. Their skull morphologies transcend many aspects of their biology and are linked intimately with their behavioral ecology. The hallmark of mammals is the differentiation of teeth and complex patterns of mastication. However, many marine mammals have secondarily modified or lost these typical mammalian characteristics.

The skull of modern cetaceans is perhaps the most derived among mammals. In contrast to the dog, cetaceans have drastically remodeled the rostrum, nares, cranium, ear bones (petrosal bones), and mandible (Fig. 3). The maxilla and premaxilla elongate the facial region, but the cranium is shortened due to the overlapping (telescoping) of cranial bones and is dome like in appearance. This disparity of facial length vs cranial length is variable among cetaceans [e.g., the short blunt face of pilot whales (*Globicephala* spp.) and the long narrow rostra of river dolphins]. The concomitant shortening of the cranial vault with the elongation of the rostrum results in the posterior migration of the nares and associated structures to the dorsum of the skull, posterior to the orbits. The position of the nares is important during locomotion and allows quick and efficient gas exchange without breaking "stride."

Odontocete mandibles apparently perform two functions: sound reception and food acquisition. The mandibular bone is relatively thin and the medullar canal is greatly expanded and filled with fat. Its posterior–medial surface is absent, exposing the medullar canal and mandibular fat. Due to shortening of the cranium, the end of the mandible lies in close proximity to the ear bones (Fig. 3B). The mandibular fat extends posteriorly and attaches to the ear bone. It is hypothesized that returning sound (generated by echolocation) is picked up by the mandible and delivered to the ear along the length of the mandibular fat. In all modern delphinoids the ear bones are completely separated and detached from the rest of the skull, suspended by a series of five ligaments, and surrounded by a mucous foam-like substance. These ligaments acoustically isolate the ear bones

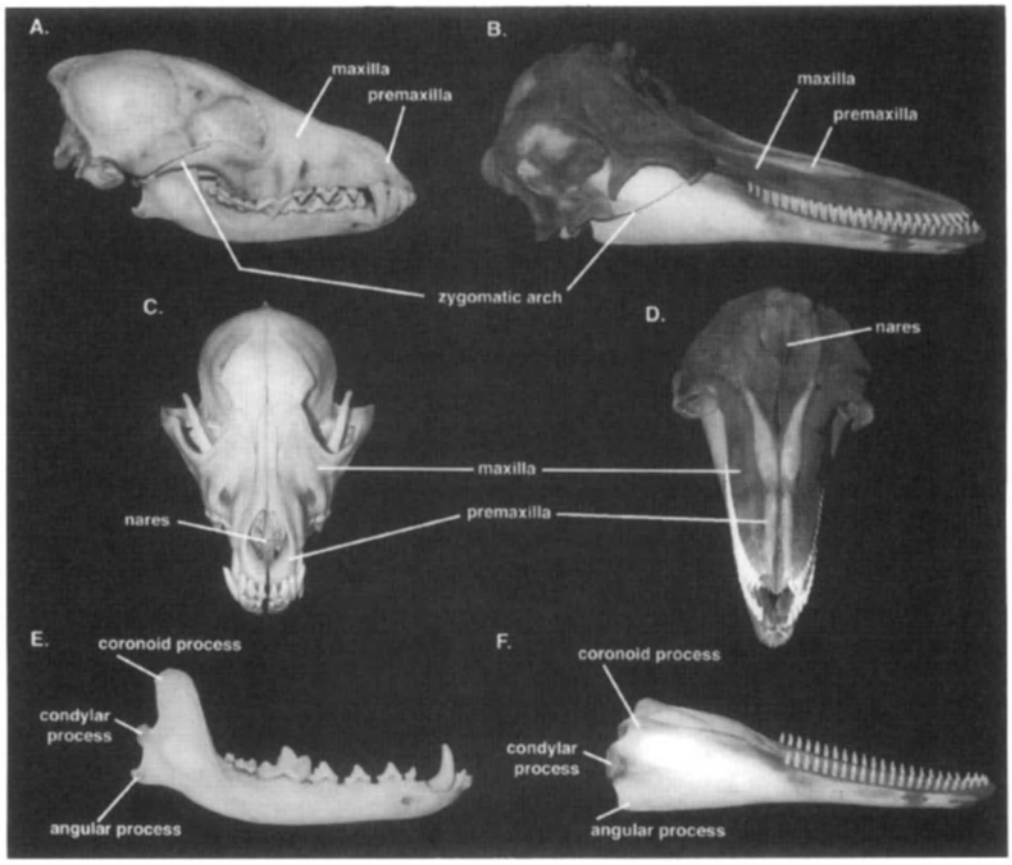

Figure 3 *Comparison of the skull morphology of a dog (A) with a typical odontocete, the bottlenose dolphin (B). Note the elongation of the premaxillary and maxillary bones, thin zygomatic arch, and simple mandible.*

from the skull. This would permit a single acoustic pathway to the ear by way of the mandible. Odontocete jaws can be virtually edentulous (ziphiids) or filled with several hundred simple, single-rooted homodont TEETH (plantanistids). The condylar process of the mandible (articulation of the mandible with the skull) is simple (Fig. 3F) and allows for only a simple dorsal–ventral motion; most mammals can also move their jaws side-to-side (herbivores excel at this). In general, delphinid muscles of mastication (temporalis, masseter, and pterygoids) are relatively small. The pterygoid muscles seem to be the dominant muscle group—a condition found elsewhere only in anteaters. The killer whale (*Orcinus orca*) is an exception; this delphinid has a dominant temporalis, perhaps related to the requirements of taking large prey. Compared to the dog, skull attachments for the temporalis and masseter are also reduced (i.e., zygomatic arch, and coronoid and angular processes; Figs. 3E and 3F).

The facial region of mysticetes dominates the skull even more so than in odontocetes (Fig. 4D). The maxilla arches higher above the mandible compared to odontocetes. Among mysticetes the height of the maxillary arch in balaenids (whales of the family Balaenidae) is distinctively greater than in balaenopterids. The jaws are edentulous; teeth have been replaced by baleen—these sheets of keratinized epidermis (much like hair, nails, and horns) are used to filter water. The mysticete mandible is loosely articulated with the skull, and the mandibular symphysis (anterior region of the mandible where right and left sides join) is not fused. These features allow the mandible to open at nearly 90° to the long axis of the body. As in delphinids, the muscles of mastication of mysticetes and their bony attachments are also relatively small (Slijper, 1962). Clearly the oral apparatus of cetaceans is not designed for mastication.

The sirenian skull is also derived relative to other mammals. The facial region also dominates the skull; however, whereas cetaceans have evolved a relatively enlarged maxilla, sirenians exhibit pronounced and expanded premaxillary bones (Figs. 4G and 4H). This is particularly true of dugongs (*Dugong dugon;* Fig. 4H). The large anterior bones of both manatees and dugongs increase the surface area for the attachment of large facial muscles that form a muscular hydrostat and are involved in feeding; the large narial basin possibly allows for greater movement of these facial muscles. Sirenians are unique in that they are the only herbivorous marine mammals in existence. Unlike cetaceans, sirenians do masticate. The temporalis muscle is well developed but the masseter muscle is relatively simple (unlike terrestrial herbivores). The coronoid process of the mandible is expanded and modified. The condylar process

Figure 4 *Diversity of skull morphology among marine mammals: (A) California sea lion, (B) harbor seal, (C) walrus, (D) gray whale, (E) sea otter, (F) polar bear, (G) West Indian manatee, and (H) dugong.*

is small and flat. The mandibular fossa is shallow, allowing for great mobility of the tympano-mandibular joint. The mandible is large and heavy; only cheek teeth are present. An unusual skull character is the massive pterygoid process, which may provide a second jaw articulation (ptyergoid-mandibular) that could allow the lower jaw to rotate and produce transverse (side-to-side) movements during mastication (Domning, 1978). Such an articulation would displace the fulcrum of the lower jaw from the condyles to the pterygoid processes; an unusual situation among mammals.

Pinnipeds represent a diverse group of marine mammals with varying life histories. However, some generalizations are possible. Among marine mammals, their skulls are most similar to that of the dog (Figs. 3A, 4A, and 4B), with notable exceptions such as walruses (Fig. 4C). Pinnipeds are characterized by a large rounded cranium, short snout, large orbits, and narrow interorbital distance. In general, the skulls of otariids are less variable than those of phocids, although some species show sexually dimorphic characteristics. In small phocids the orbits (and therefore the eyes) encompass a greater proportion of the skull than in larger phocids. The narial basin of elephant seals (*Mirounga* spp.) and hooded seal (*Cystophora cristata*) skulls is enlarged; as in sirenians, it is presumed that this allows greater movement of their mobile proboscises. Pinnipeds that employ suction feeding [walruses, bearded (*Erignathus barbatus*), crabeater (*Lobodon carcinophaga*), ringed (*Pusa hispida*), and harp (*Pagophilus groenlandicus*) seals] tend to have short, wide rostra with jaws that have scoop-like anterior ends and a long mandibular symphysis or a mandible in which the ventral borders are angled toward the oral cavity. The skull of the walrus differs significantly from other pinnipeds. Most of these differences are linked with its specialized feeding and ecology and the presence of tusks (the dominant feature of the skull, Fig. 4C). The maxillary bones are enlarged and adapted to accommodate and anchor the tusks to the skull. The short, wide rostrum is advantageous for benthic (bottom) feeding and increases the surface area for highly mobile whiskers. The posterior head is flat and broad, providing a large surface area for the attachment of neck flexor muscles. The enlargement of the maxillary bones to anchor the tusks to the skull and large

regions for attachment of neck muscles are important for hauling-out behavior. Walruses commonly use their tusks to pull and lift their bodies from the water. Hence the derivation of their Latin name *Odobenus* (tooth walker).

IV. Digestive System

The digestive system is responsible for acquiring food, its mechanical and chemical processing, absorption of nutrients, and excretion of waste products. Methods of acquiring food are quite variable among mammals and include behaviors such as manipulating, shearing, or grasping food with the anterior teeth, lips, tongue, or oral appendages. Acquiring and processing food are largely dependent on adaptations of the skull and associated structures. Because ingestion occurs at the interface between the environment and the body, it is the only portion of food processing that can be seen. Therefore, acquisition of food comprises a large proportion of our current understanding of feeding mechanics in marine mammals.

A. Food Acquisition

1. Cetacean Feeding Cetaceans have developed some of the most specialized and varied FEEDING mechanisms among mammals. This should not be a surprise, as cetaceans exhibit an amazing amount of ecological diversity and inhabit a diverse number of habitats ranging from the tropics to the polar regions. These mechanisms can be generalized to four categories that are specific to the major cetacean groups. Mysticetes are generally categorized as skimmers and engulfers, while the feeding modes of odontocetes involve grasping and suction of prey.

A. MYSTICETES All mysticetes possess BALEEN and most feed on plankton. However, the diet of some rorquals is predominantly fish and squid, whereas gray whales (*Eschrichtius robustus*) feed on marine amphipods and fish in addition to plankton. The method in which prey are captured differs significantly between balaenids and balaenopterids. In general, balaenids are skimmers and balaenopterids are engulfers.

As mentioned previously, the maxilla of balaenids has a greater arching curvature. This accommodates the taller, narrower, and greater number of baleen plates relative to balaenopterids. Baleen plates have a straight outer edge; the inner edge is rounded and wider at the top. A fringe of hair lines the inner edge of each plate, and multiple plates result in the intertwining of the hairs into a woven mat, which can strain plankton when water is passed through. The greater number and height of balaenid baleen plates increase the surface area for straining. Balaenids feed by SWIMMING slowly at the surface with their mouths slightly open. Water flows into the mouth, through the baleen plates where plankton are filtered, and out the corner of the mouth. Periodically the mouth is closed and plankton are removed from the baleen by the tongue and ingested. A model of hydrodynamic flow through the oral cavity of a bowhead whale suggests that the unique morphological structures and actions of the oral apparatus, such as the subrostral gap, orolabial sulcus, curvature of baleen, mandibular rotation, and lingual mobility, permit the steady flow of water through the baleen and may improve the efficiency of filtration.

Instead of skimming the water, balaenopterids engulf large quantities of water, which is then strained through the baleen. This requires several unique adaptations, including numerous throat grooves that allow for an expansion of the gular region (ventral region between the two bodies of the mandible) and a frontomandibular stay apparatus (Fig. 5). This feeding strategy relies on the momentum of the body to operate. Despite their enormous size, rorquals are slender, streamlined, and faster than the relatively bulky and slow-swimming balaenids; body shape is linked with feeding strategy. As whales approach prey, the mouth is opened during active swimming. The forward momentum and sudden increase of inertial drag force the mouth open and cause the throat grooves to expand. Throat grooves in balaenopterids are pleats of blubber that undergo large-scale deformation to provide an expansive cavity (cavum ventrale) that enables these whales to engulf enormous quantities of water. The throat blubber of fin whales (*Balaenoptera physalus*) can expand to as much as 4 times its resting length circumferentially and up to 1.5 times its resting length longitudinally. This extensibility is a direct result of the material properties of the grooved blubber. The small and weak mandibular articulation with the skull is not capable of preventing the mandible from being detached from the head during the forceful engulfment event. The frontomandibular stay apparatus involves a strong ligament extending from the supraorbital process of the frontal bone to the coronoid process of the mandible (Lambertsen *et al.*, 1995; Fig. 5). This innovation allows the mouth to open to 90° while protecting the jaw joint from overextension

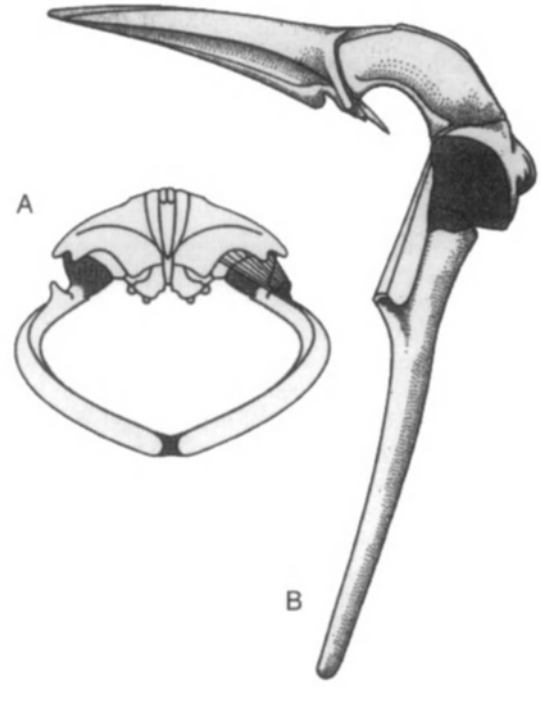

Figure 5 *Frontomandibular stay apparatus of Balaenopteridae. (A) Frontal view. Dark areas represent nonbony, flexible connective tissue at mandibular symphysis and the jaw joint. (B) Lateral view. Note the location of the fibrous connection between the skull and the mandible that prevents overextension of the jaw. From Lambertsen* et al. *(1995), by permission.*

and damage. The stay apparatus also allows each side of the mandible to rotate ventrodorsally along its long axis (the dorsal surface rotates medially, the ventral surface rotates laterally). This is possible due to the loose articulation of the mandible with the skull and the unfused and flexible mandibular symphysis. Mandibular rotation further increases the amount of water the whale is able to engulf and may assist in the expansion of the throat grooves. After the mouth is closed, water is forced through the baleen and plankton, fish, or other prey are ingested. This water movement is powered by the retraction of the elastic throat grooves, contraction of muscles deep to the grooved blubber, and the return of the tongue to its original position.

The oral apparatus of gray whales possesses many characteristics of both balaenids and rorquals. Instead of filtering water, gray whales filter sediment for marine amphipods. Feeding is not completely understood but is accomplished with the animal swimming on its side and using its jaws to excavate long troughs on the sea floor. The baleen of gray whales is unusually thick and sturdy, and it is presumed that amphipods are strained through it in a manner similar to balaenids straining plankton from water. Gray whales also skim surface water for plankton in the same manner as balaenids but are capable of engulfing prey in a manner similar to balaenopterids. This diversity in feeding modes allows for dietary flexibility so that alternate food sources can be used when prey distribution changes.

B. ODONTOCETES Although the odontocete oral apparatus is not as derived as that of mysticetes, it is still greatly modified compared to terrestrial mammals. One reason is that the mandible plays a dual role in feeding and sound reception. The number of teeth is variable; some species may possess 200–300 homodont teeth (e.g., river dolphins) within long pincher-type jaws, whereas other odontocetes are characterized by a drastic reduction in tooth number, tooth function, and possess blunt rostra. These odontocetes are suspected of using suction as a primary method of feeding [e.g., pilot whales (*Globicephala* spp.), beaked whales (Ziphiidae), and sperm whales (*Physeter macrocephalus*)].

Although anatomical data and anecdotal information regarding feeding in cetacean abound, little functional data exist for feeding mechanics among odontocetes. The delphinid jaw is often called a clap trap, which refers to the grasping method of prey capture. The elongation of the skull and mandible results in a lower mechanical advantage but increases the velocity of jaw closure. The modifications of the teeth, a relatively diminished masticatory muscle mass, and a low mechanical advantage are modifications for quickly grasping and capturing prey, which are then swallowed whole without mastication.

Another odontocete feeding strategy is suction feeding, which requires a mechanism that lowers the intraoral pressure relative to that of the surrounding water. An increase in the volume of the oral and pharyngeal cavities can create this pressure difference. Suction feeding in terrestrial vertebrates generates intraoral pressure differences by the retraction and depression of a large, piston-shaped tongue. These animals typically have a suite of anatomical features such as a smooth, flat palate and a robust hyoid apparatus with large lingual and hyoid musculature (e.g., genioglossus, styloglossus and hyoglossus). Cetaceans thought to use suction to feed display many of these morphologies and probably generate negative intraoral pressures in the same way as other vertebrates. Throat grooves may allow for greater expansion of the gular region and would assist in generating greater negative pressures. Much of the evidence for suction feeding among odontocetes is anecdotal. One published account describes belugas sucking a 50-cent coin (about 11.2 grams) off the bottom of their tank from 4 inches away. Similar observations have been made for pilot and killer whales. Sucking has been observed in live-stranded beaked whale (*Mesoplodon carlhubbsi*) calves; investigative palpation suggested that the motion originated in the region of the throat grooves. Manipulation of ziphiid cadavers demonstrated that the tongue could be retracted easily toward the hyoid apparatus by the extrinsic tongue muscles. Retraction of the tongue by manipulation of these muscles resulted in distention of the throat grooves.

2. Sirenian Feeding The most striking characteristic of sirenian feeding is the mobility and use of the lips and associated vibrissae. Vibrissae are specialized hairs that transmit tactile information from the environment to the central nervous system. The follicles of these tactile hairs have a blood-filled sinus that surrounds the hair shaft; within the walls of this sinus are numerous mechanoreceptors. It is thought that deflections of the hair shaft are amplified and transmitted to these mechanoreceptors by the blood sinus. All sirenians possess muscular snouts that are covered by short tactile hairs and modified vibrissae. The lips of West Indian manatees (*Trichechus manatus*) move groups of the modified vibrissae or bristles to grasp vegetation and introduce it into the mouth (Hartman, 1979; Marshall *et al.*, 1998). These bristles are homologous with mystacial and mental vibrissae of the dog but are short, thick, and robust. The use of vibrissae by sirenians to manipulate objects in their environment is a departure from the classical sensory function of mammalian vibrissae. For example, many other mammals use vibrissae to detect tactile cues. Pinnipeds employ whisking movements for more directed tactile exploration. The sniffing behavior and related vibrissal movement during exploration by rodents involve sweeping of the mystacial vibrissae forward and backward in conjunction with protraction and retraction of the rhinarium and head. The modification of manatee bristles to actively manipulate food and other objects appears to be unique to sirenians.

Deflection of the rostrum is related to sirenian feeding ecology (Figs. 4G and 4H). Dugongs are seagrass specialists. Their rostrum is strongly downturned (~70°), which is advantageous for benthic feeding. The Amazonian and West African manatee (*T. inunguis* and *T. senegalensis*) possess the least deflected rostra (~30° and 26°, respectively). The Amazonian manatee is a feeding specialist on floating plants and meadows of the freshwater Amazonian tributaries. The neck musculature of Amazonian manatees differs from other sirenians and allows for greater extension of the neck. The diet of West African manatees is not well known, but is likely similar due to the similar habitat. West Indian manatees have rostral deflections that are intermediate between those of dugongs and Amazonian and West African manatees. West Indian manatees are generalist feeders and can feed anywhere in the water column.

Manatees possess an unusual dentition and form of tooth replacement. Only cheek teeth, which number six to eight at any one time, are present. Teeth erupt in the back of the mouth and move anteriorly as they wear. The bony septa between the teeth are reabsorbed in front of a tooth and redeposited behind it. This allows the teeth to move through the bone of the mandible. As teeth wear they progress forward. When the teeth reach the anteriormost portion of the tooth row and are completely worn, the roots are absorbed and the tooth is shed. A new tooth erupts in the posterior tooth row that continues the conveyer-like process. Manatees are apparently able to produce an unlimited number of cheek teeth. Dugongs possess simplified peg-like teeth that are open rooted. Enlarged horny pads on the upper and lower palate play an important role in mechanical reduction and processing of sea grasses. Incisors are present but erupt only in males. These are often referred to as tusks but are not homologous with the canine tusks of walruses.

3. Pinniped Feeding Prey capture by pinnipeds has not been widely investigated. However, vibrissae appear to be important for prey capture and discrimination. Vibrissal tactile discrimination by California sea lions (*Zalophus californianus*) and harbor seals (*Phoca vitulina*) has been shown to be as sensitive as the hands of monkeys (Dehnhardt and Ducker, 1996). Vibrissae in harbor seals form a hydrodynamic receptor system that is tuned to the frequency of water movement made by fish (Dehnhardt, 1998). The number of teeth is reduced in pinnipeds compared to the dog and the teeth are more uniform, changes presumed to relate to eating fish. At least two species, the leopard seal (*Hydrurga leptonyx*) and crabeater seal (*Lobodon carcinophaga*), have specialized teeth. The leopard sea feeds primarily on large vertebrates, such as penguins and other seals. The distinctive cheek teeth possess three long shearing cusps. Crabeater seals actually feed on KRILL, not crabs. The cusps of their cheek teeth are complicated and modified to form a sieve. The seal swims into a krill patch with mouth open, sucking in water. Water is drained through the sieve and the krill are consumed. Walruses excel at suction feeding. Powerful intraoral pressures are generated by the piston-like tongue and design of the oral cavity. The rostrum of walruses is broad and covered with hundreds of sensitive vibrissae used to detect shellfish. The use of suction for feeding is likely more prevalent among pinnipeds. The masticatory apparatus of most pinnipeds appears to be similar to other carnivores.

4. Sea Otter and Polar Bear Feeding Sea otters forage on the bottom in waters as deep as 40 m. Their diet is varied, but shellfish and urchins comprise a large portion. Otters use their forepaws to excavate clams and to pry shellfish and urchins from the rocky substrate, sometimes using tools. Food is usually consumed at the surface, and behavioral observations suggest that otters do not use their teeth underwater, even when feeding on fish. Upon surfacing, fish are killed by a bite to the head. A rock or some other tool is usually carried in a flap of skin in the axilla region (under the arm) and is used to pound open shellfish. The spines of urchins are simply bitten off and the test (shell) of the urchin is crushed with the cheek teeth. Their cheek teeth are broad, flat, and covered with thick enamel. The shearing cusps of the carnassial teeth have been lost; sea otters are adapted for crushing their food (Kenyon, 1969).

Very little is known about the feeding mechanics of polar bears. Polar bears grasp their prey with their mouths and break the neck or skull with their large masticatory muscles and robust dentition. Their masticatory apparatus appears to resemble that of other bears.

B. Mechanical and Chemical Digestion

In general, the stomach of cetaceans is four chambered (although the number of chambers is variable) and bears a striking resemblance to that of the ox and other ruminants, despite the fact that cetaceans are carnivores. The morphology of the cetacean stomach is more likely related to phylogeny than to function.

The sirenian gastrointestinal tract is of interest because of this group's herbivorous diet. All sirenians are hindgut fermenters. The stomach of West Indian manatees is simple (one chamber) with a prominent muscular ridge that projects into the stomach lumen, partially dividing it into anterior and posterior regions. Both manatees and dugongs possess a discrete digestive accessory gland, the gastric or cardiac gland, which contains parietal and chief cells. This gland protrudes from the greater curvature of the stomach wall. The segregation of digestive acid-secreting cells from the rest of the stomach is an unusual feature among mammalian digestive systems. Although its function is unclear, this segregation may protect acid-secreting cells, and therefore the rest of the stomach, from the abrasive nature of the sirenian diet. The small intestine of West Indian manatees is long and may exceed 20 m. In both West Indian manatees and dugongs, a pair of blind pouches, or diverticula, extend from the expanded portion of the duodenum (duodenal ampulla). The mucosal glands of the duodenum are unusual in that they secrete an acidic mucous instead of an alkaline mucous. This represents an unusual feature among mammalian digestive tracts; the function of acidic mucous in the duodenal region of the small intestine is not understood. It is interesting to note that two other mammals, the koala (*Phascolarctos cinereus*) and the wombat (*Vombatus hirsutus*), also possess a discrete cardiac or gastric gland and secrete acidic mucous in the duodenum. Except for its length, the rest of the small intestine does not differ significantly from that of other mammals. The large intestine of West Indian manatees is also long (>20 m) and wide (~15 cm). At the junction of the small and large intestines is a large cecum with two diverticula. Histology of the region, volatile fatty acid (VFA) analysis, and the existence of large populations of symbiotic microbes all point to the proximal large intestinal and cecum as sites of cellulose breakdown in both manatees and dugongs.

V. Cardiovascular System

Several important morphological modifications of the cardiovascular system exist in marine mammals. These include (1) the blood supply to the brain, (2) arterial–venous anastomoses, (3) countercurrent heat exchangers, and (4) modifications to the venous system and circulation. The cardiovascular system of marine mammals is modified to solve three critical physiological problems of life at sea: conserving oxygen, protecting

oxygen-sensitive tissues during deep dives, and protecting body tissues from the cold environment (thermoregulation).

A. Diving Adaptations of the Cardiovascular System

Among marine mammals foraging for food requires diving. For marine mammals that engage in prolonged deep dives (cetaceans and pinnipeds), efficient oxygen use translates to a greater percentage of time foraging at depth. Some of the greatest modifications of the mammalian cardiovascular system occur among cetaceans and pinnipeds. One possible way to increase dive time is to take more oxygen on a dive. This is exactly what some marine mammals do. One might think that this is done by increasing lung capacity. With the exception of the sea otter, marine mammals have not greatly increased lung size relative to body size. In fact, many deep divers have smaller-than-predicted lungs for mammals of their body weight. Instead cetaceans and pinnipeds store oxygen in blood and muscle tissue (oxygen binds to the molecules hemoglobin and myoglobin, respectively). To facilitate oxygen storage, these mammals possess a greater volume of blood, a higher density of red blood cells (higher hematocrit), and a greatly increased concentration of muscle myoglobin relative to terrestrial mammals. Dives can be prolonged further by efficient use of these extended oxygen stores. Stereotypical changes in the cardiovascular circulation called the diving reflex function to conserve oxygen. Most diving mammals (including humans) exhibit bradycardia (slowing of the heart rate) and peripheral vasoconstriction during a dive. Vasoconstriction increases peripheral resistance and therefore maintains blood pressure during bradycardia. During a dive, blood flow is decreased or shut off to tissues that are tolerant of hypoxic conditions. For example, blood supply to the diaphragm, pancreas, liver, and skeletal muscle is reduced to approximately one-twentieth of normal circulation while blood flow to the heart and brain is maintained. The brain and the heart are profoundly sensitive to hypoxic conditions; even a few minutes of ischemia can cause severe damage or death. Blood flow to the intestines, which hold up to 50% of the normal blood volume, is completely shut off. Although muscles can utilize the oxygen bound to myoglobin, this supply is quickly used up and cannot explain the long dive durations observed. Muscle tissue can work anaerobically. Pinnipeds have a high tolerance for lactic acid buildup, a by-product of anaerobic metabolism and the cause of muscle fatigue during exercise.

B. Blood Supply to the Brain

In the dog and most terrestrial mammals, blood supply to the BRAIN is provided by two bilateral arteries: the internal carotid and the vertebral arteries. The vertebral artery enters the skull through the foramen magnum and the internal carotid artery enters at the base of the skull. Both arteries join a circular anastomosing vasculature at the base of the brain called the circle of Willis. From this circle, cerebral arteries emerge to supply specific regions of the brain. The function of the circle of Willis is not known but is thought to provide collateral blood supply in the event of vessel blockage and to dampen pulses of pressure emanating from the heart that could damage the delicate brain tissue.

The blood supply to the brain in cetaceans is unusual. The internal carotid artery does not reach the brain and they do not possess vertebral arteries (Walmsley, 1938; Slijper, 1962). Instead, the cetacean brain receives blood from a series of vessels called dorsal intercostal arteries. In the dog, arteries branch off the thoracic aorta to supply the regions between each rib (dorsal intercostal arteries) and the muscles on the dorsal side of the vertebral column (epaxial muscles). In cetaceans, the dorsal intercostal arteries form a dense network of small anastomosing arteries called rete mirabile (literally "wonderful net"). These retia are extensive and form the main blood supply to the brain. The functional significance of the retial system in cetaceans is not known but many functional hypotheses exist. The most popular hypothesis is that the retia dampen pulse pressures from the heart and protect the delicate tissues of the brain, as does the circle of Willis in terrestrial mammals. A histological investigation of the rete mirabile in the foramen magnum of bowhead whales (*Balaena mysticetus*) reported an exceptionally thick smooth muscle layer (tunica media) of retial arteries. Previous investigators have reported an absence of nerve fibers within the rete mirabile in other cetaceans. In the bowhead, diffuse nerve fibers were not observed; however, ganglion-like complexes were found within the thick smooth muscle layer. This finding suggests that retia mirabile are under neural control and blood flow may be modulated by vasoconstriction. Physiological data have demonstrated that in a retial system composed of hundreds of muscular anastomosing vessels, the mean blood pressure remains unchanged but periodic increases in pressure are reduced.

C. Arteriovenous Anastomoses

Arteriovenous anastomoses (AVAs) are direct connections between arterioles and venules that allow blood to bypass capillary beds. Blood flow continues directly from the arterial system to the venous system without gas and solute exchange with the tissues. Although these structures usually occur at the level of the capillary beds, they also connect larger vessels further away from the capillaries. Cetaceans and pinnipeds make extensive use of AVAs in regions of blood supply to the integument. These structures are particularly important for thermoregulation and oxygen conservation. Decreased blood flow to the skin, accomplished by shunting blood through an AVA, reduces heat loss through the skin. Conversely, increased blood flow to the skin can bypass the insulation of the blubber and dump excessive heat to the environment. Arteriovenous anastomoses are also used to conserve oxygen by shunting blood away from oxygen-insensitive organs, such as the intestines, during dives.

D. Countercurrent Heat Exchangers

A countercurrent heat exchanger (CCHE) is an organization of arteries and veins that transfers heat from the arterial system to the venous system; the function of this vascular organization is to control the amount of heat lost to the environment. These structures are found in many terrestrial and aquatic vertebrates in regions of the body that are poorly insulated. In marine mammals, they are particularly well developed in locations that have little to no blubber, such as the dorsal and pec-

toral fins of cetaceans, limbs of pinnipeds and sea otters, and pectoral flippers of sirenians. In cetaceans, arteries that supply the fins and flukes (central arteries) are surrounded by numerous veins (circumarterial veins); heat from warm arterial blood is transferred to cool venous blood returning to the heart (Fig. 6). The amount of heat transferred to veins is proportional to the length of the CCHE. Arterial blood reaching the periphery is significantly cooler and therefore less heat is lost to the environment [the difference between T_b and T_e has been reduced; see Eq. (2)]. Cool venous blood traveling from the periphery is warmed and therefore does not significantly reduce core body temperature. Countercurrent heat exchangers can be bypassed by dilation of the central artery, which compress and collapse the circumarterial veins. Venous blood flow is then rerouted to veins further away from the central artery and nearer to the surface of the skin (Fig. 6). This allows excessive heat to be dumped to the environment; these regions are often called thermal windows.

Countercurrent heat exchangers are especially important in the reproductive system of marine mammals. The testes of terrestrial mammals typically lie outside the abdominal cavity in the scrotum. This is because sperm production requires temperatures 1.1°C cooler than core body temperature. Sperm production at core body temperature results in malformed, nonfunctional spermatozoa. The testes of many marine mammals are intraabdominal, which increases streamlining. Not only do these marine mammals testes experience core body temperatures, but testes of cetaceans, sirenians, phocids, and walruses are located near large swimming muscles, which can generate heat one to two orders of magnitude greater than resting muscles. Bottlenose dolphins possess robust CCHEs that are adjacent to the testes. Veins carrying cooled blood from the dorsal fin and tail flukes directly supply a venous plexus that surrounds the arteries supplying the testes. The juxtaposition of a venous and arterial plexus regulates the temperature of the region near the testes. Even during exercise, the CCHE is able to maintain the testes at a lower temperature. In male phocids, anastomoses that span from the foot to the pelvis allow cool venous return through the gluteal, pelvic, and pudendoepigastic veins. This cool venous return is separate from the warmer venous return generated by the hindlimb CCHE and is directed at the venous plexus, which lies medial to the testes. Male West Indian manatees appear to possess a CCHE similar to that found in cetaceans and phocids.

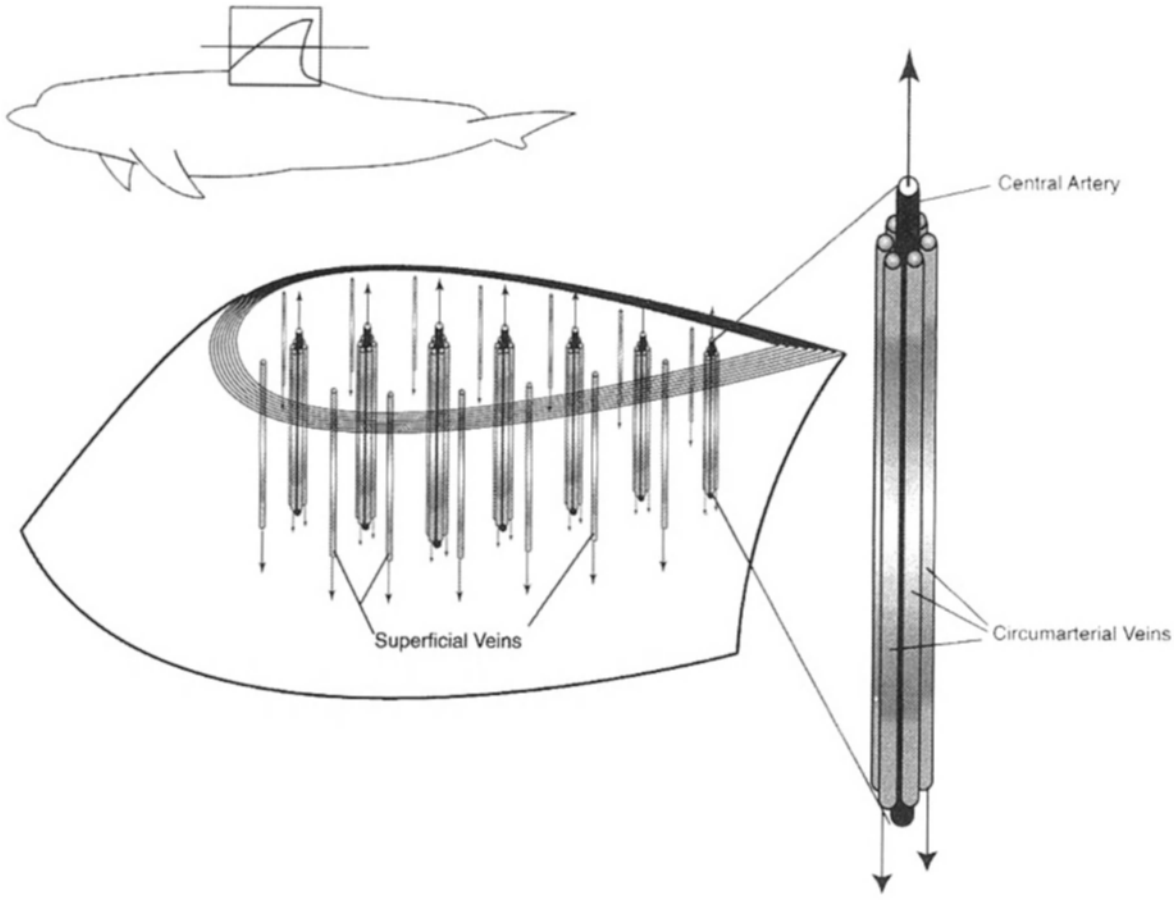

Figure 6 *Schematic of a countercurrent heat exchanger (CCHE) in the dorsal fin of a bottlenose dolphin. Note the circumarterial veins surrounding each central artery, the positions of CCHEs within the dorsal fin, and the peripheral location of the superficial veins not associated with the CCHE.*

Female marine mammals face a similar problem during pregnancy. Elevated abdominal temperatures could harm fetal development. In addition, the mammalian metabolic rate of the fetus is about twice that of maternal tissues; the fetus produces heat. Data from experimental terrestrial mammals indicate that heat is transferred to the abdomen and then to the external environment through the thermal window of the ventral abdomen. Because of their thick blubber, female marine mammals do not have this option. Cetacean and phocid females possess CCHEs that may regulate the temperature of the reproductive organs and abdomen. The system in cetaceans involves the juxtaposition of the lumboposterior venous plexus with the uterovarian arterial plexus in a manner similar to the cetacean testicular CCHE. The system in female pinnipeds involves cool venous return from the three anastomoses in the hindlimb directed toward the abdominal wall plexus that lies lateral to the uterus. Thus, cool venous return could lower the regional temperature of the uterus.

E. Modifications of the Venous System

The venous systems of pinnipeds and cetaceans are modified and more complex relative to the dog. These modifications are related to diving as well as thermoregulation. Much of our current knowledge of cardiovascular function in marine mammals has been derived from *in vivo* angiographies of a few phocid species during experimentally elicited diving responses (Ronald *et al.*, 1977).

Due to the lack of data on a wide range of pinniped species, one must be careful not to overgeneralize cardiovascular function to all pinnipeds. Important differences exist among phocids, walruses, and otariids. For example, in those otariids investigated, the major cranial venous drainage is accomplished largely by the external jugular vein, and secondarily by the vertebral veins. As in dogs, otariids have small extradural veins. However, the major intracranial drainage in phocids is through the modified extradural intravertebral veins (Fig. 7); the external jugular vein is reduced in size.

1. Abdominal Venous Plexus and the Hepatic Sinus The extradural vein in phocids spans from the cranium to the sacrum. Many peripheral veins drain into it along its entire length. In the neck, extradural veins communicate extensively with vertebral veins (cervical vertebral system) and provide a major connection to the heart. In the thorax, the extradural vein communicates with intercostal veins and therefore indirectly with the azygous vein (another major route of return to the heart, Fig. 7). Near the sacrum, branches of the extradural vein communicate directly with the posterior vena cava (PVC) and indirectly with the PVC through a large bilateral abdominal wall plexus. The PVC is the major venous drainage of the abdomen and bifurcates just below the level of the kidneys. Anterior to the kidneys, the right and left branches of the PVC join. At the level of the liver, large hepatic veins join the PVC to form an enlarged sinus called the hepatic sinus. As the PVC passes through the diaphragm and into the thorax, it becomes the anterior vena cava (the major venous drainage of the thorax). A band of striated muscle from the diaphragm encircles the PVC to form a sphincter as it passes into the thorax (Fig. 7). This caval sphincter is innervated by the right and left phrenic nerves. *In vivo* stimulation of the right phrenic nerve produced a strong contraction of this band of striated muscle that occluded the PVC. Constriction of the PVC would severely limit (if not stop) most venous return from the abdomen to the heart. *In vivo* angiography of harbor and harp seals at rest and during forced dives gives us some idea of the function of their venous system. Shortly after the beginning of the dive, smooth muscles surrounding the cervical vertebral system contract, forcing venous blood further posteriorly. Blood from the intestinal arteries is shunted away into the venous system (via the portal system) by AVAs. The large quantity of still oxygenated blood in the portal system is pumped into the PVC by the contraction of smooth muscle surrounding the veins. Almost no blood is present in the intestinal vessels during a dive. The hepatic sinus expands to accommodate the large influx of oxygenated blood. The bifurcation of the PVC also accommodates the increased blood volume. The caval sphincter prevents

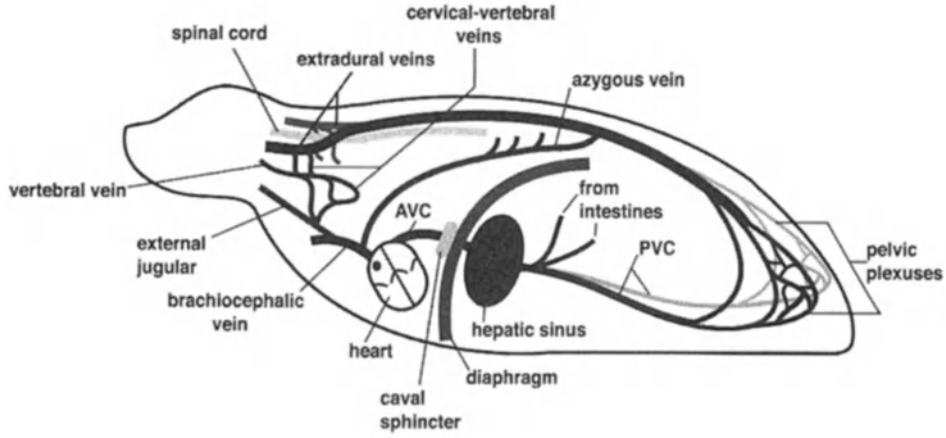

Figure 7 *Schematic of a simplified phocid venous system (after King, 1983). AVC, anterior vena cava; PVC, posterior vena cava. Note the bifurcation of the PVC and the locations of the extradural veins near the spinal cord, hepatic sinus, and caval sphincter.*

movement of this blood to the heart. As the heart expands and a bolus of blood from the anterior vena cava enters the heart, the caval sphincter synchronously opens momentarily, and a bolus of oxygenated blood from the PVC enters the anterior vena cava. Deoxygenated blood draining from the brain flows posteriorly down the extradural vein and is held in the lateral abdominal wall plexus. In this way, deoxygenated venous blood is segregated from oxygenated venous blood. At the end of the dive the circulation returns to normal: the cervical vertebral system opens and flow is reestablished to the heart. Flow from the head to the abdominal venous plexus (through the thoracic epidural vein) reverses and drains venous blood by way of the azygous vein and cervical vertebral route. The caval sphincter opens and blood held in the PVC and abdominal lateral wall plexus is quickly flushed into the anterior vena cava and to the heart. Blood flow returns to the intestines.

The otariid vascular system is not as well studied as the phocid system. However, there are several important differences. A hepatic sinus and caval sphincter are present in both otariids and walruses, but the caval sphincter is not as well developed as in phocids. Phocids have a higher hematocrit, greater blood volume, and twice the myglobin concentration in muscle than otariids and walruses. Based on current knowledge, it appears that the phocid cardiovascular system is more specialized for diving.

The venous vasculature of cetaceans is also highly derived compared to that of the dog. A large extradural spinal vein runs posteriorly down the spinal cord in close association with the spinal, cervical, thoracic, and lumbar rete mirabile. This spinal vein has many communicating branches with the anterior and posterior vena cava, as well as with an elaborate lateral abdominal wall plexus. The PVC is bifurcated and communicates directly with the pelvic venous plexus. Odontocetes also possess a hepatic sinus and caval sphincter; the presence of such structures in mysticetes in uncertain. The venous vasculature of odontocetes bears striking similarities to the phocid vasculature.

VI. Respiratory System

The function of the respiratory system is to deliver air to the alveoli in the lungs and facilitate gas exchange. Additionally, the respiratory system protects the delicate tissues of gas exchange from physical and pathological damage, permits vocalization, and houses the olfactory receptors.

A. Aquatic Respiratory Adaptations

One of the most obvious traits of the respiratory system in cetaceans is the position of the nares. The dorsal position allows for quick and convenient exhalation and inhalation with little to no interruption during locomotion. Cetaceans lack conchae (turbinate bones of the nasal cavity), which allows for a rapid and forceful exhalation and inhalation. As the nasal passage emerges from the top of the skull, an adipose cushion sits within the entrance like a thick plug (nasal plug). In its relaxed state, the nasal plug occludes the nasal passage. Strong muscles spanning the skull pull the plug forward and open the blowhole. The nasal plug prevents water from entering the respiratory system, even at high pressures experienced when diving at depths. Sirenians possess similar paired nasal plugs. Pinnipeds nares are not as specialized. Annular muscles encircle the opening of each nostril to keep them closed. Opening the nares requires voluntary relaxation of these muscles.

The larynx of marine mammals is generally similar to terrestrial mammals. In most mammals, the epiglottis, that most anterior cartilage of the larynx (responsible for keeping food out of the airway), rests above the soft palate of the mouth. Many mammals are able to remove and reinsert the tip of the epiglottis above the soft palate. The larynx of odontocetes is highly modified compared to that of the dog. The odontocete epiglottis and other laryngeal cartilages are elongated; this part of the larynx is aptly named the goosebeak. The goosebeak projects far into the nasal pharynx; at the laryngeal end of the nasal pharynx a strong muscular sphincter creates a tight seal around the goosebeak. Tliis condition completely separates the foodway from the airway so that odontocetes are obligate nasal breathers, much like the horse. This modification prevents water from the oral cavity from entering the airway but may also be implicated in supplying air to specialized nasal diverticula (air sacs) for sound generation used for echolocation.

B. Respiratory Adaptations to Diving

Air is composed of 79% nitrogen and 21% oxygen. Under pressure all gases will go into solution. Remove the pressure and gas comes out of solution, sometimes very quickly. This is what happens when a carbonated drink is opened. Nitrogen in the lungs of a scuba diver at depth enters the bloodstream in the same way because the air in the lungs is compressed by water pressure. Water pressure forces nitrogen into the bloodstream and peripheral tissues. The longer a scuba diver spends at depth, the more nitrogen enters the bloodstream. If the scuba diver ascends slowly, the nitrogen will come out of solution slowly and the diver can exhale the gas. However, if the scuba diver ascends rapidly, nitrogen comes out of solution faster than can be possibly exhaled. Gas bubbles collect in respiratory tissues and in the tissues surrounding the peripheral circulatory system, such as the joints. This phenomenon is called decompression sickness (the bends) and can result in serious injury or death. Marine mammals do not get the bends. Cartilaginous rings of the conduction tract extend to the level of the alveoli in marine mammals. At depth, the rib cage is compressed and the lungs of cetaceans and pinnipeds collapse under pressure, but the conducting tract does not occlude. Air from the collapsed alveoli is forced into the conduction system. Without these structures, air would be trapped at the respiratory surfaces and nitrogen could enter the bloodstream. Water pressure decreases upon ascent, allowing air to expand and reenter the alveoli. This source of oxygen could be important to the animal at the end of a prolonged dive. Most pinnipeds do not fill their lungs prior to a dive and many actually have smaller than predicted lung size relative to mammals of the same body size (e.g., Weddell seal, *Leptonychotes weddellii*). Small lung size circumvents the additional expenditure of energy to overcome the increased buoyancy of filled lungs. For deep diving marine mammals, the lungs are not a source of oxygen storage; instead oxygen is stored in the blood (by binding to hemoglobin) and in muscle (by binding to myoglobin).

VII. Reproductive System

The reproductive system of marine mammals differs little from that of terrestrial mammals. The morphology of the organs and glands of this system reveals much about the phylogenetic relationships among marine and terrestrial mammals. Many of the aquatic specializations of the reproductive system involve thermoregulation of the testes and the developing fetus, which have been discussed. Cetaceans and sirenians, being obligate marine mammals, give birth to large-bodied precocial young. Nursing underwater requires certain adaptations of both mother and calf to be successful. Cetacean mammary glands are paired and lie within the subcutaneous connective tissues on each side of the ventral midline just anterior and adjacent to the genital slit. The nipples (teats) open into the genital slit and can be extruded. Milk flow appears to be a voluntary act on the part of the mother and may be initiated by the contraction of abdominal muscles. Dolphins do not possess muscular lips as do other mammals; calves must grasp the teat between the palate and tongue. The scalloped end of the tongue creates a seal around the teat to facilitate suckling. The paired mammary glands of sirenians are located in the axilla (armpit), as in elephants. Calves clamp on the posterior side of the flipper with their muscular mouths and create a tight seal to nurse; rehabilitating manatee calves are capable of suckling from a bottle and it is presumed that calves use suction when nursing from their mothers. Observations of wild mother–calf pairs report the movement of the lips in a rhythmic motion during nursing, which indicated suckling.

VIII. Concluding Remarks

The diversity of morphological adaptations for life in the aquatic environment by marine mammals attests to the power of natural selection. Marine mammals provide a tangible means to investigate the range of possibilities of mammalian form and function. As marine mammals have garnered more scientific attention recently, previous gaps in our knowledge regarding the diversity of their biology are beginning to fill in. Increased emphasis on integrative, functional research and expanding technological tools will surely provide additional fascinating insights into their functional morphology.

Musculature

J. G. M. Thewissen
Northeastern Ohio Universities College of Medicine, Rootstown

The muscular system of mammals was designed on a single blueprint; there is a remarkable constancy of muscles and associated nerves from the most agile bat to the

fastest antelope, and the largest whale. Details differ, and most of these differences reflect adaptations to specific demands of the environment. This article presents an outline of muscular anatomy of marine mammals, emphasizing how pinnipeds, cetaceans, and sirenians differ from terrestrial mammals. General summaries of cetacean muscles can be found in Slijper (1936, 1962), and of manatees in Domning (1978). Howell (1930) discussed locomotor morphology of all marine mammals.

I. Cranial Muscles

In the cranial muscles, marine mammals differ from terrestrial mammals in the arrangement of their eye muscles, facial muscles, their masticatory muscles, and the muscles of the palate, pharynx, larynx, and tongue.

The facial muscles in land mammals are attached to the skin of the face and moderate facial expressions. In all marine mammals, the facial muscles are involved in closing of the nose opening (or blowhole) to prevent the entry of water during diving. In sirenians, the most important of these muscles insert on the mobile snout and are involved in the manipulation of food. In cetaceans, the facial muscles are greatly rearranged and are positioned around the airsac system on the forehead (Purves and Pilleri, 1983). As such, they are greatly involved in the production of sound. In many mysticetes, facial muscles also extend between the two halves of the mandible where they assist in squeezing gulps of ingested water through the baleen.

One particular facial muscle, the buccinator, is unusual in that it is not near the surface of the skin in land mammals. It forms the wall of the cheek and gives the cheek a rigid wall when suction is produced. As such it is critical for nursing young. In cetaceans, partly as a result of the long snout, this muscle cannot give the cheek a rigid wall. Nursing females assist young in suckling by actively squirting milk into their mouths by the contraction of special skin muscles overlying the mammary gland.

The masticatory muscles of pinnipeds are similar to those of terrestrial carnivores, and sirenian masticatory muscles are not unlike those of herbivores. In cetaceans, the temporal muscle is greatly reduced and the muscles used to close the jaws are the pterygoids and masseter. Unlike land mammals, in which these muscles direct lateral movements of the lower jaws, simple closing of the jaws is their main function in cetaceans.

The muscles of the throat of most marine mammals do not differ greatly from those of land mammals. The throat of odontocete cetaceans (Fig. 1) is more specialized than that of other marine mammals. The larynx of odontocetes is elongate and its epiglottis projects far anteriorly, reaching the back of the palate and extending into the nasopharyngeal duct. The walls of the nasopharyngeal duct, including the soft palate, consist of a strong annular muscle that encloses the epiglottis and seals the lumen of the larynx functionally from the pharynx.

The tongue in land mammals is mostly made of muscle, and its large size in baleen whales is remarkable. In blue whales (*Balaenoptera musculus*), the tongue is the size of an adult elephant and makes up 2.5% of the whale's entire weight. However, rorqual tongues are not very muscular, consisting mainly of fat and connective tissue.

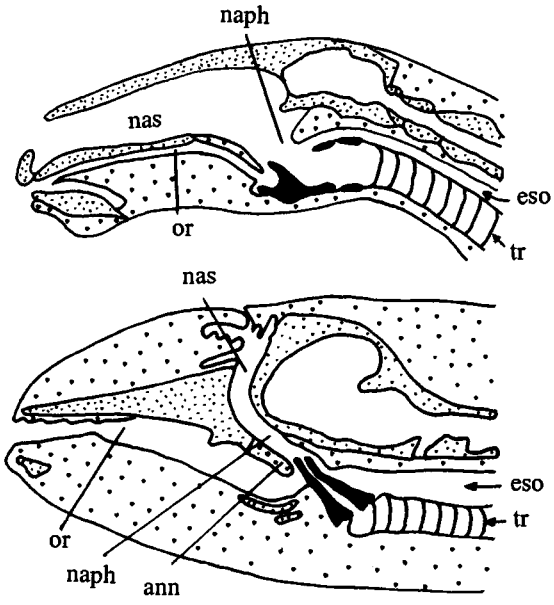

Figure 1 *Midline sections through the head of a horse (top) and common porpoise* (Phocoena phocoena, *bottom) showing the unique shape of the throat and larynx in odontocete cetaceans. Air in all mammals passes from the nasal cavity (nas) to the nasopharyngeal duct (naph), to the larynx, and to the trachea (tr). Food in all mammals passes from the oral cavity (or), to the pharynx (throat), and to the esophagus (eso). The laryngeal cartilages (colored black) form a spout in odontocetes that fits into the nasopharyngeal duct and can be closed tightly by means of annular muscles (ann). This closure causes a tight separation of the air and food passages. Modified after Slijper (1962).*

II. Axial Muscles

The neck muscles in cetaceans are unremarkable because the neck is short. The neck is long in pinnipeds and may be very muscular. It functions in balancing the body during locomotion and powers the blows that males deal their conspecifics.

Muscles extending along the back and tail are the main muscles of propulsion in cetaceans. Epaxial muscles extend along the dorsal side of the transverse processes of the vertebrae. These muscles contract and cause dorsal concavity of the back and tail, pulling the fluke up in the upstroke. These muscles, especially the multifidus and longissimus, are enormous (Fig. 2). The upstroke in cetaceans is powered mainly by the longissimus and extensor caudae lateralis (Pabst, 1993). The latter muscle inserts directly on the dorsal surface of the vertebrae of the fluke, but the longissimus exerts its power by attaching to a subdermal sheath of tendons (Fig. 2) that attaches on spinous and transverse processes along most of the back of the cetacean. It is through the connections of this sheath to the terminal tail vertebrae that the fluke is moved, allowing muscular force to be distributed evenly along the caudal peduncle. The multifidus does not insert on this sheath, instead attaching to the posterior thoracic vertebrae and the lumbar vertebrae. Its main function appears to be to stiffen the back, providing a

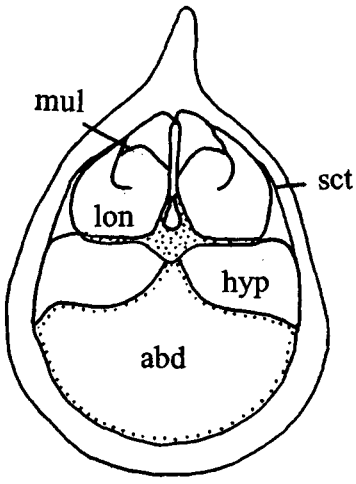

Figure 2 *Cross section through the lumbar region of a bottlenose dolphin* (Tursiops truncatus). *Note the large development muscles, which are larger in this cross section than the abdominal cavity (abd). Dorsal to the vertebra (stippled) are epaxial muscles (mul, multifidus; lon, longissimus) and ventral to the vertebra are hypaxial (hyp) muscles. Muscles are closely associated to the subdermal connective tissue sheath (sct). Modified after Pabst* et al. *(1993).*

stable platform of origin for longissimus. The longissimus is also large in sirenians and is probably important in their upstroke. Lumbar epaxial muscles are also important in powering the undulatory movements of *Enhydra lutris* (sea otter).

Epaxial and hypaxial muscles are large in phocids, where they are used to produce the side-to-side movements that propel the body in SWIMMING. Among the larger of these muscles is the iliocostalis.

III. Muscles of Thorax, Abdomen, and Pelvis

A large superficial skin muscle, the cutaneous trunci (sometimes called panniculus carnosus) covers much of the thorax and abdomen in many mammals. In sirenians, this muscle is especially large and assists in the downstroke of the tail. In cetaceans, part of this muscle is specialized and overlies the mammary gland. It can compress the gland (Fig. 3) and squirt milk into the mouth of nursing young.

The downstroke of the fluke in cetaceans is mainly powered by muscles attaching to the ventral side of the thoracic and lumbar vertebrae and inserting, via a tendon sheet, to the ventral side of the caudal vertebrae and chevron bones (Pabst, 1983). These muscles are large and are commonly called hypaxialis lumborum. In sirenians, specialized tail muscles called sacrocaudalis ventralis lateralis and medialis produce depression of the tail.

Unusual among mammals is the muscle system associated with the penis of cetaceans. Just like in most mammals, erection in cetaceans is not under muscular control. However, unlike most mammals, retraction of the penis into a pouch on the body of the cetacean is caused by contraction of the retractor penis muscles (see Fig. 1, Male Reproductive Systems). These muscles also occur in artiodactyls but are absent in other mammals.

IV. Forelimb Muscles

The forelimb of cetaceans is mainly involved in steering and does not provide propulsive force during rectilinear swimming. Shoulder movement are mainly adduction and abduction; flexion and extension are limited. The shoulder of cetaceans allows less mobility than that of most terrestrial mammals. The clavicle is absent, and tight muscles anchor the scapula to the thorax. These muscles include pectoralis, rhombdoids, serratus ventralis, and latissimus dorsi. A large additional muscle, the trapezius, occurs in most mammals, but is absent in cetaceans. At the scapulo-humeral joint, the deltoid is a strong abductor, and the latissimus dorsi probably the main adductor, assisted by the subscapularis. The joint between scapula and humerus is a ball and socket joint in cetaceans, as in all mammals, but there are no flexible synovial joints below the cetacean shoulder. Ligamentous connections at the elbow, wrist, and fingers allow for some elastic mobility. A few muscles in cetaceans (e.g., triceps) insert distal to the elbow, but there are no muscle bellies in the forearm and hand.

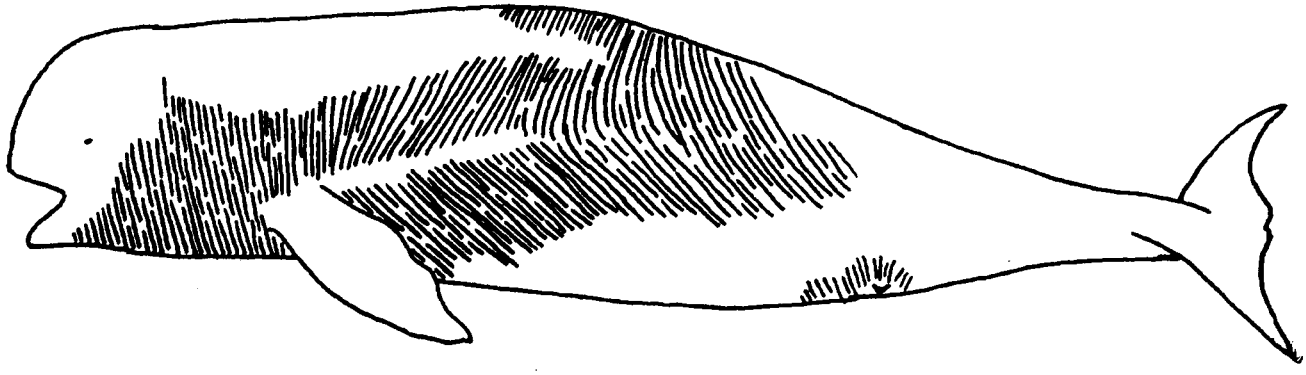

Figure 3 *The Cutaneous Trunci muscle of finless porpoise* (Neophocaena phocaenoides). *Note the muscular tissue overlying the mammary gland (ventrally, near the tail). After Howell (1930).*

Just like cetaceans, the forelimb of phocid and odobenid pinnipeds does not provide much of the propulsive force when swimming. It is, however, important in land locomotion. In contrast, otariid pinnipeds use their forelimb as the main propulsor during swimming, and the forelimbs also have an important role in land locomotion.

All pinnipeds lack a functional clavicle, and the shoulder is loosely attached to the chest. Of the shoulder muscles, the pectoralis and latissimus dorsi are the largest and probably provide most propulsive force during swimming in otariids (Fig. 4). The forearm and wrist of otariids contain synovial joints, although mobility at the wrist is reduced. The flippers that form the hands of otariids lack extensive musculature.

The forearm and hand of phocids are relatively mobile, unlike those of otariids. In the northern phocids (phocines), the hands are used in terrestrial locomotion and have well-developed muscles.

Modern Sirenia do not use their forelimbs for propulsion, but retain synovial joints at the shoulder, elbow, and wrist. The hands are used in manipulating food and retain many of the muscles that are present in land mammals. In the extinct *Hydrodamalis gigas* (Steller's sea cow), there were no wrist and hand bones and, consequently, no hand muscles.

V. Hindlimb Muscles

There are no hindlimb muscles in modern cetaceans, although they were developed in Eocene forms. A rudiment of the pelvis and sometimes the femur occurs in some modern cetaceans, but its main purpose appears to be the attachment of retractor penis.

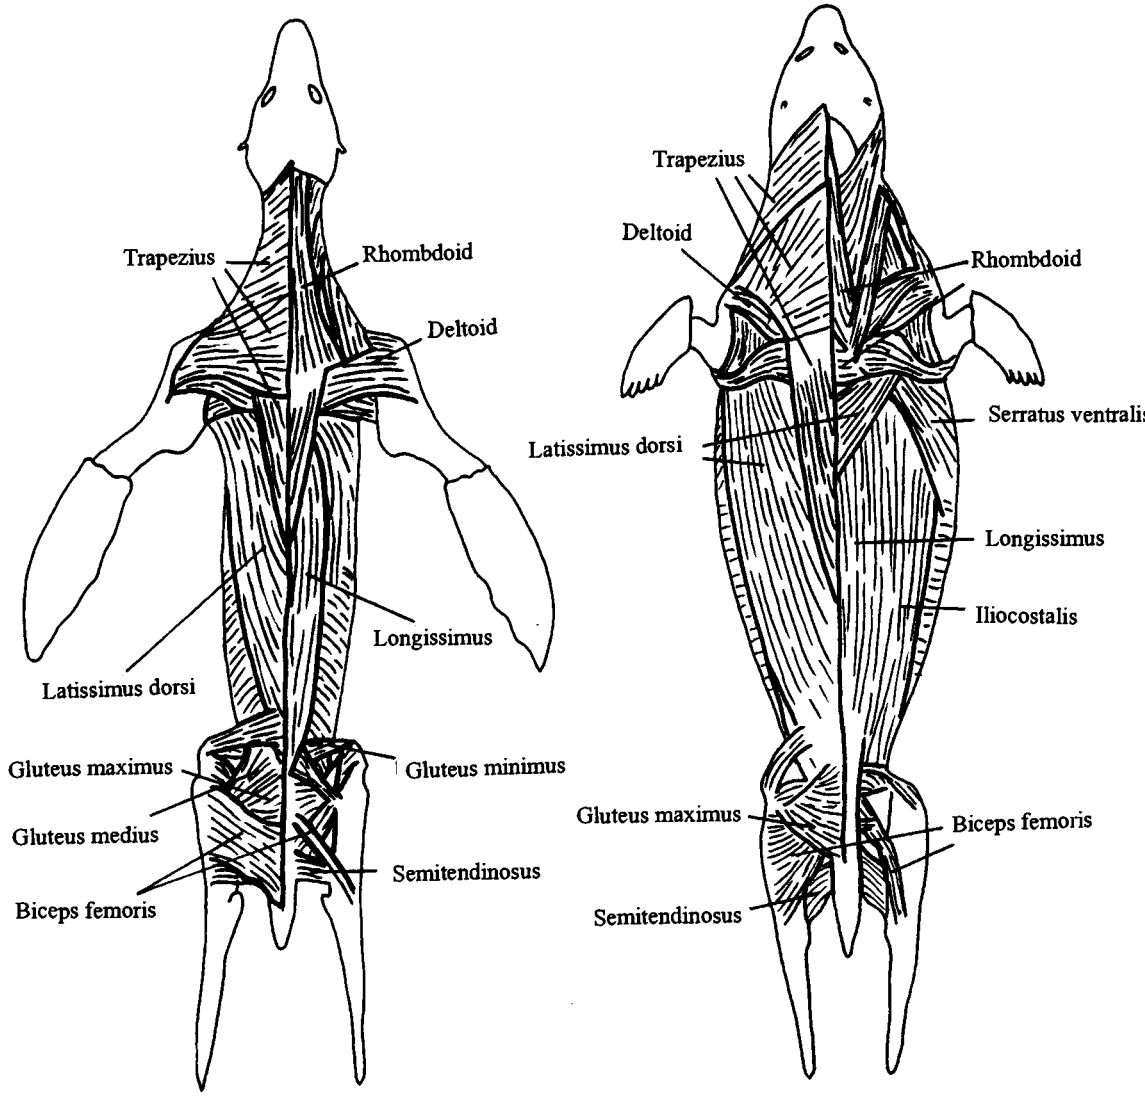

Figure 4 *Dorsal views of a partially dissected sea lion* (Zalophus, *left*) *and a harbor seal* (Phoca, *right*): *superficial muscles on left side of the animal, deeper muscles on the right. Modified after Howell (1930).*

Pelvic bones were also known in early sirenians, but these bones and all of the hindlimb musculature were lost in the extant forms.

Hindlimbs are well developed in the pinnipeds. Phocidae and Odobenidae use their hindlimbs in aquatic locomotion, making adduction/abduction movements with an inverted foot. Phocidae do not use their hindlimbs to support the body while on land. Otariidae trail their hindlimbs during swimming, but use them during locomotion on land. Odobenidae also support their body with their hindlimbs while on land.

In the phocids, the hindlimb flexors (e.g., the hamstrings) are reduced, whereas the extensors are supported by changed insertion of the adductors and obturator externus, which also serve in extension (Fig. 4). Muscles below the knee are present in all pinnipeds, but those crossing the heel are stronger in phocids than in otariids.

Museums and Collections

JOHN E. HEYNING
Natural History Museum of Los Angeles County, California

The integrative approach to studying biology is similar to constructing a jigsaw puzzle—each discipline and data set contribute in a meaningful way to understand the whole. Individual pieces may contribute more or less to the picture, but nonetheless all pieces are important. In biology, each discipline contributes its own unique set of pieces to the puzzle of a species' unique biology. Research in museums has historically focused on specimen-oriented disciplines and thus has contributed to these suites of puzzle pieces. Specimens are potential sources of data for the disciplines of systematics, paleontology, morphology, histology, genetics, pathology, life history, parasitology, toxicology, and biochemistry. In addition, museums serve as important forums of informal learning for the visitors that peruse the exhibits or engage in an educational program.

I. Biodiversity and Systematics

Perhaps the most fundamental among the specimen-oriented disciplines is the study of biodiversity, the defining of species and populations within species. Most marine mammalogists working within museums in the 19th and early 20th centuries spent their hours primarily describing new species from the vast array of specimens unloaded from some recent voyage of exploration so characteristic of that time. For instance, from the numerous marine mammals specimens collected by the Southern Hemisphere expeditions of the HMS *Erebus* and *Terror* during the years 1839–1843, John Gray of the British Museum (Natural History) described numerous new species, including the Ross seal (*Ommatophoca rossii*), the crabeater seal (*Lobodon carcinophaga*), the pygmy right whale (*Caperea marginata*), and the Chilean dolphin (*Cephalorhynchus eutropia*). While the heyday of prolific new species description peaked a century ago, the need for the ongoing study remains very relevant today. Several new species (or resurrected old species) have been defined within recent years, and most populations are just now being understood.

The classical approach of using morphology to define species continues to be relevant. However, analyses of molecular genetic data provide us with additional new tools to help define populations, species, and the relationship among species. Exemplary of this is the recent discovery of a new species of beaked whale. In the mid-1970s, several STRANDINGS occurred of a small species of beaked whale along a restricted section of southern California coastline. Because these specimens morphologically resembled the Southern Hemisphere species *Mesoplodon hectori*, scientists tentatively assigned these California animals to that taxon. A graduate student from New Zealand investigating beaked whale phylogeny sampled the DNA from these specimens along with many others held in museums, including the type specimen of *M. hectori* catalogued into the British Museum over 100 years ago. To her astonishment, these California specimens clustered nowhere near specimens of *M. hectori* from the Southern Hemisphere (Dalebout *et al.*, 1998), hence providing evidence that they represented a new species hithertofore undescribed!

Determining the evolutionary relationships, or phylogeny, among this diversity of species, both living and extinct, is the study of systematics. Systematics provides an evolutionary framework that becomes the foundation for the comparable biological approach. Phylogenies can be constructed using a variety of data sets, morphological, molecular, and fossils—all of which reside primarily within museums. Hence, researchers today can infer past events from phylogenetic reconstructions of evolutionary relationships. Most modern systematists use a philosophical approach called cladistics. The basic tenets of cladistics are quite simple: organisms are deemed to be related based on shared derived characters called synapomorphies. Derived characters are defined as having arisen in the common ancestor of the taxa and subsequently passed onto their descendant taxa.

Museums have a long-term commitment to house specimens for research. Thus material collected in the 1700s and 1800s is still available for scientific inquiry today. For many species, it is only through the accumulation of specimens and data over several decades, even over a century, that we can obtain the samples sizes needed to begin to understand even the basic biology of these species. For systematic studies it is crucial to examine a large series of specimens (Fig. 1). In order to define species or populations, one must first know the limits of variation—individual, ontogenetic, SEXUAL DIMORPHISM—in order to ascribe that the observed variation is due to limited genetic exchange.

II. Morphology

How can a blue whale engulf up to 70 tons of water? Why doesn't a narwhal break its tusk? How can a dolphin cool its testes so that spermatogenesis can occur? All these questions require the detailed examination of anatomical structures. This in turn requires that some specimens are readily available. Some studies are limited to hard parts and can be answered by examining osteological material. However, studies of soft anatomy require that these structures be preserved. For most organisms, storage of the whole beast can be accomplished easily by plunking the specimen into a jar of formalin and/or alcohol. Preservation for future study of a good-sized dolphin, let alone a whale, presents far more of a logistical challenge. As the immense specimens typically need be dissected without preservation, the task can be demanding, as these large, oil-laden mammals produce a rich organic bouquet as they decompose. Fortunately, there is now a renaissance of morphological work requiring innovative ways of preserving and studying cetacean anatomy.

III. History of Museum Research

The first large collections of marine mammals had their genesis in the grand museums of Europe. Baron von Cuvier amassed and published on a very important collection in the early 1800s, which now resides in the Museum National d'Histoire Naturelle in Paris. By the mid-1800s, the British Museum of Natural History (now the Natural History Museum, London) had built major collections as the British Empire explored the world. Two of the preeminent marine mammalogists of this era, William Henry Flower and John Edward Gray, increased our knowledge considerably by studying the specimens within this venerable museum. Aside from the collections amassed from expeditions, museums in Britain had a distinct advantage for growing their collections. In 1324, stranded whales and dolphin were declared "Royal Fishe" and therefore property of the Crown. The original intent of this decree was to ensure that an economically valuable stranded fresh whale would enhance the coffers of the government. An unforeseen benefit was that the majority of strandings were of the economically nonvaluable uneatable variety and therefore available for government supported museums. Hence, the first stranding program began (Fraser, 1977). This original decree and subsequent museum-oriented mindset was passed along to the then British colonies. These former colonies now have museums with major collections including those in Australia, New Zealand, South Africa, and the United States.

Marine mammals as museum specimens are difficult to acquire, store, and maintain. As a result, there are very few large collections for researchers to use. Of the largest collection of land mammals, well over one dozen have more than 100,000 specimens. The majority of specimens in these collections are

Figure 1 *A series of pilot whale skulls* (Globicephala *spp.*). *Series such as these allow biologists to define species and to understand populations within species. Defining these biological units is crucial to conservation biology among other disciplines.*

the taxonomically diverse and numerically abundant rodents and bats. In striking contrast, less than a dozen or so museums have collections of marine mammals numbering over a mere 1000 or so. These include the National Museum of Natural History (Smithsonian); Natural History Museum of Los Angeles County; National Science Museum, Tokyo; The Natural History Museum London; National Museum of New Zealand; American Museum of Natural History; California Academy of Sciences; South Australian Museum; Museum National d'Histoire Naturelle, Paris; and South African Museum.

For a specimen to be of greatest utility for answering questions, it needs to have as much associated data with it as possible. Such archives provide context for the additional data collected by scientists. Originally, museum curators collected only skulls or skeletons along with occasional sketches of the living beast. Early in this century, following the lead set by the systematic collection of data from whaling stations, museum workers began documenting more data from each specimen. As the number of questions regarding marine mammal biology have increased concurrent with new analytical tools to address these questions, far more is being collected. Now it is not uncommon to collect the complete skeleton, frozen tissues, measurements, fluid-preserved tissues, photographs, and notes.

IV. Public Display

Over the past century and a half, museums have served an increasing role as important centers for the public to learn about the natural world. Accurately mounted exhibits can convey great biological detail and grand-scale presence that would be difficult for the public to ever experience in the wild.

Many museums have also capitalized on the immensity of whales to create exhibit icons, most notably the articulated skeleton of a large whale (Fig. 2) or a model of a living blue whale (*Balaenoptera musculus*). In 1907, a model created from a 74.4-foot blue whale went on display at the American Museum of Natural History. Subsequently, the British Museum of Natural History erected its own blue whale model measuring some 88 feet in length. In the early 1960s, the Smithsonian unveiled their 92-foot model. Not to be outdone, the American Museum christened their new and anatomically more accurate 94-foot (28.7 m) model in 1969!

Museums hold collections in the public trust so that they are available to scholars in perpetuity. Thus they serve as guardians of the tangible evidence of the past and the archivists of our current natural heritage. In addition, museums serve as important centers at which the public can learn.

Mustelidae

Ronald E. Heinrich
Ohio University, Athens

Mustelidae is one of the most successful families of the order Carnivora; its 23 genera and 65 extant species of weasels, badgers, otters, and skunks have a nearly worldwide distribution. These small to medium-sized mammals tend to have long and slender bodies, exhibit sexual dimorphism (males are generally 25% larger than females), and possess well-developed anal scent glands. Several cranial and dental characters, including flooring of the suprameatal fossa (an expansion into the roof of the auditory canal), reduction/loss of the upper second molar (M2), reduction/loss of the metaconule and lingual expansion of the upper first molar (M1), and loss of the carnassial notch on the last upper premolar (P4), have been argued to be synapomorphies of a monophyletic Mustelidae (Fig. 1). Recent molecular analyses, however, suggest that skunks are distantly related to other mustelids and occupy a phylogenetic position as sister taxon to Musteloidea, a clade consisting of Mustelidae (minus skunks) and Procyonidae (raccoons and their relatives).

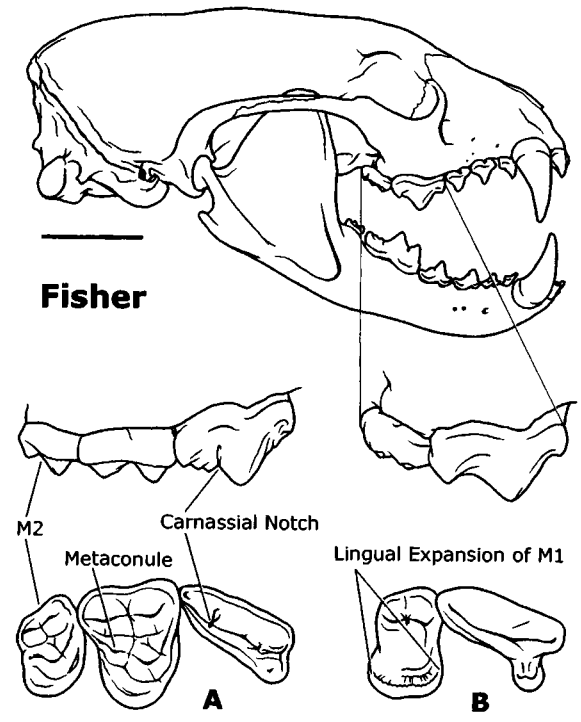

Figure 1 *Characteristics of upper carnassial (P4) and molar (M1) teeth in mustelids. The dentitions of a canid (gray fox, A) and mustelid (fisher, B) are compared in lateral (top) and occlusal views (bottom). Eumustelids have lost the second molar, the metaconule on M1 and the carnassial notch on P4, and expanded the lingual surface of M1. Scale bar = 2 cm.*

I. Palaeomusteloids, Early Eumustelids, and Origins of Lutrinae

The earliest mustelid-like fossils are assigned to *Mustelavus* from the late Eocene of western North America and *Mustelictis* and *Plesictis* from the early Oligocene of France. Because these animals retain upper and lower second molars and an upper carnassial notch, they are conservatively placed in an undifferentiated musteloid stem group. Others have argued, however, that the small size of the second molars and reduction of the metaconule are indicative of mustelid affinities and place all three genera in the family Mustelidae (Baskin, 1998). An increased diversity of palaeomusteloids occurred in the late Oligocene–early Miocene of North America and Europe, and although most of these taxa have little to do with later mustelid evolution, two European genera, *Paragale* and *Plesiogale*, lose the carnassial notch, exhibit some flooring of the suprameatal fossa, and show rudimentary lingual expansion of the upper first molar suggesting an ancestral relationship to eumustelids (Hunt, 1996). Although eumustelids evolved in Eurasia, the earliest representatives of this group are found in the early Miocene of North America, suggesting a late Oligocene immigration event, with immigration events into Africa and South America occurring in the early Miocene and late Pliocene, respectively. By the late Miocene there is considerable mustelid diversity in the fossil record and all of the extant mustelid subfamilies are represented.

One enigmatic taxon that has been included with the palaeomusteloids by some workers and as an incertae sedis member of Arctoidea [Musteloidea + Ursidae (bears) + Pinnipedia] by others is the late Oligocene *Potamotherium*. Known from a number of complete and well-preserved skeletons, this aquatically adapted otter-like genus exhibits a combination of musteloid and pinniped characters that have suggested to some that it may be transitional between mustelids and phocids (Tedford, 1976), although others have argued that these morphological similarities are convergent. The earliest widely accepted fossil otter is the early to mid-Miocene genus *Mionictis* known from dental remains in North America, Europe, and China. Diversification of the major lutrine clades likely occurred by the mid-Miocene (Koepfli and Wayne, 1998), although fossil records for most lineages tend to be Plio-Pleistocene in age. One exception to this is the fossil record of the sea otter (*Enhydra lutris*), the most marine and one of the most morphologically derived of all otters. Remains of *Enhydritherium* and *Enhydriodon*, the consecutive outgroups to

Enhydra, respectively, have been described from throughout the late Miocene, sharing with the living sea otter loss of upper and lower first premolars, a short robust jaw, and lower first molars with low, inflated cusps (Berta and Morgan, 1985).

II. Phylogenetic Relationships of Musteloids
